Publisher’s Notice

Please note that this version of the ebook does not include access to any media or print supplements that are sold packaged with the printed book.

OceanofPDF.com

W. W. Norton & Company has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The firm soon expanded its program beyond the Institute, publishing books by celebrated academics from America and abroad. By midcentury, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of five hundred and hundreds of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

About the Authors

Robert A. Weinberg is a Founding Member of the Whitehead Institute for Biomedical Research. He is the Daniel K. Ludwig Professor for Cancer Research and Professor in the Massachusetts Institute of Technology (MIT) Department of Biology. His research is focused on the molecular and cellular mechanisms of cancer pathogenesis. He was awarded the U.S. National Medal of Science in 1997.

Contributing authors

Richard Goldsby is a Professor of Biology emeritus, Amherst College, Amherst, with a longstanding involvement and expertise in immunology.

Michael Hemann is a Member, Koch Institute for Integrative Cancer Research and Professor of Biology, MIT with an interest in how current cancer therapies succeed or fail.

Tyler Jacks is a Member, Koch Institute for Integrative Cancer Research and Professor of Biology, MIT with an interest in how mouse models of human cancer shed critical light on mechanisms of disease pathogenesis.

Front Cover

When propagated in a three-dimensional gel matrix *in vitro*, mammary epithelial cells can be induced to form the alveoli and ducts closely resembling comparable structures developed naturally in the mammary gland. The fluorescent stains reveal cytokeratins associated with the basal and with the luminal epithelial cells in this experimental model. (From E. S. Sokol, D.H. Miller, A. Breggia et al., *Breast Cancer. Res*. 18:19–32, 2016).

Dedication

Robert A. Weinberg dedicates this third edition, as the first and second ones, to his dear wife, Amy Shulman Weinberg, who endured long hours of inattention, hearing from him repeatedly the claim that the writing of this edition was almost complete, when in fact years of work lay ahead. She deserved much better! With much love.

OceanofPDF.com

Preface

“No one can trust you scientists. You’re always changing your minds.” So said a neighbor of mine in the green woods of New Hampshire, to which I responded “If it makes any difference to you, 99% of what I learned as an undergraduate is still considered to be accurate and true.” This brief exchange highlighted the two worlds that scientists live in, surrounded in one world by the fixed certainties of accepted wisdom and, when moving through the other, trying to maintain balance on constantly shifting ground, never knowing how much the landscape will change from one year to the next.

This dichotomy afflicted the textbook authors in major ways, in this edition myself (R.A.W.) and the three co-authors—Tyler Jacks, Michael Hemann, and Richard A. Goldsby—who have wrestled repeatedly with this question. What should we portray with a voice of certainty and conviction and what to describe in a very tentative and uncertain voice? If there is a measure of uncertainty, should we present something nevertheless, doing so with the conviction that several years down the road, it will be seen as the precursor of a major, highly topical breakthrough? Which recent discoveries will emerge as truly important and which will fade into insignificance, being nothing more than trivial distractions?

Then, there is a second major problem: How much material to present? This issue is, if anything, an even greater challenge. The problem is dictated by the subject matter, in this case the vast and ever-expanding area of contemporary cancer research. Some readers are entranced by the wealth of precisely documented detail presented in a textbook, but far more will, instead, be driven away by too much. Independent of the limitations of the human mind to absorb and process the details is the far more pressing problem, specifically, that of losing would-be readers who, having confronted a forbidding mass of complex information, will simply run away and search for more readily accessible, simple prose and logic. Cancer research, as the authors of this textbook truly believe, should be truly accessible with relatively little advanced preparation, unlike theoretical

physics or complex organic chemistry. Turning away would-be readers will thwart our achieving the major goal of this book—to recruit a new generation of young people to the ranks of the cancer research community.

These dynamics also influence the detailed contents of each chapter in another way: We consciously aspired to present concepts and the logical development of various lines of cancer research rather than providing encyclopedic assemblies of all known facts. Hence, this book is decidedly not a reference book but rather one that hopes to explain scientific logic and paths of discovery. This also touches on a related agenda of this book: to provide by example instruction to students who are learning precisely how biomedical research actually proceeds.

We embrace the existence of a logical backbone that threads its way through each of the chapters and the research subspecialities presented here. Cancer research is an area that does indeed have a conceptual coherence rather than being a grab bag of unrelated and arbitrarily encountered phenomena. All four of us feel a need to move away from compilations of facts and focus instead on underlying principles. In my own case, this drive comes from a chance encounter in the early 1980s with an older, by-then cynical researcher in England, who was disillusioned by what he perceived was the mindless phenomenology of cancer research at the time and warned me sternly that “you should never ever confuse cancer research with science.” This textbook is written with the intent of proving him wrong.

Reassuringly, the initial chapters of this book, which reflect the foundations of this field of modern cancer research, have not changed much from the earlier editions. We present these chapters in their largely unchanged form without apology, because they continue to represent the sturdy logical foundations on which all that follows rests. A need to revise them substantially would indicate that many of our assumptions of what were solid scientific truths were nothing more than illusions. The later chapters of this book, in contrast, address the more dynamic, rapidly changing areas of cancer research whose ultimate outcomes are not yet totally clear.

Compared with other areas of biological research, the science of molecular oncology is a recent arrival; its beginning can be traced with precision to a milestone discovery in 1975. In that year, the laboratory of Harold Varmus

and J. Michael Bishop in San Francisco, California demonstrated that normal cell genomes carry a gene—they called it a proto-oncogene—that has the potential, following alteration, to incite cancer. Before that time, we knew essentially nothing about the molecular mechanisms underlying cancer formation; since that time an abundance of information has accumulated that now reveals how normal cells become transformed into tumor cells and how these neoplastic cells collaborate to form life-threatening tumors.

In spite of this abundance of findings, there are major gaps in our knowledge that remain to be filled. Most critically, the lessons about cancer's origins, laid out extensively in this book, have not yet been successfully applied to make major inroads into the prevention and cure of many common types of neoplastic disease. This represents the major frustration of contemporary cancer research: the lessons of disease causation have rarely been followed, as day follows night, by the development of definitive cures.

And yes, there are still major questions that remain murky and poorly resolved. We still do not understand precisely how many types of human cancers are triggered. We still possess a woefully incomplete understanding of the role of the immune system in preventing cancer development. And while we know much about the individual signaling molecules operating inside individual human cells, we lack a clear understanding of how the complex signaling circuitry assembled by these molecules makes the life-and-death decisions that govern the fate of individual cells within our body. Those decisions ultimately determine whether or not one or another of our cells begins the journey down the long road leading to cancerous proliferation and, finally, to a life-threatening tumor.

Contemporary cancer research has enriched numerous other areas of modern biomedical research. Consequently, much of what you will learn from this book will be useful in understanding many aspects of cell biology, immunology, neurobiology, developmental biology, and a dozen other biomedical research fields. Enjoy the ride!

On behalf of my three co-authors, Richard Goldsby, Michael Hemann, and Tyler Jacks,

Robert A. Weinberg

Cambridge, Massachusetts

A Note to the Reader on the Third Edition

The third edition of this book is organized into 17 chapters of differing lengths. The conceptual structure that was established in the first two editions still seemed to be highly appropriate for this one, and so it was retained. The chapters are meant to be read in the order that they appear, in that each builds on the ideas that have been presented in the chapters before it. The first chapter is a condensed refresher course for undergraduate biology majors and pre-doctoral students; it lays out many of the foundational concepts that are assumed in the subsequent chapters. The driving force of these three editions has been a belief that modern cancer research represents a conceptually coherent field of science that can be presented as a clear, logical progression. Embedded in these discussions is an anticipation that much of this information will one day prove useful in devising novel diagnostic and therapeutic strategies that can be deployed in oncology clinics. Each text chapter has pedagogical elements that will help you navigate these concepts. Also, certain experiments are described in detail to indicate the logic supporting many of these concepts.

- You will find numerous **schematic drawings**, often coupled with **micrographs**, that will help you to appreciate how experimental results have been assembled, piece-by-piece, generating the syntheses that underlie molecular oncology.
- Scattered about the text are "**Sidebars**," which consist of commentaries that represent detours from the main thrust of the discussion. Often these Sidebars contain anecdotes or elaborate on ideas presented in the main text. Read them if you are interested, or skip over them if you find them too distracting. They are presented to provide additional interest—a bit of extra seasoning in the rich stew of ideas that constitutes contemporary research in this area.
- The same can be said about the "**Supplementary Sidebars**," which are available in the ebook. These also elaborate upon topics that are laid out in the main text and are cross-referenced throughout the book,

and they appear in a section at the end of each ebook chapter. Space constraints dictated that the Supplementary Sidebars could not be included in the hardcopy versions of the textbook.

- Throughout the main text you will find extensive **cross-references** whenever topics under discussion have been introduced or described elsewhere. Many of these have been inserted in the event that you read the chapters in an order different from their presentation here. These cross-references should not provoke you to continually leaf through other chapters in order to track down cited sections or figures. If you feel that you will benefit from earlier introductions to a topic, use these cross-references; otherwise, ignore them.
- Each chapter except the first one ends with a forward-looking summary titled "**Synopsis and Prospects**." This section synthesizes the main concepts of the chapter and often addresses ideas that remain matters of contention. It also considers where research might go in the future. This overview is extended by a list of key concepts and a set of questions. Some of the questions are deliberately challenging and we hope they will provoke you to think more deeply about many of the issues and concepts developed.
- Each of the chapters has at its end an **Additional Reading** section, which presents a list of especially useful articles from research journals. Most of these are reviews of specific, circumscribed areas of the scientific literature. These will be useful if you wish to explore a particular topic in more detail.
- Perhaps the most important goal of this book is to enable you to move beyond the textbook and jump directly into the primary research literature. This explains why some of the text is directed toward teaching the elaborate, specialized vocabulary of the cancer research literature, and many of its terms are defined in the **Glossary**. Boldface type has been used throughout to introduce and highlight key terms that you should understand.
- Cancer research, like most areas of contemporary biomedical research, is plagued by numerous abbreviations and acronyms that pepper the text of many published reports; the book provides a key to deciphering this alphabet soup by defining these acronyms. You will find a list of such **abbreviations** in the back.

Because this book describes an area of research in which new and exciting findings are being announced all the time, some of the details and interpretations presented here will become outdated (or, equally likely, proven to be wrong) once this book is in print. Still, the primary concepts presented here will remain, as they rest on solid foundations of experimental results.

The author and the publisher would greatly appreciate your feedback. Every effort has been made to minimize errors. Nonetheless, you may find them here and there, and it would be of great benefit if you took the trouble to communicate them. Even more importantly, much of the science described herein will require reinterpretation in coming years as new discoveries are made. Please email us at biology@wwnorton.com with your suggestions, which will be considered for incorporation into future editions.

Digital Resources for Instructors and Students

The third edition has a number of exciting digital resources for instructors and students to use that are available at wwnorton.com.

OceanofPDF.com

Instructor Resources

Image files

Much of the art from the book, sized for classroom display, is available in PowerPoint with alt text and in JPEG format.

Test Bank

Norton uses evidence-based assessment practices to deliver high quality and pedagogically effective quizzes and testing materials. The framework to develop our test banks, quizzes, and support materials is the result of a collaboration with leading academic researchers and advisers. Questions are classified by section and difficulty, making it easy to construct tests and quizzes that are meaningful and diagnostic. Norton Testmaker brings Norton's high-quality testing materials online. Create assessments for your course from anywhere with an Internet connection, without downloading files or installing specialized software. Search and filter test bank questions by chapter, type, difficulty, and other criteria. You can also customize test bank questions to fit your course. Easily export your tests to Microsoft Word or Common Cartridge files for your LMS.

Primary Research Suggestions with Discussion Questions

Primary literature suggestions for every chapter are available to instructors for download on wwnorton.com/instructors along with questions to prompt discussion.

OceanofPDF.com

Student Resources

Ebook

Norton Ebooks offer an enhanced reading experience at a fraction of the cost of a print textbook. They provide an active reading experience, enabling students to highlight, take notes, search, and read offline. Instructors can add their own content and notes that students can see as they are reading the text. Supplementary Sidebars that elaborate on and further illustrate concepts and figures in the main text are available for the first time within the ebook in a section at the end of each chapter. Norton Ebooks can be viewed on all devices and are born accessible, with content and features designed from the start for all learners. Available at digital.wwnorton.com/cancer3.

Animations

Narrated animations cover selected topics. These animations for *The Biology of Cancer* are available online and in the ebook.

MP3 mini-lectures

Audio files of mini-lectures by the author are available at digital.wwnorton.com/cancer3.

Acknowledgments

The science described in this book is the opus of a large, highly interactive research community stretching across the globe. Its members have moved forward our understanding of cancer immeasurably over the past generation. The colleagues listed below have helped the authors in countless ways, large and small, by providing sound advice, referring us to critical scientific literature, analyzing complex and occasionally contentious scientific issues, reviewing individual chapters, and providing much-appreciated critiques over the past three editions. Their scientific expertise and their insights into pedagogical clarity have proven to be invaluable. Their help extends and complements the help of an equally large roster of colleagues who helped with the preparation of the first two editions. These individuals are representatives of a community, whose members are, virtually without exception, prepared and pleased to provide a helping hand to those who request it. We are most grateful to them. Not listed below are the many colleagues who generously provided high-quality versions of their published images; they are acknowledged through the literature citations in the figure legends.

Special thanks to Prof. Makoto Mark Taketo for truly extraordinary help in critiquing the previous editions of this textbook.

W. W. Norton & Company: The authors would like to thank the extraordinary staffs at W.W. Norton, and before them, at Garland Science, who made the assembling of this book possible. While the prose of the authors is the most visible component of this book, supporting it and lying behind it are hundreds of hours of detailed editing, production, permissions, and sales efforts on the part of these staffs, including most prominently the leading editorial roles of Denise Schanck at Garland Science and Cailin Barrett-Bressack at W.W. Norton, as well as the work of our extraordinary illustrator, Nigel Orme. While their respective contributions are critical to publication of a book like this one, their work often passes unrecognized,

and so we, the authors, would like to thank them for their greatly appreciated work!

Media contributors: A sincere thank you to all of those involved in writing, curating, or reviewing the digital resources for the third edition. Your hard work, creative vision, and thoughtful contributions to the test bank, animations, audio lectures, ebook, and primary research discussion questions will provide support to many instructors and students.

Detailed Contents

Chapter 1: The Biology and Genetics of Cells and Organisms 1

- 1.1 Mendel establishes the basic rules of genetics 2
- 1.2 Mendelian genetics helps to explain Darwinian evolution 4
- 1.3 Mendelian genetics governs how both genes and chromosomes behave 6
- 1.4 Chromosomes are altered in most types of cancer cells 9
- 1.5 Mutations causing cancer occur in both the germ line and the soma 9
- 1.6 Genotype embodied in DNA sequences creates phenotype through proteins 12
- 1.7 Gene expression patterns also control phenotype 17
- 1.8 Modification of chromatin proteins and DNA controls gene expression 20
- 1.9 Unconventional RNA molecules also affect the expression of genes 24
- 1.10 Metazoa are formed from components conserved over vast evolutionary time periods 26
- 1.11 Gene cloning techniques revolutionized the study of normal and malignant cells 27
- Additional reading 29
- Supplementary Sidebars S:1

Chapter 2: The Nature of Cancer 31

- 2.1 Tumors arise from normal tissues 32
- 2.2 Tumors arise from many specialized cell types throughout the body 34
- 2.3 Some types of tumors do not fit into the major classifications 42
- 2.4 Cancers seem to develop progressively 44
- 2.5 Tumors are monoclonal growths 49
- 2.6 Cancers occur with vastly different frequencies in different human populations 51
- 2.7 The risks of cancers often seem to be increased by assignable influences, including lifestyle 54

- 2.8 Specific chemical agents can induce cancer 56
- 2.9 Both physical and chemical carcinogens act as mutagens 57
- 2.10 Mutagens may be responsible for some human cancers 60
- 2.11 Synopsis and prospects 61
- Key concepts 63
- Thought questions 64
- Additional reading 65
- Supplementary Sidebars S:6

Chapter 3: Cancer as an Infectious Disease 67

- 3.1 Peyton Rous discovers a chicken sarcoma virus 68
- 3.2 Rous sarcoma virus is discovered to transform infected cells in culture 69
- 3.3 The continued presence of RSV is needed to maintain transformation 72
- 3.4 Viruses containing DNA molecules are also able to induce cancer 74
- 3.5 Tumor viruses induce multiple changes in cell phenotype including acquisition of tumorigenicity 77
- 3.6 Tumor virus genomes persist in virus-transformed cells by becoming part of host-cell DNA 79
- 3.7 Retroviral genomes become integrated into the chromosomes of infected cells 82
- 3.8 A version of the *src* gene carried by RSV is also present in uninfected cells 84
- 3.9 RSV exploits a kidnapped cellular gene to transform cells 86
- 3.10 The vertebrate genome carries a large group of proto-oncogenes 88
- 3.11 Slowly transforming retroviruses activate proto-oncogenes by inserting their genomes adjacent to these cellular genes 89
- 3.12 Some retroviruses naturally carry oncogenes 92
- 3.13 Bacterial cancers 94
- 3.14 Synopsis and prospects 95
- Key concepts 97
- Thought questions 98
- Additional reading 99
- Supplementary Sidebars S:18

Chapter 4: Cellular Oncogenes 101

- 4.1 Transfection of DNA provides a strategy for detecting nonviral oncogenes 102
- 4.2 Oncogenes discovered in human tumor cell lines are related to those carried by transforming retroviruses 104
- 4.3 Proto-oncogenes can be activated by genetic changes affecting either protein expression level or structure 107
- 4.4 Variations on a theme: the *myc* oncogene can arise via at least three additional distinct mechanisms 111
- 4.5 A diverse array of structural changes in proteins can also lead to oncogene activation 117
- 4.6 Synopsis and prospects 120
- Key concepts 122
- Thought questions 123
- Additional reading 123
- Supplementary Sidebars S:29

Chapter 5: Growth Factors, Receptors, and Cancer 125

- 5.1 Normal metazoan cells control each other's lives 126
- 5.2 The *Src* protein functions as a tyrosine kinase 129
- 5.3 The EGF receptor functions as a tyrosine kinase 132
- 5.4 An altered growth factor receptor can function as an oncoprotein 135
- 5.5 A growth factor gene can become an oncogene: the case of *sis*138
- 5.6 Transphosphorylation underlies the operations of many receptor tyrosine kinases 141
- 5.7 Yet other types of receptors enable mammalian cells to communicate with their environment 147
- 5.8 Nuclear receptors sense the presence of low–molecular-weight lipophilic ligands 153
- 5.9 Integrin receptors sense association between the cell and the extracellular matrix 154
- 5.10 The Ras protein, an apparent component of the downstream signaling cascade, functions as a G-protein 159
- 5.11 Synopsis and prospects 162
- Key concepts 167
- Thought questions 169
- Additional reading 169

- Supplementary Sidebars S:41

Chapter 6: Cytoplasmic Signaling Circuitry Programs Many of the Traits of Cancer 171

- 6.1 A signaling pathway reaches from the cell surface into the nucleus 172
- 6.2 The Ras protein stands in the middle of a complex signaling cascade 176
- 6.3 Tyrosine phosphorylation controls the location and thereby the actions of many cytoplasmic signaling proteins 177
- 6.4 SH2 and SH3 groups explain how growth factor receptors activate Ras and acquire signaling specificity 182
- 6.5 Ras-regulated signaling pathways: A cascade of kinases forms one of three important signaling pathways downstream of Ras 184
- 6.6 Ras-regulated signaling pathways: a second downstream pathway controls inositol lipids and the Akt/PKB kinase 189
- 6.7 Ras-regulated signaling pathways: a third downstream pathway acts through Ral, a distant cousin of Ras 198
- 6.8 The JAK–STAT pathway allows signals to be transmitted from the plasma membrane directly to the nucleus 200
- 6.9 Cell adhesion receptors emit signals that converge with those released by growth factor receptors 202
- 6.10 The canonical and non-canonical Wnt pathways control diverse cellular phenotypes 204
- 6.11 G-protein–coupled receptors can also drive normal and neoplastic proliferation 208
- 6.12 Four additional “dual-address” signaling pathways contribute in various ways to normal and neoplastic proliferation 211
- 6.13 The Hippo signaling circuit integrates diverse inputs to govern diverse cell phenotypes 217
- 6.14 Well-designed signaling circuits require both negative and positive feedback controls 218
- 6.15 Synopsis and prospects 221
- Key concepts 229
- Thought questions 230
- Additional reading 231

- Supplementary Sidebars S:52

Chapter 7: Tumor Suppressor Genes 233

- 7.1 Cell fusion experiments indicate that the cancer phenotype is recessive 234
- 7.2 The recessive nature of the cancer cell phenotype requires a genetic explanation 235
- 7.3 The retinoblastoma tumor provides a solution to the genetic puzzle of TSGs 236
- 7.4 Incipient cancer cells eliminate wild-type copies of TSGs by a variety of mechanisms 240
- 7.5 The Rb gene often undergoes loss of heterozygosity in tumors 242
- 7.6 Loss-of-heterozygosity events can be used to find TSGs 244
- 7.7 Promoter methylation represents an important mechanism for inactivating TSGs 247
- 7.8 TSGs and their encoded proteins function in diverse ways 253
- 7.9 The NF1 protein acts as a negative regulator of Ras signaling 254
- 7.10 APC facilitates egress of cells from colonic crypts 259
- 7.11 KEAP1 regulates cellular response to oxidative stress 265
- 7.12 Not all familial cancers can be explained by inheritance of mutant TSGs 268
- 7.13 Synopsis and prospects 268
- Key concepts 272
- Thought questions 273
- Additional reading 273
- Supplementary Sidebars S:62

Chapter 8: pRb and Control of the Cell Cycle Clock 275

- 8.1 Cell growth and division is coordinated by a complex array of regulators 276
- 8.2 Cells make decisions about growth and quiescence during a specific period in the G_1 phase 280
- 8.3 Cyclins and cyclin-dependent kinases constitute the core components of the cell cycle clock 282
- 8.4 Cyclin–CDK complexes are also regulated by CDK inhibitors 287

- 8.5 Viral oncoproteins reveal how pRb blocks advance through the cell cycle 292
- 8.6 pRb is deployed by the cell cycle clock to serve as a guardian of the restriction-point gate 295
- 8.7 E2F transcription factors enable pRb to implement growth-versus-quiescence decisions 297
- 8.8 A variety of mitogenic signaling pathways control the phosphorylation state of pRb 301
- 8.9 The Myc protein governs decisions to proliferate or differentiate 302
- 8.10 TGF-β prevents phosphorylation of pRb and thereby blocks cell cycle progression 307
- 8.11 pRb function and the controls of differentiation are closely linked 309
- 8.12 Control of pRb function is perturbed in most if not all human cancers 311
- 8.13 Synopsis and prospects 315
- Key concepts 318
- Thought questions 320
- Additional reading 320
- Supplementary Sidebars S:69

Chapter 9: p53: Master Guardian and Executioner 323

- 9.1 DNA tumor viruses lead to the discovery of p53 324
- 9.2 *p53* is discovered to be a tumor suppressor gene 324
- 9.3 Inherited mutations affecting *p53* predispose individuals to a variety of tumors 327
- 9.4 Mutant versions of p53 interfere with normal p53 function 327
- 9.5 p53 protein molecules usually have short lifetimes 330
- 9.6 Various signals cause p53 induction 332
- 9.7 DNA damage and deregulated growth signals cause p53 stabilization 333
- 9.8 Mdm2 destroys its own creator 335
- 9.9 ARF and p53-mediated apoptosis protect against cancer by monitoring intracellular signaling 340
- 9.10 p53 functions as a transcription factor that halts cell cycle advance in response to DNA damage and attempts to aid in the

repair process 341
- 9.11 Prolonged DNA damage and oncogene activation can induce p53-dependent senescence 345
- 9.12 The apoptosis program participates in normal tissue development and maintenance 348
- 9.13 Apoptosis is a complex biochemical program that often depends on mitochondria 349
- 9.14 Both intrinsic and extrinsic apoptotic programs can lead to cell death 359
- 9.15 Cancer cells deploy numerous ways to inactivate their apoptotic machinery 363
- 9.16 p53 inactivation provides an advantage to incipient cancer cells at a number of steps in tumor progression 366
- 9.17 Additional forms of cell death may limit the survival of cancer cells 367
- 9.18 Synopsis and prospects 370
- Key concepts 372
- Thought questions 373
- Additional reading 373
- Supplementary Sidebars S:81

Chapter 10: Eternal Life: Cell Immortalization and Tumorigenesis 375

- 10.1 Normal cell populations appear to register the number of cell generations separating them from their ancestors in the early embryo 376
- 10.2 Cells need to become immortalized in order to form a cell line 378
- 10.3 Cancer cells need to become immortal in order to form tumors 380
- 10.4 The proliferation of cultured cells is also limited by the telomeres of their chromosomes 384
- 10.5 Telomeres are complex molecular structures that are not easily replicated 389
- 10.6 Incipient cancer cells can escape crisis by expressing telomerase 391
- 10.7 Telomerase plays a key role in the proliferation of human cancer cells 396

- 10.8 Some immortalized cells can maintain telomeres without telomerase 399
- 10.9 Telomeres play different roles in the cells of laboratory mice and in human cells 401
- 10.10 Telomerase-negative mice show both decreased and increased cancer susceptibility 403
- 10.11 The mechanisms underlying cancer pathogenesis in telomerase-negative mice may also operate during the development of human tumors 406
- 10.12 Synopsis and prospects 409
- Key concepts 412
- Thought questions 413
- Additional reading 413
- Supplementary Sidebars S:87

Chapter 11: Multi-Step Tumorigenesis 415

- 11.1 Most human cancers develop over many decades of time 416
- 11.2 Histopathology provides evidence of multi-step tumor formation 419
- 11.3 Cells accumulate genetic and epigenetic alterations as tumor progression proceeds 424
- 11.4 Cancer development seems to follow the rules of Darwinian evolution 429
- 11.5 Multi-step tumor progression helps to explain familial polyposis and field cancerization 431
- 11.6 Intra-tumor diversification can outrun Darwinian selection 432
- 11.7 Tumor stem cells further complicate the Darwinian model of clonal succession and tumor progression 437
- 11.8 Multiple lines of evidence reveal that normal cells are resistant to transformation by a single mutated gene 443
- 11.9 Human cells are constructed to be highly resistant to immortalization and transformation 448
- 11.10 Mammalian evolution contributed to the complexity of human cell transformation 451
- 11.11 Nonmutagenic agents, including those favoring cell proliferation, make important contributions to tumorigenesis 453

- 11.12 Mitogenic agents, key governors of human cancer incidence, can act as human tumor promoters 458
- 11.13 Chronic inflammation often serves to promote tumor progression in mice and humans 460
- 11.14 Inflammation-dependent tumor promotion operates through defined signaling pathways 462
- 11.15 Metabolism is the elusive heart of the cancer process 465
- 11.16 Synopsis and prospects 470
- Key concepts 475
- Thought questions 476
- Additional reading 476
- Supplementary Sidebars S:97

Chapter 12: Shaping and Characterizing the Cancer Genome 479

- 12.1 Tissues are organized to minimize the progressive accumulation of mutations 480
- 12.2 The properties of stem cells make them good candidates to be cells-of-origin of cancer 483
- 12.3 Apoptosis, drug pumps, and DNA replication quality control mechanisms offer tissues a way to minimize the accumulation of mutant preneoplastic cells 485
- 12.4 Cell genomes are under constant attack from endogenous biochemical processes 491
- 12.5 Cell genomes are under occasional attack from exogenous mutagens and their metabolites 494
- 12.6 Cells deploy a variety of defenses to protect DNA molecules from attack by mutagens 501
- 12.7 Repair enzymes fix DNA that has been altered by mutagens 502
- 12.8 Inherited defects in nucleotide-excision repair, base-excision repair, and mismatch repair lead to specific cancer susceptibility syndromes 508
- 12.9 A variety of other DNA repair defects confer increased cancer susceptibility 514
- 12.10 The karyotype of cancer cells is often changed through alterations in chromosome structure 520
- 12.11 The karyotype of cancer cells is often changed through alterations in chromosome number 524

- 12.12 Advances in genome sequencing technologies have fueled a revolution in cancer genomics 528
- 12.13 Genomic analysis reveals that human cancers differ with respect to mutational burden, patterns of mutations, and copy number gains and losses 529
- 12.14 Cancer genomes contain driver and passenger gene mutations 534
- 12.15 Cancer genomic studies reveal both inter-tumoral and intra-tumoral heterogeneity 535
- 12.16 Synopsis and prospects 539
- Key concepts 546
- Thought questions 547
- Additional reading 547
- Supplementary Sidebars S:116

Chapter 13: Dialogue Replaces Monologue: Heterotypic Interactions and the Biology of Angiogenesis 549

- 13.1 Normal and neoplastic epithelial tissues are formed from interdependent cell types 551
- 13.2 The extracellular matrix represents a critical component of the tumor microenvironment 561
- 13.3 Tumors resemble wounded tissues that do not heal 563
- 13.4 Experiments directly demonstrate that stromal cells are active contributors to tumorigenesis 575
- 13.5 Macrophages and myeloid cells play important roles in activating the tumor-associated stroma 576
- 13.6 Endothelial cells and the vessels that they form ensure tumors adequate access to the circulation 582
- 13.7 Tripping the angiogenic switch is essential for tumor expansion 588
- 13.8 The angiogenic switch initiates a highly complex process 592
- 13.9 Anti-angiogenesis therapies have been employed to treat cancer 594
- 13.10 Nervous tissue contributes to tumor growth 599
- 13.11 Synopsis and prospects 601
- Key concepts 606
- Thought questions 607

- Additional reading 607
- Supplementary Sidebars S:133

Chapter 14: Moving Out: Invasion and Metastasis 609

- 14.1 The invasion–metastasis cascade begins with local invasiveness 612
- 14.2 Epithelial–mesenchymal transitions profoundly reshape the phenotypes of carcinoma cells 615
- 14.3 Epithelial–mesenchymal transitions are often induced by contextual signals 622
- 14.4 EMTs are programmed by transcription factors that orchestrate key steps of embryogenesis 633
- 14.5 Signals released by an array of stromal cell types contribute to the induction of invasiveness and intravasation 637
- 14.6 EMT-inducing transcription factors may enable entrance into the stem cell state 643
- 14.7 EMT-inducing transcription factors help drive malignant progression including metastatic dissemination 646
- 14.8 The invasiveness of carcinoma cells depends on clearance of obstructing ECM 651
- 14.9 Motility enables cancer cells to move into space excavated by MMPs 656
- 14.10 Intravasation and the formation of circulating tumor cells: first steps in perilous journeys 657
- 14.11 Colonization represents the most complex and challenging step of the invasion–metastasis cascade 667
- 14.12 Successful metastatic colonization often involves complex adaptations 677
- 14.13 An example of extreme metastatic specialization: metastasis to bone requires the subversion of osteoblasts and osteoclasts 679
- 14.14 Occult micrometastases threaten the long-term survival of many cancer patients 685
- 14.15 Synopsis and prospects 686
- Key concepts 692
- Thought questions 693
- Additional reading 694
- Supplementary Sidebars S:149

Chapter 15: Crowd Control: Tumor Immunology 697
- 15.1 The immune system continuously conducts surveillance of tissues 698
- 15.2 The human immune system plays a critical role in warding off various types of human cancer 700
- 15.3 The immune system functions to destroy foreign invaders and abnormal cells in the body's tissues 704
- 15.4 The diversity of B cell and T cell receptors arises from the stochastic diversification of the genes that encode them 708
- 15.5 MHC molecules play key roles in antigen recognition by T cells 710
- 15.6 T cells that recognize MHC-I have different roles from those that recognize MHC-II 714
- 15.7 Dendritic cell activation of naive T cells is a key step in the generation of functional helper and cytotoxic T cells 714
- 15.8 Tumor antigens are targets of the immune response to cancer 717
- 15.9 Natural killer cells contribute to anti-cancer immunity 721
- 15.10 Macrophages make multiple contributions to tumor development 722
- 15.11 Regulatory T cells are indispensable negative regulators of the immune response that are co-opted by tumors to counteract immune attack 725
- 15.12 Immune checkpoints act to limit immune responses 727
- 15.13 Synopsis and prospects 730
- Key concepts 734
- Thought questions 736
- Additional reading 736
- Supplementary Sidebars S:171

Chapter 16: Cancer Immunotherapy 737
- 16.1 Vaccination can prevent cancer caused by infectious agents 738
- 16.2 Vaccination against human papillomaviruses prevents cervical cancer 740
- 16.3 Therapeutic vaccination is a potential treatment for cancer 742

- 16.4 Passive immunization with antibodies can be used to treat cancer 745
- 16.5 Lymphoma and breast cancer can be treated with monoclonal antibodies 748
- 16.6 Antibody–drug conjugates deliver toxic drugs to cells displaying tumor antigens 750
- 16.7 Cancer can be treated by adoptive cell transfer 754
- 16.8 CAR T cells have predetermined specificity and bypass MHC-dependent antigen presentation 757
- 16.9 Checkpoint inhibition is a distinct type of immunotherapy that modifies the behavior of immune cells 761
- 16.10 Checkpoint immunotherapies based on mouse studies have been applied in the oncology clinic 767
- 16.11 Resistance to immune checkpoint inhibitors commonly arises 768
- 16.12 Lethal encounters between T cells and cancer cells can be encouraged by constructing bi-specific antibodies 769
- 16.13 T-cell–dependent immunotherapies can be hampered by T-cell exhaustion 771
- 16.14 Synopsis and Prospects 773
- Key Concepts 777
- Thought questions 778
- Additional reading 778
- Supplementary Sidebars S:172

Chapter 17: The Rational Treatment of Cancer 781

- 17.1 The development and clinical use of effective therapies will depend on accurate diagnosis of disease 784
- 17.2 Surgery, radiotherapy, and chemotherapy are the major pillars on which current cancer therapies rest 792
- 17.3 The present and future use of chemotherapy requires improved understanding of how anti-cancer drugs work 796
- 17.4 Differentiation, synthetic lethality, and cell cycle checkpoints can be exploited to kill cancer cells 801
- 17.5 Functional and biochemical considerations dictate that only a subset of the defective proteins in cancer cells are attractive targets for drug development 803

- 17.6 Pharmaceutical chemists can generate and explore the biochemical properties of a wide array of potential drugs 811
- 17.7 Drug candidates and their targets must be examined in cell models as an initial measurement of their utility in whole organisms 815
- 17.8 Studies of a drug's action in laboratory animals are an essential part of pre-clinical testing 819
- 17.9 Promising candidate drugs are subjected to rigorous clinical tests in Phase I trials in humans 821
- 17.10 Phase II and III trials provide credible indications of clinical efficacy 824
- 17.11 Tumors often develop resistance to initially effective therapy 826
- 17.12 Targeting Bcl-2 to induce cell death 827
- 17.13 Gleevec paved the way for the development of many other highly targeted compounds 830
- 17.14 EGF receptor antagonists may be useful for treating a wide variety of tumor types 841
- 17.15 Proteasome inhibitors yield unexpected therapeutic benefit 847
- 17.16 B-Raf discoveries have led to inroads into the melanoma problem 852
- 17.17 Synopsis and prospects: challenges and opportunities on the road ahead 855
- Key concepts 863
- Thought questions 864
- Additional reading 864

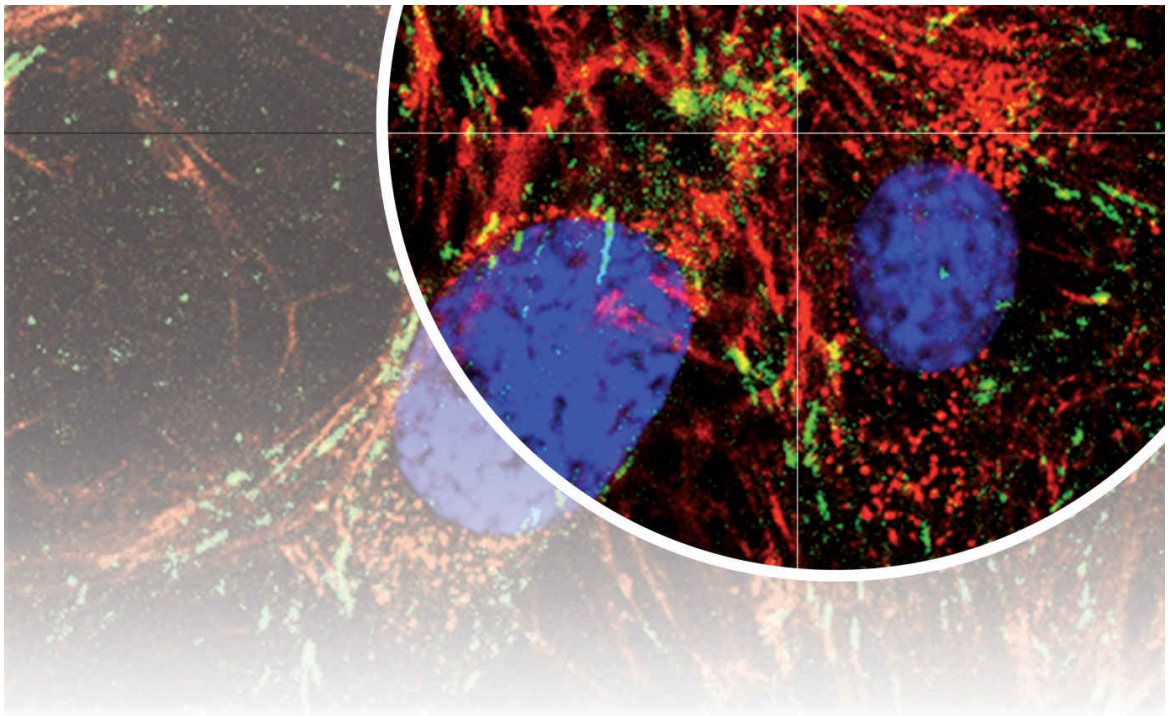
Chapter 1
The Biology and Genetics of Cells and Organisms



A fluorescence microscopy image with blue, green, and red staining.

Protoplasm, simple or nucleated, is the formal basis of all life... Thus it becomes clear that all living powers are cognate, and that all living forms are fundamentally of one character. The researches of the chemist have revealed a no less striking uniformity of material composition in living matter.

Thomas Henry Huxley, evolutionary biologist, 1868

Anything found to be true of *E. coli* must also be true of elephants.

Jacques Monod, pioneer molecular biologist, 1954

The biological revolution of the twentieth century totally reshaped all fields of biomedical study, cancer research being only one of them. The fruits of this revolution were revelations of both the outlines and the minute details of genetics and heredity, of how cells grow and divide, how they assemble to form tissues, and how the tissues develop under the control of specific genes. Everything that follows in this text draws directly or indirectly on this new knowledge.

This revolution, which began in mid-century and was triggered by Watson and Crick's discovery of the DNA double helix, continues to this day. Indeed, we are still too close to this breakthrough to properly understand its true importance and its long-term ramifications. The discipline of molecular biology, which grew from this discovery, delivered solutions to the most profound problem of twentieth-century biology—how does the genetic constitution of a cell or organism determine its appearance and function?

Without this molecular foundation, modern cancer research, like many other biological disciplines, would have remained a descriptive science that cataloged diverse biological phenomena without being able to explain the mechanics of how they occur. Today, our understanding of how cancers arise is being continually enriched by discoveries in diverse fields of biological research, most of which draw on the sciences of molecular biology and genetics. Perhaps unexpectedly, many of our insights into the origins of malignant disease are not coming from the laboratory benches of cancer researchers. Instead, the study of diverse organisms, ranging from yeast to worms to flies, provides us with much of the intellectual capital that fuels the forward thrust of the rapidly moving field of cancer research.

Those who fired up this biological revolution stood on the shoulders of nineteenth-century giants, specifically, Darwin and Mendel. Without the concepts established by these two, which influence all aspects of modern biological thinking, molecular biology and contemporary cancer research would be inconceivable. So, throughout this chapter, we frequently make reference to evolutionary processes as proposed by Charles Darwin and genetic systems as conceived by Gregor Mendel.

OceanofPDF.com

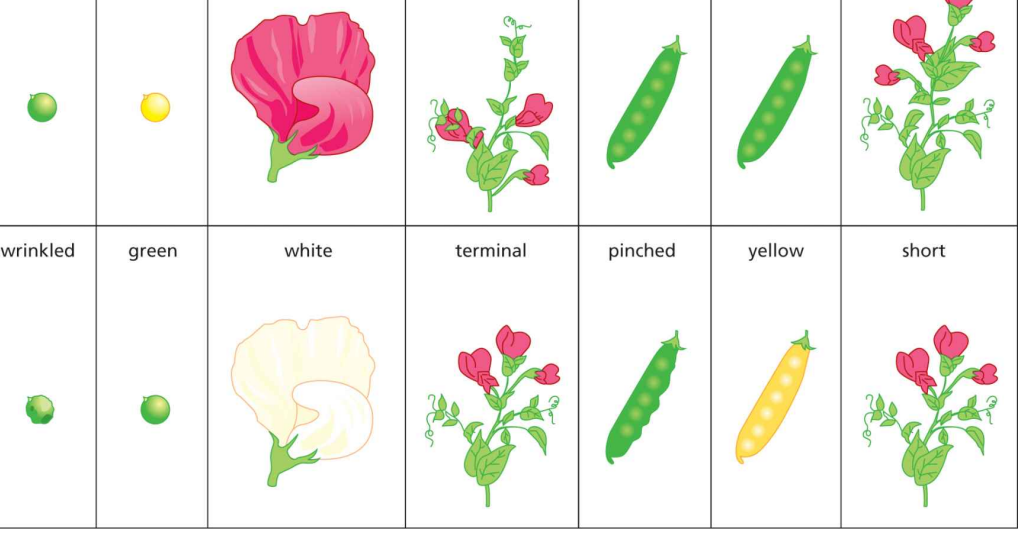
1.1 Mendel establishes the basic rules of genetics

Many of the basic rules of genetics that govern how genes are passed from one complex organism to the next were discovered in the 1860s by Gregor Mendel and have come to us basically unchanged. Mendel's work, which tracked the breeding of pea plants, was soon forgotten, only to be rediscovered independently by three researchers in 1900. During the decade that followed, it became clear that these rules—we now call them Mendelian genetics—apply to virtually all sexual organisms, including metazoa (multicellular animals), as well as metaphyta (multicellular plants).

Mendel's most fundamental insight came from his realization that genetic information is passed in particulate form from an organism to its offspring. This implied that the entire repertoire of an organism's genetic information—its genome, in today's terminology—is organized as a collection of discrete, separable information packets, now called genes. Only in recent years have we begun to know with any precision how many distinct genes are present in the genomes of mammals; many current analyses of the human genome—the best studied of these—place the number in the range of 20,000 protein-coding genes, somewhat more than the ~14,500 genes identified in the genome of the fruit fly, *Drosophila melanogaster*. In addition, a still-unresolved number of genes—numbering in the thousands—that specify functionally important noncoding RNAs reside in the mammalian genome.

Mendel's research implied that the genetic constitution of an organism (its genotype) could be divided into hundreds, perhaps thousands of discrete information packets, paralleling the observable appearance of the organism (its phenotype), which also could be divided into a large number of discrete physical traits (**Figure 1.1**).

	seed shape	seed color	flower color	flower position	pod shape	pod color	plant height
one form of trait (dominant)	round	yellow	violet-red	axial	inflated	green	tall
a second form of trait (recessive)	wrinkled	green	white	terminal	pinched	yellow	short



A table of the dominant and recessive forms of seven pea plant traits. For seed shape, round is dominant and wrinkled is recessive. For seed color, yellow is dominant and green is recessive. For flower color, violet-red is dominant and white is recessive. For flower position, axial (that is, near the center of the plant) is dominant and terminal (off the ends of a stem) is recessive. For pod shape, inflated is dominant and pinched is recessive. For pod color, green is dominant and yellow is recessive. For plant height, tall is dominant and short is recessive.

Figure 1.1 A particulate theory of inheritance One of Gregor Mendel's principal insights was that the genetic content of an organism consists of discrete parcels of information, each responsible for a distinct observable trait. Shown are the seven pea-plant traits that Mendel studied through breeding experiments. Each trait had two observable (phenotypic) manifestations, which we now know to be specified by the alternative versions of genes that we call alleles. When the two alternative alleles coexisted within a single plant, the "dominant" trait (*above*) was always observed while the "recessive" trait (*below*) was never observed. (Courtesy of J. Postlethwait and J. Hopson.)

Mendel's thinking launched a century-long research project among geneticists, who applied his principles to studying thousands of traits in a variety of

experimental animals, including flies (*Drosophila melanogaster*), worms (*Caenorhabditis elegans*), and mice (*Mus musculus*). In the mid-twentieth century, geneticists also began to apply Mendelian principles to the study of the genetic behavior of single-celled organisms, such as the bacterium *Escherichia coli* and baker's yeast, *Saccharomyces cerevisiae*. The principle of genotype governing phenotype was directly transferable to these simpler organisms and their genetic systems.

While Mendelian genetics represents the foundation of contemporary genetics, it has been adapted and extended in myriad ways since its embodiments of 1865 and 1900. For example, the notion that each attribute of an organism can be traced to instructions carried in a single gene was realized to be simplistic. The great majority of observable traits of an organism are traceable to the cooperative interactions of multiple genes. Conversely, almost all the genes carried in the genome of a complex organism play roles in the development and maintenance of multiple organs, tissues, and physiologic processes.

Mendelian genetics revealed for the first time that genetic information is carried redundantly in the genomes of complex plants and animals. Mendel deduced that there were two copies of a gene for flower color and two for pea shape. Today we know that this twofold redundancy applies to the entire genome with the exception of the genes carried in the sex chromosomes. Hence, the genomes of higher organisms are termed diploid.

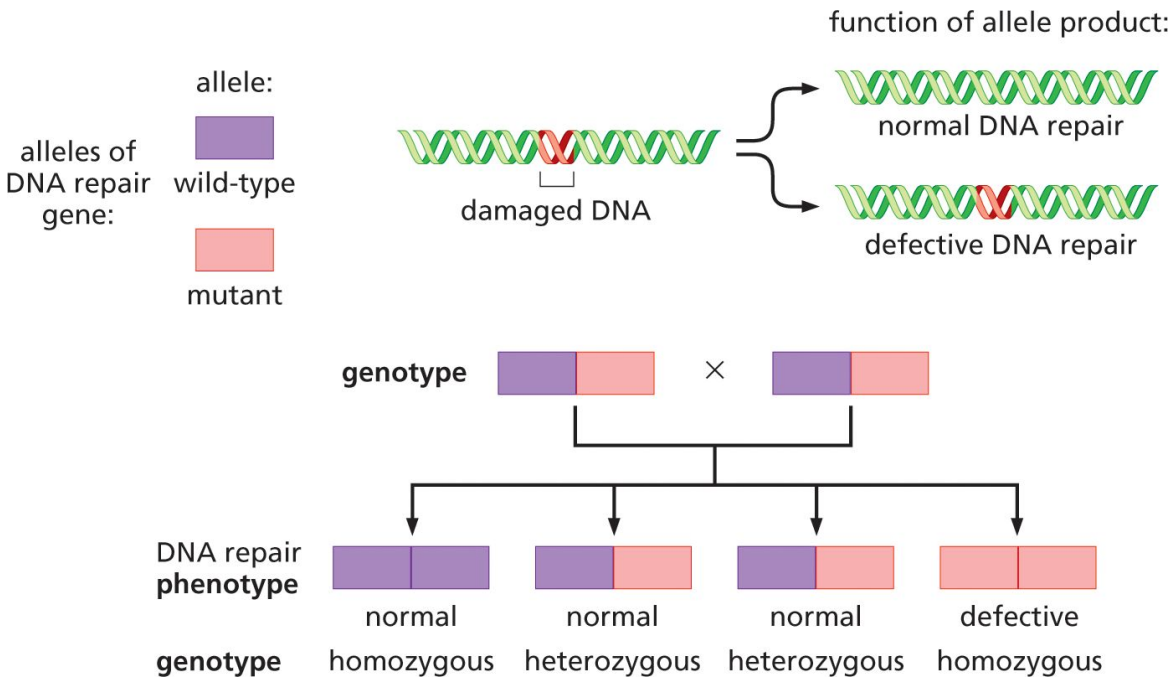
Mendel's observations also indicated that the two copies of a gene could convey different, possibly conflicting information. Thus, one gene copy might specify rough-surfaced and the other smooth-surfaced peas. In the twentieth century, these different versions of a gene came to be called alleles. An organism may carry two identical alleles of a gene, in which case, with respect to this gene, it is said to be homozygous. Conversely, the presence of two different alleles of a gene in an organism's genome renders this organism heterozygous with respect to this gene.

Because the two alleles of a gene may carry conflicting instructions, our views of how genotype determines phenotype become more complicated. Mendel found that in many instances, the action of one allele may dominate over that of the other in deciding the ultimate appearance of a trait. For example, a pea genome may be heterozygous for the gene that determines the shape of peas, carrying one round and one wrinkled allele. However, the pea plant carrying this pair of alleles will invariably produce round peas. This indicates that the round allele is

dominant, and that it will invariably overrule its recessive counterpart allele (wrinkled) in determining phenotype (see Figure 1.1). (Strictly speaking, using proper genetic parlance, we would say that the phenotype encoded by one allele of a gene is dominant with respect to the phenotype encoded by another allele, the latter phenotype being recessive.)

In fact, classifying alleles as being either dominant or recessive oversimplifies biological realities. The alleles of some genes may be **co-dominant**, in that an expressed phenotype may represent a blend of the actions of the two alleles. Equally common are examples of incomplete penetrance, in which case a dominant allele may be present but its phenotype is not manifested because of the actions of other genes within the organism's genome. Therefore, the dominance of an allele is gauged by its interactions with other allelic versions of its gene, rather than its ability to dictate phenotype.

With such distinctions in mind, we note that the development of tumors also provides us with examples of dominance and recessiveness. For instance, one class of alleles that predispose cells to develop cancer encode defective versions of enzymes involved in DNA repair and thus in the maintenance of genomic integrity (discussed again in Chapter 12). These defective alleles are relatively rare in the general population and function recessively. Consequently, their presence in the genomes of many heterozygotes (of a normal/mutant genotype) is not apparent. However, two heterozygotes carrying recessive defective alleles of the same DNA repair gene may mate. One-fourth of the offspring of such mating pairs, on average, will inherit two defective alleles, exhibit a specific DNA repair defect in their cells, and develop certain types of cancer at greatly increased rates (**Figure 1.2**).



The relationship between genotype and phenotype, illustrated using a gene for D N A repair. The normal, dominant, wild-type allele is associated, phenotypically, with an ability to repair damaged D N A, while the mutant, recessive allele is associated with a lack of that capability, or lack of the capability to perform the repair properly. Suppose a cross between two heterozygous individuals, each with one of each type of allele, produces four offspring. Genotypically, on average one individual will be homozygous with two normal alleles, two individuals will be heterozygous with one allele of each type, and one individual will be homozygous with two mutant alleles. Phenotypically, the first three offspring will, like their parents, have normal D N A repair capability. The last one, with two mutant alleles, will lack the ability to repair D N A.

Figure 1.2 Discrepancy between genotype and phenotype The phenotype of an individual often does not indicate genotype. For example, individuals who are phenotypically normal for a trait may nevertheless, at the level of genotype, carry one wild-type (normal) and one mutant (defective) allele of the gene that specifies this trait; this mutant allele will be recessive to the wild-type allele, the latter being dominant. Such individuals are heterozygous with respect to this gene. In the example shown here, two individuals mate, both of whom are phenotypically normal but heterozygous for a gene specifying a DNA repair function. On average, of their four children, three will be phenotypically normal and their cells will exhibit normal DNA repair

function; of these three, one of the children will receive two wild-type alleles (be a homozygote) and two will be heterozygotes like their parents. A fourth child, however, will receive two mutant alleles (i.e., be a homozygote) and will be phenotypically mutant, in that this child's cells will lack the DNA repair function specified by this gene. Individuals whose cells lack proper DNA repair function are often cancer-prone, as described in Chapter 12.

Glossary

metaphyta
: Plants composed of many cells.

genotype
: Genetic constitution of a cell or an organism.

phenotype
: (1) A measurable or observable trait of an organism. (2) The sum of all such traits of an organism.

diploid
: Describing a genome in which all chromosomes are present in pairs, one of each pair being inherited from a father and the other from a mother, with the exception of the sex chromosomes, which in placental mammals are paired in either the XX or the XY configuration.

allele
: One alternative among different versions of a gene that may be defined by the phenotype that it creates, by the protein that it specifies, or by its nucleotide sequence.

homozygous
: Referring to the configuration of a genetic locus in which the two copies of the associated gene carry identical alleles of the gene. *See also* **heterozygous**.

heterozygous
: Referring to the configuration of a genetic locus in which the two copies of the associated gene carry different versions (alleles) of the gene that represents this locus. *See also* **homozygous**.

dominant
: (1) Referring to one of several alternative traits (phenotypes) that can be specified by a genetic locus; when the locus is heterozygous and carries information specifying two distinct traits, the dominant trait will be the one actually exhibited. (2) Describing an allele of a gene that determines phenotype in spite of the concomitant presence of a second allele, considered to be recessive, that specifies a different, alternative phenotype. *See also* **recessive**.

recessive

(1) Referring to one of several alternative traits that can be specified by a genetic locus; when the locus is heterozygous and carries information specifying two distinct traits, the dominant trait will be exhibited phenotypically by the organism and the recessive will not. (2) Referring to an allele of a gene that is unable to dictate phenotype when expressed in the presence of a second allele that acts dominantly. *See also* **dominant**.

incomplete penetrance

Situation in which a dominant allele fails to affect phenotype because of the actions of other genes present in an organism's genome. *See also* **penetrance**.

heterozygote

Individual cell or organism that carries two distinct alleles of a gene of interest. *See also* **heterozygous**.

metazoan

Referring to animals composed of many cells. *Compare* **protozoan**.

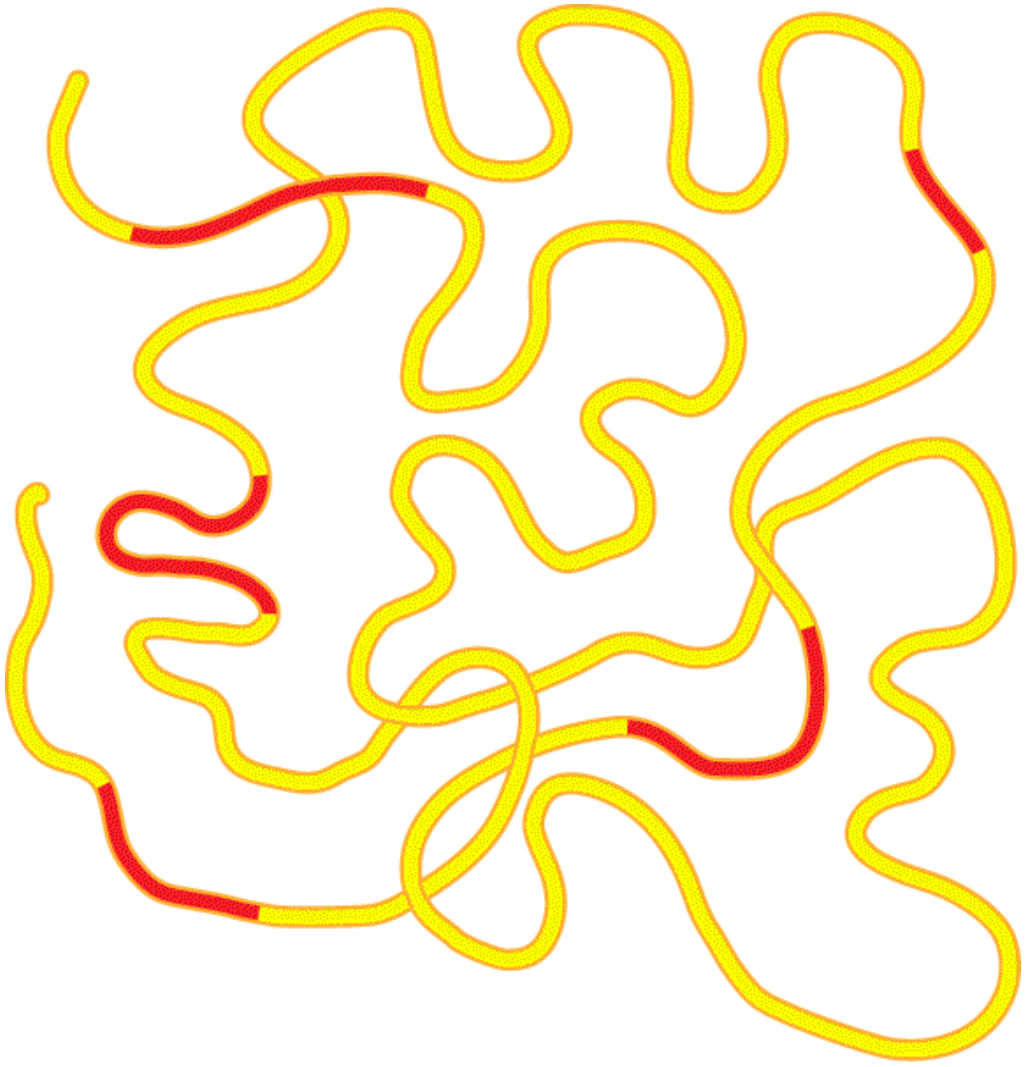
1.2 Mendelian genetics helps to explain Darwinian evolution

In the early twentieth century, it was not apparent how the distinct allelic versions of a gene arise. At first, this variability in information content seemed to have been present in the collective gene pool of a species from its earliest evolutionary beginnings. This perception changed only later, beginning in the 1920s and 1930s, when it became apparent that genetic information is corruptible. The information content in genetic texts, like that in all texts, can be altered. Mutations were found to be responsible for changing the information content of a gene, thereby converting one allele into another or creating a new allele from one previously widespread within a species. An allele that is present in the great majority of individuals within a species is usually termed wild type, the term implying that such an allele, being naturally present in large numbers of apparently healthy organisms, is compatible with normal structure and function.

Mutations alter genomes continually throughout the evolutionary life span of a species, which usually extends over millions of years. They strike the genome and its constituent genes randomly. Mutations provide a species with a method for continually tinkering with its genome, for trying out new versions of genes that offer the prospect of novel, possibly improved phenotypes. The lifetime of a species begins with a small founding, ancestral population. During the subsequent evolutionary history of the species, a continuing rain of mutations on the genomes carried by its individual members creates a progressive increase in the genetic diversity within this species. Thus, the collection of alleles present in the genomes of all members of a species—the gene pool of this species—becomes progressively more heterogeneous as the species grows older.

The continuing diversification of alleles in a species' genome, occurring over millions of years, is countered to some extent by the forces of natural selection that Charles Darwin first described. Some alleles of a gene may confer more advantageous phenotypes than others, so individuals carrying these alleles have a greater probability of leaving numerous descendants than do those members of the same species that lack them. Consequently, natural selection results in a continual discarding of many of the alleles that have been generated by random mutations. In the long run, all things being equal, disadvantageous alleles are lost from the pool of alleles carried by the members of a species, advantageous alleles increase in number, and the overall fitness of the species improves incrementally.

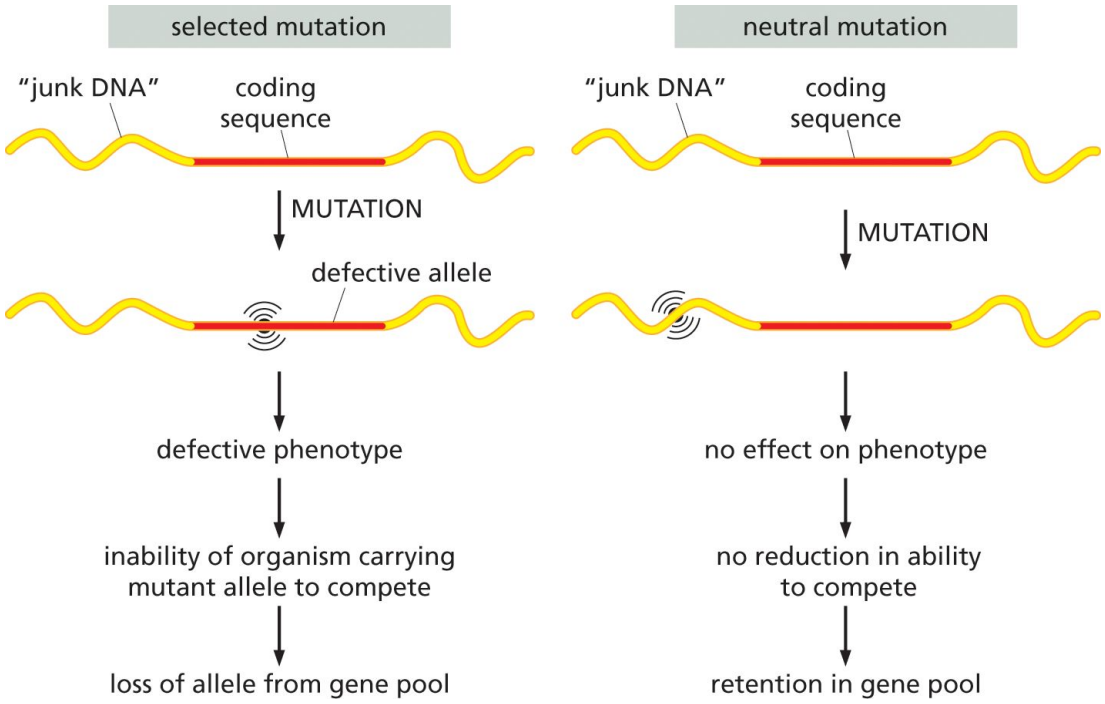
Now, more than a century after Mendel was rediscovered and Mendelian genetics revived, we have come to realize that most of the genetic information in our own genome—indeed, in the genomes of all mammals—does not seem to specify phenotype and is often not associated with specific genes. Reflecting the discovery in 1944 that genetic information is encoded in DNA molecules, these "noncoding" stretches in the genome have been called, for want of a better term, "junk DNA" (**Figure 1.3**). Only about 1.5% of a mammal's genomic DNA carries sequence information that encodes the structures of proteins. Recent sequence comparisons of human, mouse, and dog genomes suggest that another ~2% encodes important information regulating gene expression and mediating other, still-poorly understood functions. (While some have proposed that as much as 80% of the human genome has important functions, a 2017 estimate of how much of the genome is likely to be truly important for organismic development and viability suggested an upper limit of 25%. So, the debate about the appropriateness of the term "junk DNA" continues unabated, with as much as one-quarter of it having possible biological function.)



A single strand of D N A, twisted and folded irregularly like loose spaghetti on a plate. Most of the strand is yellow, but five short segments are red.

Figure 1.3 Biologically important sequences in the human genome The human genome can be characterized as a collection of relatively small islands of biologically important sequences (∼3.5% of the total genome; *red*) floating amid a sea of "junk DNA" (*yellow*). The proportion of sequences carrying biological information has been greatly exaggerated for the sake of illustration. (With the passage of time, genes that appear to play important roles in cell and organismic physiology and specify certain noncoding RNA species have been localized to these intergenic regions, as have short DNA segments involved in regulating gene expression; hence the depiction of all genomic sequences localized between a human cell's ∼20,000 protein-coding genes as useless junk is simplistic and incorrect.)

Because mutations act randomly on a genome, altering true genes and junk DNA indiscriminately, the great majority of mutations alter genetic information—nucleotide sequences in the DNA—that have no effect on cellular or organismic phenotype. These mutations remain silent phenotypically and are said, from the point of view of natural selection, to be neutral mutations, being neither advantageous nor disadvantageous (**Figure 1.4**). Since the alleles created by these mutations are functionally silent, their existence could not be discerned by early geneticists whose work depended on gauging phenotypes. However, with the advent of DNA sequencing techniques, it became apparent that upward of a million functionally silent mutations can be found scattered throughout the genomes of organisms such as humans. The genome of each human carries its own unique array of these functionally silent genetic alterations.

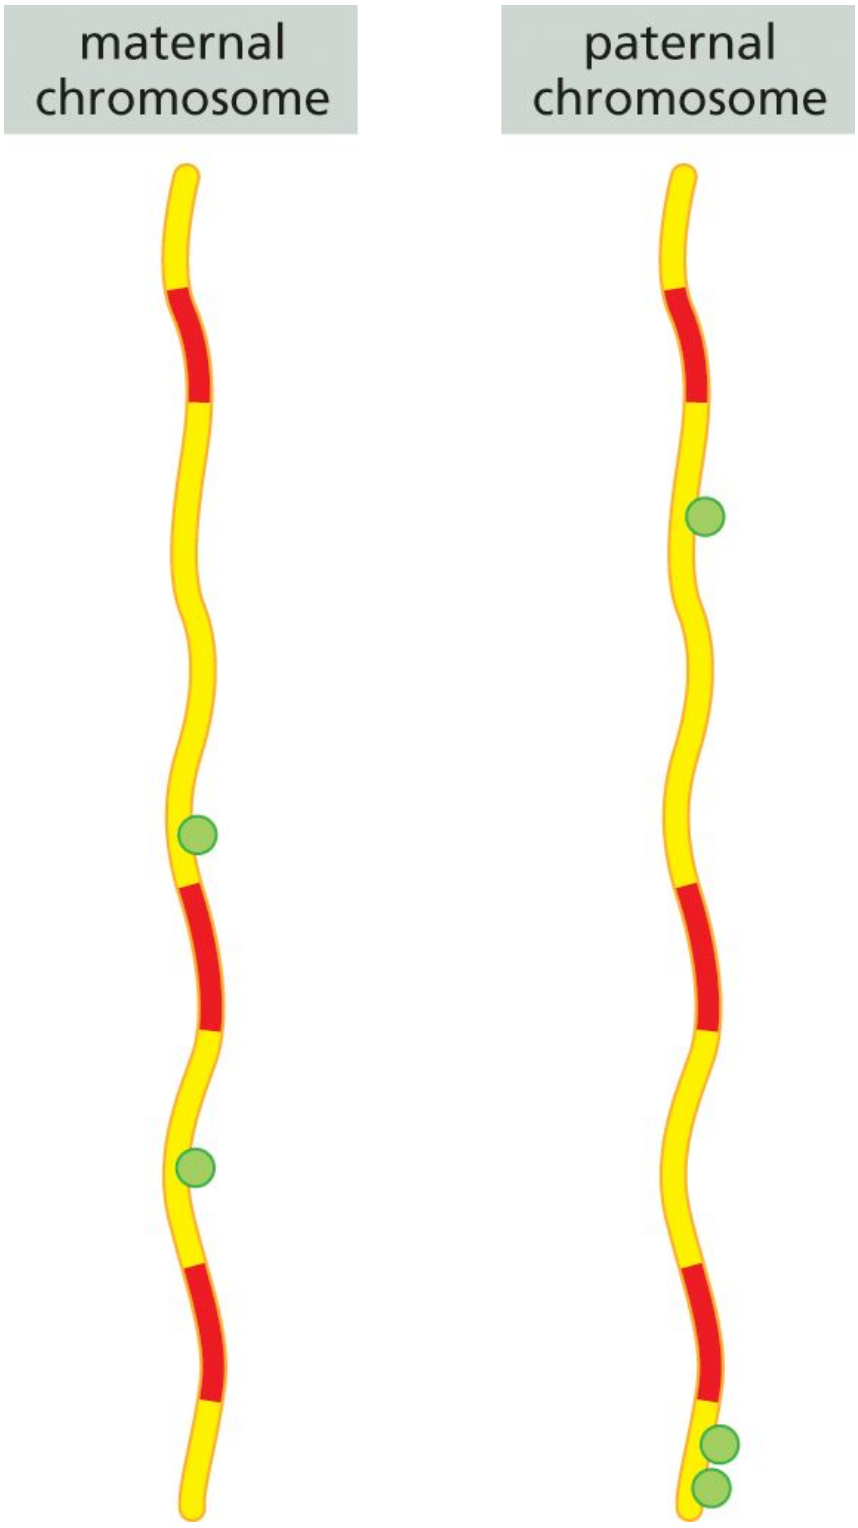


A segment of D N A has a coding sequence in the middle, shown in red, and junk D N A at each end, shown in yellow. Two types of mutation are shown acting on the segment. A selected mutation occurs when the mutation takes places in the coding sequence. The result is a defective allele, leading to a defective phenotype, leading to an inability of the organism carrying the mutant allele to compete, leading to a loss of the allele from gene pool. A neutral mutation occurs when the mutation takes place in one of the junk D N A ends. The coding sequence remains unchanged, so there is no effect on the phenotype and therefore no reduction in the organism's ability to compete. The allele is retained in the gene pool.

Figure 1.4 Neutral mutations and evolution The coding sequences (*red*) of most genes that encode protein structure were optimized in the distant evolutionary past. Hence, many mutations affecting amino acid sequence and thus protein structure (*left*) often create alleles that compromise the organism's ability to survive. For this reason, these mutant alleles are likely to be eliminated from the species' gene pool by the process of natural selection. In contrast, mutations striking "junk DNA" (*yellow*) have no effect on phenotype and are therefore often preserved in the species' gene pool (*right*). This explains why, over extended periods of evolutionary time, coding DNA sequences change slowly, while noncoding DNA sequences change far more rapidly.

The term *polymorphism* was originally used to describe variations in shape and form that distinguish normal individuals within a species from each other. These days,

geneticists use the term genetic polymorphisms to describe the inter-individual differences in DNA sequence at various sites throughout the genome, most of which, as discussed above, are registered as minor variations in sequence that have no effect on biological function (**Figure 1.5**). Recent estimates of the rate of spontaneously arising point mutations (affecting single DNA nucleotides) striking the genomes of proliferating normal human cells suggest that these mutations are accumulated at a rate of less than one nucleotide per genome per cell division, that is, only about one base pair per three billion base pairs per division—a stunning testimonial to the fidelity of DNA replication and repair. (Even lower mutational rates may affect the genes in germ cells, that is, those that give rise to eggs and sperm.) As we will see later (Chapter 12), these rates are increased in the genomes of replicating cancer cells.



A pair of chromosomes, one maternal and the other paternal. They are similar in length and have yellow non-functional stretches and red functional, coding stretches in all the same places. The only differences between the two

chromosomes are in the locations of a few green dots appearing randomly along the yellow stretches.

Figure 1.5 Polymorphic diversity in the human gene pool Because the great majority of human genomic DNA does not encode biologically important information (*yellow*), it has evolved relatively rapidly and has accumulated many subtle differences in sequences—polymorphisms—that are phenotypically silent (see Figure 1.4). Such polymorphisms are transmitted like Mendelian alleles, but their presence in a genome can be ascertained only by molecular techniques such as DNA sequencing. The dots (*green*) indicate where the sequence on this chromosome differs from the sequence that is most common in the human gene pool. For example, the prevalent sequence in one stretch may be TAACTGG, while the variant sequence TTACTGG may be carried by a minority of humans and constitute a polymorphism. The presence of a polymorphism in one chromosome but not the other represents a region of heterozygosity, even though a nearby gene (*red*) may be present in the identical allelic version on both chromosomes and therefore exist in a homozygous configuration.

During the course of evolution, the portion of the genome that encodes and affects biological function behaves much differently from the junk DNA. Junk DNA sequences suffer mutations that have no effect on the viability of an organism. Consequently, countless mutations in the noncoding sequences of a species' genome survive in its gene pool and accumulate progressively during its evolutionary history. In contrast, mutations affecting, for example, the protein-coding sequences of genes (see Section 1.6) often lead to loss of function and, as a consequence, reduction in organismic viability; hence, these mutations are usually weeded out of the gene pool by the hand of natural selection, explaining why genetic sequences that do indeed specify biological functions generally change very slowly over long evolutionary time periods (**Sidebar 1.1**).

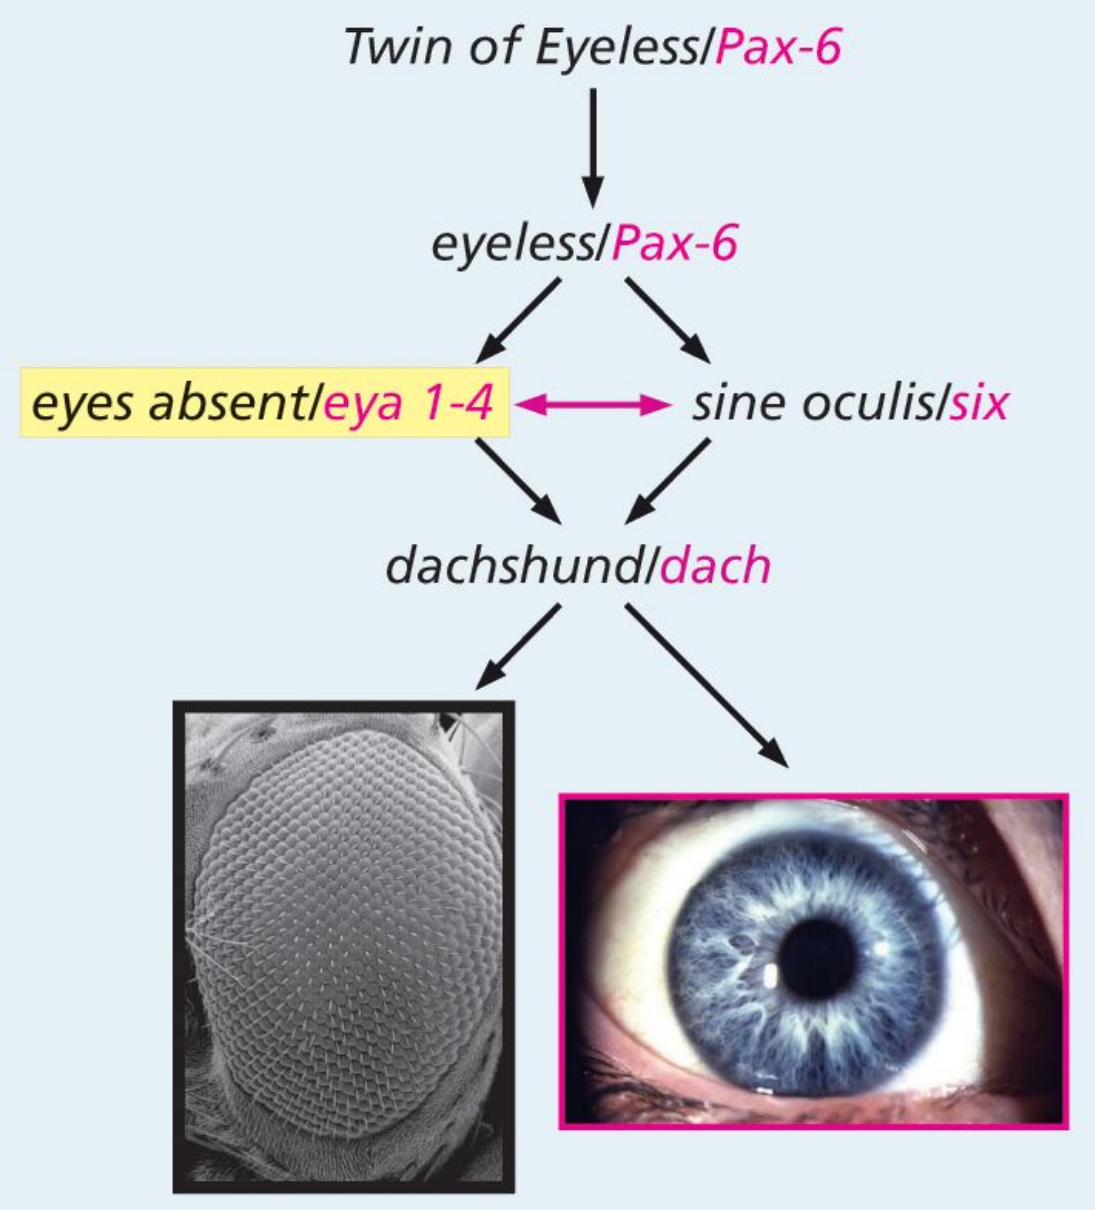
Sidebar 1.1 Evolutionary forces dictate that certain genes are highly conserved

Many genes encode cellular traits that are essential for the continued viability of the cell. These genes, like all others in the genome, are susceptible to the ever-tinkering hand of mutation, which is continually creating new gene sequences by altering existing ones. Natural selection tests these novel sequences and determines whether they specify phenotypes that are more advantageous than the preexisting ones.

The actual agents that create phenotypes are the proteins encoded by the genes. The amino acid sequences of the proteins required for cell and therefore organismic viability were already optimized hundreds of millions of years ago. Consequently, almost all subsequent changes in the amino acid sequences of such critical proteins

(resulting from mutations in the genes encoding them) would have been deleterious and would have compromised the viability of the cell and, in turn, the organism. These mutant alleles were soon lost from the gene pool of a species, because the mutant organisms carrying them failed to leave descendants. This dynamic explains why the sequences of many proteins have been highly conserved over vast evolutionary time periods. This dynamic can also be viewed in a different light: once certain genes and proteins developed, dozens and then hundreds of subsequent evolutionary inventions depended on the continued functioning of these earlier inventions. Any changes in the latter would cause the entire biological edifice to crumble, much like the removal of a playing card from a house of cards or a key foundation stone from a building. As we will read later in this book (Chapter 11), similar evolutionary dynamics influence the development of tumors within the human body.

In fact, the almost half of the proteins that are present in our own cells and are required for cell viability developed during the evolution of single-cell eukaryotes. This is indicated by numerous observations showing that many of our proteins have clearly recognizable counterparts in single-cell eukaryotes, such as baker's yeast. Another large repertoire of highly conserved genes and proteins is traceable to the appearance of the first multicellular animals (metazoa); these genes enabled the development of distinct organs and of organismic physiology. Hence, another large group of our own genes and proteins is present in counterpart form in worms and flies (**Figure 1.6**).



Two similarly structured sequences of genes that regulate eye development, in fruit flies and in mice. The sequences start with a gene called twin of eyeless in flies and PAX 6 in mice. Next is a gene called eyeless in flies and PAX 6 in mice. Here the sequence branches. On one side is a gene called eyes absent. The mouse version has variants 1 through 4. On the other side is a gene called sine oculis in flies and six in mice. Finally, the sequence converges again, to a gene called dachshund in flies and dachs in mice. These genes lead to photos of a fly eye and a human eye.

(A)

S. cerevisiae	DQIFKIPRVLGTPNEAIWPDIVYLPDFKPSFP

A comparison of the amino acid sequence of a human protein with the sequences of the corresponding proteins from S. pombe and S. cerevisiae. For the 96 amino acid positions shown, the amino acid is the same across all three species in 60 of them. Where the amino acids are not all the same, sometimes the human protein matches one of the two yeast proteins but not the other.

(C)

Figure 1.6 Extraordinary conservation of gene function The last common ancestor of flies and mammals lived more than 600 million years ago. Moreover, fly (i.e., arthropod) eyes and mammalian eyes show totally different architectures. Nevertheless, the genes that orchestrate their development (*eyeless* in the fly, *Pax-6/small eye* in the mouse) are interchangeable—the gene from one organism can replace the corresponding mutant gene from the other and restore wild-type function. (A) Thus, the genes encoding components of the signal transduction cascades that operate downstream of these master regulators to trigger eye development (*black* for flies, *pink* for mice) are also highly conserved and interchangeable. (B) The expression of the mouse *Pax-6/small eye* gene, like the *Drosophila eyeless* gene, in an ectopic (inappropriate) location in a fly embryo results in the fly developing a fly eye on its leg (*arrow*), demonstrating the interchangeability of the two genes. (C) The conservation of genetic function over vast evolutionary distances is often manifested in the amino acid sequences of homologous proteins. Here, the amino acid sequence of a human protein is given together with the sequences of the corresponding proteins from two yeast species, *Schizosaccharomyces pombe* and *S. cerevisiae*. The amino acid residues present identically in the three proteins are indicated in a *white* background whereas those that have diverged from one another are indicated in a *light blue* background. The last common ancestor of the corresponding organisms is estimated to have lived more than 1 billion years ago. (A, left from I. Rebay et al., *Genetics 154*: 695-712, 2000. With permission from Oxford University Press; right, courtesy of Helga Kolb. B, courtesy of Walter Gehring, University of Basel. C, adapted from B. Alberts et al., Essential Cell Biology, 5th ed. New York: W. W. Norton & Company, 2019.)

By the time the ancestor of all mammals first appeared more than 200 million years ago, virtually all the biochemical and molecular features present in contemporary mammals had already been developed. The fact that they have changed little in the intervening time points to their optimization and essentiality long before the appearance of the various mammalian orders. This explains why the embryogenesis, physiology, and biochemistry of all mammals is very similar, indeed, so similar that lessons learned through the study of laboratory mice are almost always transferable to an understanding of human biology.

OceanofPDF.com

Glossary

mutation
: Change in the genotype of a virus or cell that involves an alteration in the nucleotide sequence of its genome, in the arrangement of a segment within a chromosome, in the number of copies of a segment, in the physical structure of a chromosome, or in the number of copies of a structurally normal chromosome.

wild type
: The allele of a gene that is commonly present in the great majority of individuals in a species and is usually presumed to be fully functional.

gene pool
: Collection of genes and associated alleles that are carried by the members of a species or by a group of individual organisms.

junk DNA
: Genomic DNA that cannot be associated with any biological function.

neutral mutation
: Change in DNA sequence that has no effect on phenotype, including mutations that have no effect on protein structure.

genetic polymorphism
: A genetic element that is present in the gene pool of a species in multiple variant forms. Polymorphisms are often implied to have small or no effects on phenotype or evolutionary fitness. *See also* **polymorphism**.

eukaryotic
: Referring to the large, complex, nucleated cells of metazoa, metaphyta, and many protozoa. *See also* **prokaryotic.**

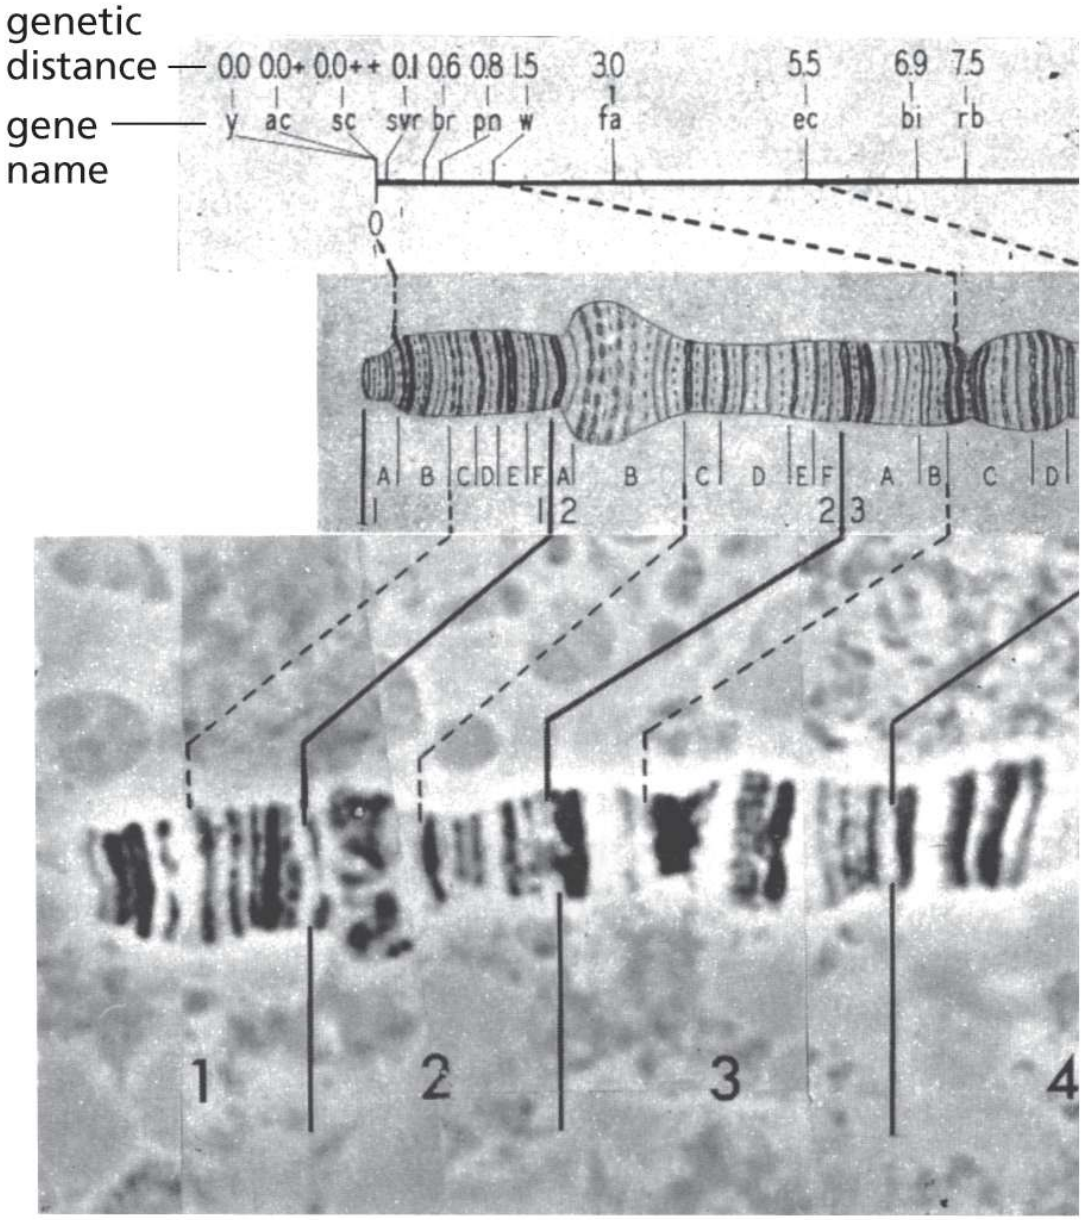
1.3 Mendelian genetics governs how both genes and chromosomes behave

In the first decade of the twentieth century, Mendel's rules of genetics were found to have a striking parallel in the behavior of the chromosomes that were then being visualized under the light microscope: Mendel's genes and the chromosomes were both found to be present in pairs. Soon it became clear that an identical set of chromosomes is present in almost all the cells of a complex organism. This chromosomal array, often termed the karyotype, was found to be duplicated each time a cell went through a cycle of growth and division.

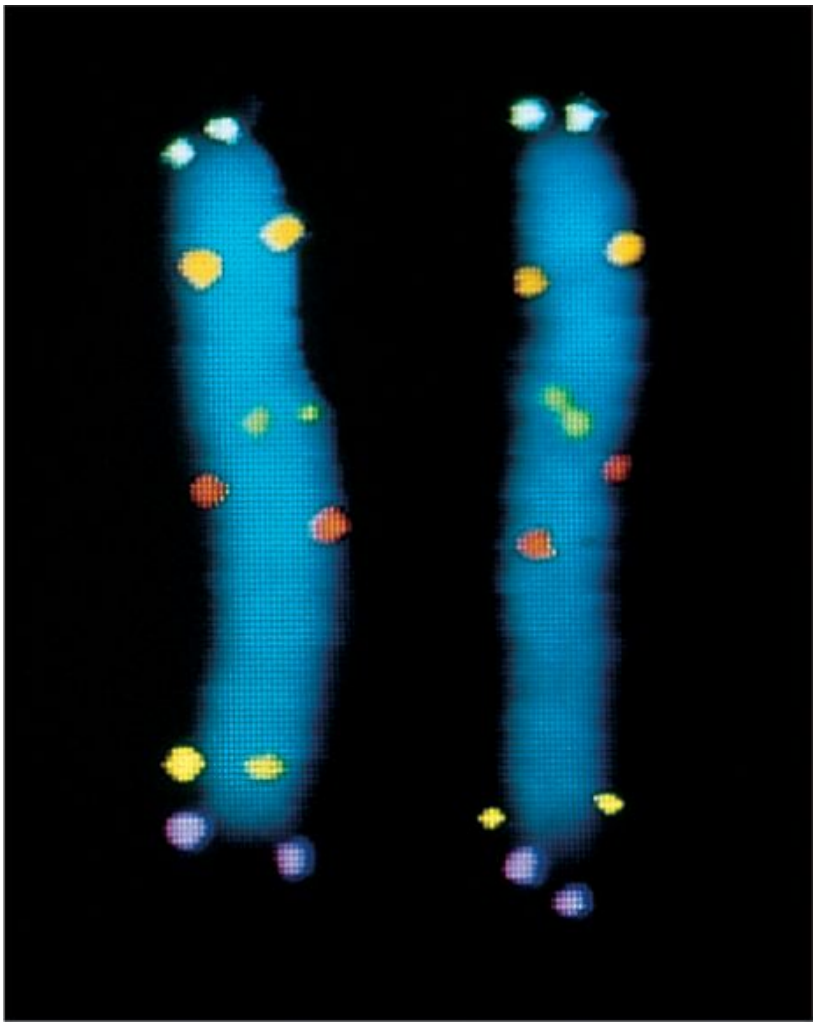
The parallels between the behaviors of genes and chromosomes led to the speculation, soon validated in hundreds of different ways, that the mysterious information packets called genes were carried by the chromosomes. Each chromosome was realized to carry its own unique set of genes in a linear array. Today we know that as many as several thousand genes may be arrayed along a mammalian chromosome. (Human Chromosome 1—the largest of the set—carries ~8% of the human genome.)

Each gene was found to be localized to a specific site on a specific chromosome. This site is often termed a genetic locus. Much effort was expended by geneticists throughout the twentieth century to map the sites of genes—genetic loci—along the chromosomes of a species (**Figure 1.7**).



A physical banding map of a drosophila chromosome. Above it is a linear map of various genetic loci along with their genetic distance and gene name. Below the physical banding map is a micrograph of the chromosome. Lines between the three images show correspondences.

(A)



A micrograph shows two human chromosomes lying side by side like two blue worms. Brightly colored dots denote gene sites. Each chromosome has on it, from top to bottom, two white dots, two orange dots, two green dots, two red dots, two yellow dots, and two purple dots.

(B)

Figure 1.7 Localization of genes along chromosomes (A) The physical structure of *Drosophila* chromosomes was mapped (*middle*) by using the fly's salivary gland chromosomes, which exhibit banding patterns resulting from alternating light (sparse) and dark (condensed) chromosomal regions (*bottom*). Independently, genetic crosses yielded linear maps (*top*) of various genetic loci arrayed along the chromosomes. These loci could then be aligned with physical banding maps, like the one shown here for the beginning of the left arm of *Drosophila* chromosome 1. (B) The availability of DNA probes that hybridize specifically to various genes now makes it possible to localize genes along a chromosome by tagging each

probe with a specific fluorescent dye or combination of dyes. Shown are six genes that were localized to various sites along human Chromosome 5 by using fluorescence *in situ* hybridization (FISH) during metaphase. (There are two dots for each gene because chromosomes are present in duplicate form during metaphase of mitosis.) (A, top from C.B. Bridges, *J. Hered*. 26:60, 1935. With permission from Oxford University Press; bottom from M. Singer and P. Berg, *Genes and Genomes*. University Science Books, 1991. With permission from University Science Books. B, courtesy of David C. Ward.)

The diploid genetic state that reigns in most cells throughout the body was found to be violated in the *germ cells*, sperm and egg. These cells carry only a single copy of each chromosome and gene and thus are said to be haploid. During the formation of germ cells in the testes and ovaries, each pair of chromosomes is separated and one of the pair (and thus associated genes) is chosen at random for incorporation into the sperm or egg. When sperm and egg combine subsequently during fertilization, the two haploid genomes fuse to yield the new diploid genome of the fertilized egg. All cells in the organism descend directly from this diploid cell and, if all goes well, inherit precise replicas of its diploid genome. In a large multicellular organism like the human, this means that a complete copy of the genome is present in almost all of the approximately 3×10^{13} cells throughout the body!

With the realization that genes reside in chromosomes, and that a complete set of chromosomes is present in almost all cell types in the body, came yet another conclusion that was rarely noted: genes create the phenotypes of an organism through their ability to act *locally* by influencing the behavior of its individual cells. The alternative—that a single set of genes residing at some unique anatomical site in the organism controls the entire organism's development and physiology—was now discredited.

The rule of paired, similarly appearing chromosomes was found to be violated by some of the sex chromosomes. In the cells of female placental mammals, there are two similarly appearing X chromosomes, and these behave like the autosomes (the nonsex chromosomes). But in males, an X chromosome is paired with a Y chromosome, which is smaller and carries a much smaller repertoire of genes. In humans, the X chromosome is thought to carry about 900 genes, compared with the 78 distinct genes on the Y chromosome, which, because of redundancy, specify only 27 distinct proteins (see **Supplementary Sidebar 1.1**).

This asymmetry in the configuration of the sex chromosomes puts males at a biological disadvantage. Many of the 900 or so genes on the X chromosome are vital to normal organismic development and function. The twofold redundancy created by the paired X chromosomes in female cells guarantees more robust biology. If a gene

copy on one of the X chromosomes is defective (that is, represents a nonfunctional mutant allele), chances are that the second copy of the gene on the other X chromosome can continue to carry out the task of the gene, ensuring normal biological function. Males lack this genetic fail-safe system in their sex chromosomes. One of the more benign consequences of this is color blindness, which strikes males frequently and females infrequently, due to the localization on the X chromosome of the genes encoding the color-sensing proteins of the retina.

Color blindness reveals the virtues of having two redundant gene copies around to ensure that biological function is maintained. If one copy is lost through mutational inactivation, the surviving gene copy is often capable of specifying a wild-type phenotype. Such functional redundancy operates for the great majority of genes carried by the autosomes. As we will see later, this dynamic plays an important role in cancer development, since virtually all of the genes that operate to prevent runaway proliferation of cells are present in two redundant copies, both of which must be inactivated in a cell before their growth-suppressing functions are lost and malignant cell proliferation can occur. Of additional interest, the asymmetry of X-chromosome complements between males and females is compensated in part by the mechanism of X-chromosome inactivation (see **Supplementary Sidebar 1.1**).

OceanofPDF.com

Glossary

karyotype
: (1) The array of chromosomes carried by a cell, as determined by detailed microscopic examination of these chromosomes usually performed with condensed chromosomes at metaphase. (2) Images of the metaphase chromosomes of a cell arrayed systematically by homologous pairs from the largest to the smallest pair.

locus
: (1) Chromosome site that can be studied genetically and is presumed to be associated with a specific gene. (2) A genetic element that can be mapped by genetic analysis.

haploid
: Describing a genome in which all chromosomes are present in a single copy.

autosome
: A chromosome that is not a sex chromosome, i.e., neither an X nor a Y chromosome.

OceanofPDF.com

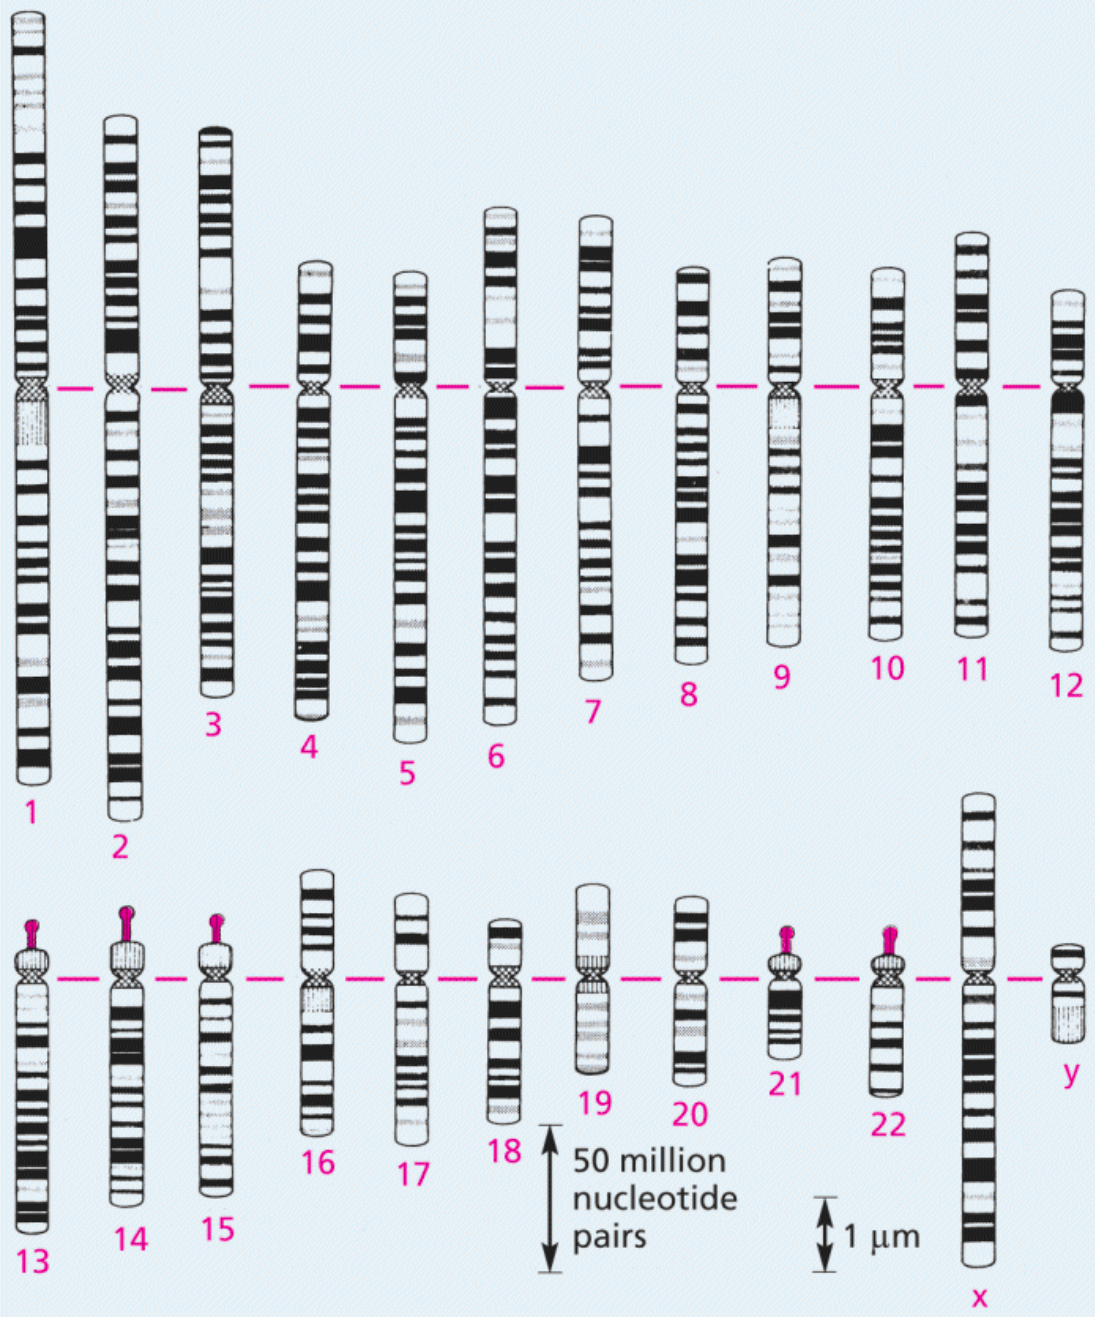
1.4 Chromosomes are altered in most types of cancer cells

Individual genes are far too small to be seen with a light microscope, and subtle mutations within a gene are smaller still. Consequently, the great majority of the mutations that play a part in cancer cannot be visualized through microscopy. However, the examination of chromosomes through the light microscope can give evidence of large-scale alterations of the cell genome. Indeed, such alterations were noted as early as 1892, specifically in cancer cells.

Today, we know that cancer cells often exhibit aberrantly structured chromosomes of various sorts, the loss of entire chromosomes, the presence of extra copies of others, and the fusion of the arm of one chromosome with part of another (**Sidebar 1.2**; see Figure 1.8). These changes in overall chromosomal configuration expand our conception of how mutations can affect the genome: since alterations of overall chromosomal structure and number also constitute types of genetic change, these changes must be considered to be the consequences of mutations. And importantly, the abnormal chromosomes seen initially in cancer cells provided the first clue that these cells might be genetically aberrant, that is, that they were mutants.

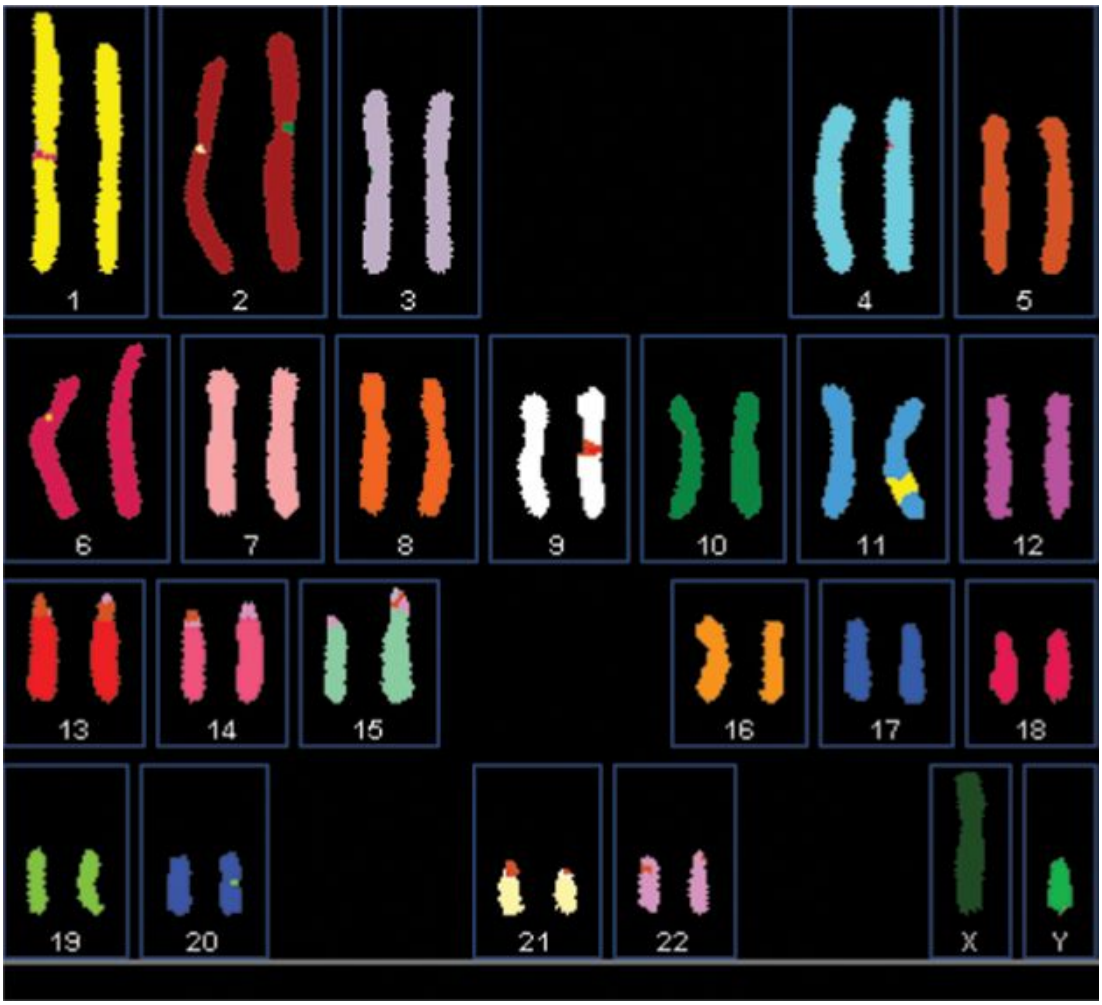
Sidebar 1.2 Cancer cells are often aneuploid

The presence of abnormally structured chromosomes and changes in chromosome number provided the first clue, early in the twentieth century, that changes in cell genotype often accompany and perhaps cause the uncontrolled proliferation of malignant cells. These deviations from the normal euploid karyotype can be placed into a number of categories. Chromosomes that seem to be structurally normal may accumulate in extra copies, leading to three, four, or even more copies of these chromosomes per cancer cell nucleus (**Figure 1.8**); such deviations from normal chromosome number are manifestations of *aneuploidy*.



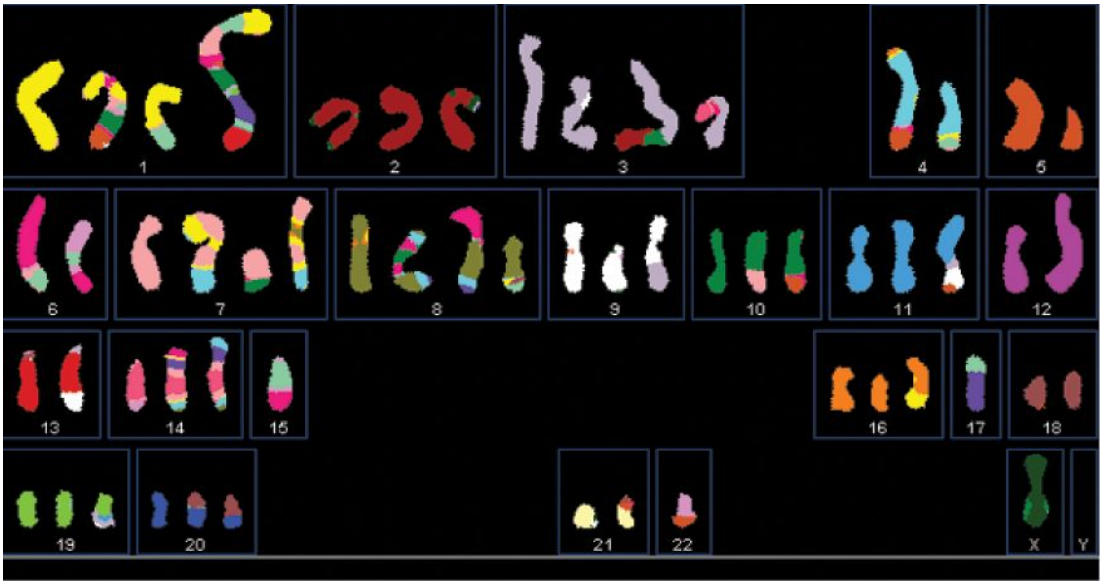
Banding patterns from 22 numbered human chromosomes, plus an X and a Y. They vary in length from about 1.4 microns long to about 10.6 microns long and contain between 35 million and 265 million base pairs.

(A)



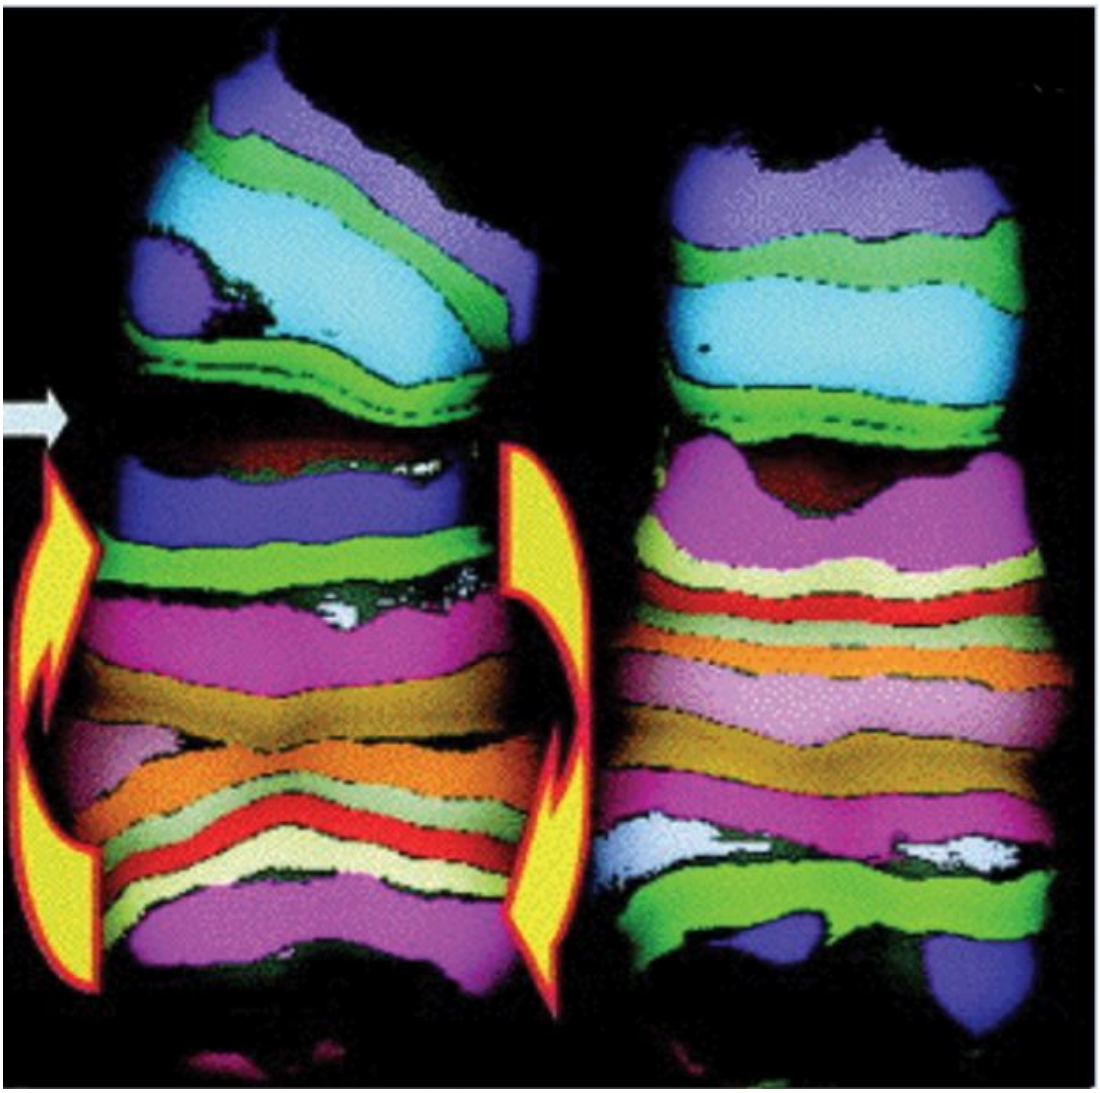
A color-coded image of 22 numbered human chromosome pairs, one color per pair, plus an X-Y pair. The image represents the chromosomes in their normal condition.

(B)



A color-coded image of what should be 22 numbered human chromosome pairs, one color per pair, plus an X-Y pair. In most cases, what should be a pair appears as three or four chromosomes, and quite a few of the chromosomes have stripes of many colors, like multicolored candy-canes. The Y chromosome is absent.

(C)



Two versions of a short segment of human chromosome. Colored stripes in each chromosome reveal that, as two curved arrows indicate, the version on the left has a portion that was flipped 180 degrees from the version on the right such that what was once on the bottom is now in the middle.

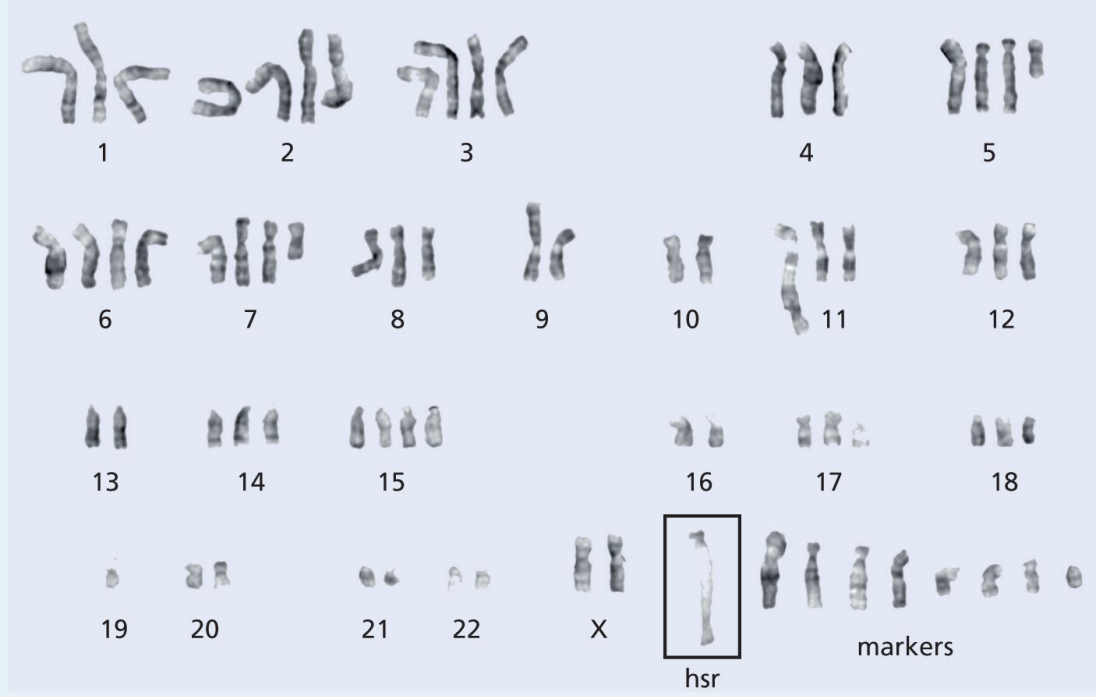
(D)

Figure 1.8 Normal and abnormal chromosomal complements (A) Staining of metaphase chromosomes reveals a characteristic light-and-dark banding pattern for each. The full array of human chromosomes is depicted; their centromeres are aligned (*pink line*). (B) The techniques of spectral karyotype (SKY) analysis and multicolor fluorescence *in situ* hybridization (mFISH) allow an experimenter to "paint" each metaphase chromosome with a distinct color (by hybridizing chromosome-specific DNA probes labeled with various fluorescing dyes to the chromosomes). The actual colors in images such as these are generated by

computer. The diploid karyotype of a normal human male cell is presented. (The small regions in certain chromosomes that differ from the bulk of these chromosomes represent hybridization artifacts.) (C) The aneuploid karyotype of a human pancreatic cancer cell, in which some chromosomes are present in inappropriate numbers and in which numerous translocations (exchanges of segments between chromosomes) are apparent. (D) Here, mFISH (multicolor FISH) was used to label intrachromosomal subregions with specific fluorescent dyes, revealing that a large portion of an arm of normal human Chromosome 5 (*right*) has been inverted (*left*) in cells of a worker who had been exposed to plutonium in the nuclear weapons industry of the former Soviet Union. The site where the normal chromosome was broken and then rejoined with the inverted remainder of the chromosome is indicated by a *white arrow.* (A, adapted from U. Francke, *Cytogenet. Cell Genet.* 31:24–32, 1981. B and C, courtesy of M. Grigorova, J.M. Staines, and P.A.W. Edwards. D, from M.P. Hande et al., *Am. J. Hum. Genet.* 72:1162–1170, 2003. With permission from Elsevier.)

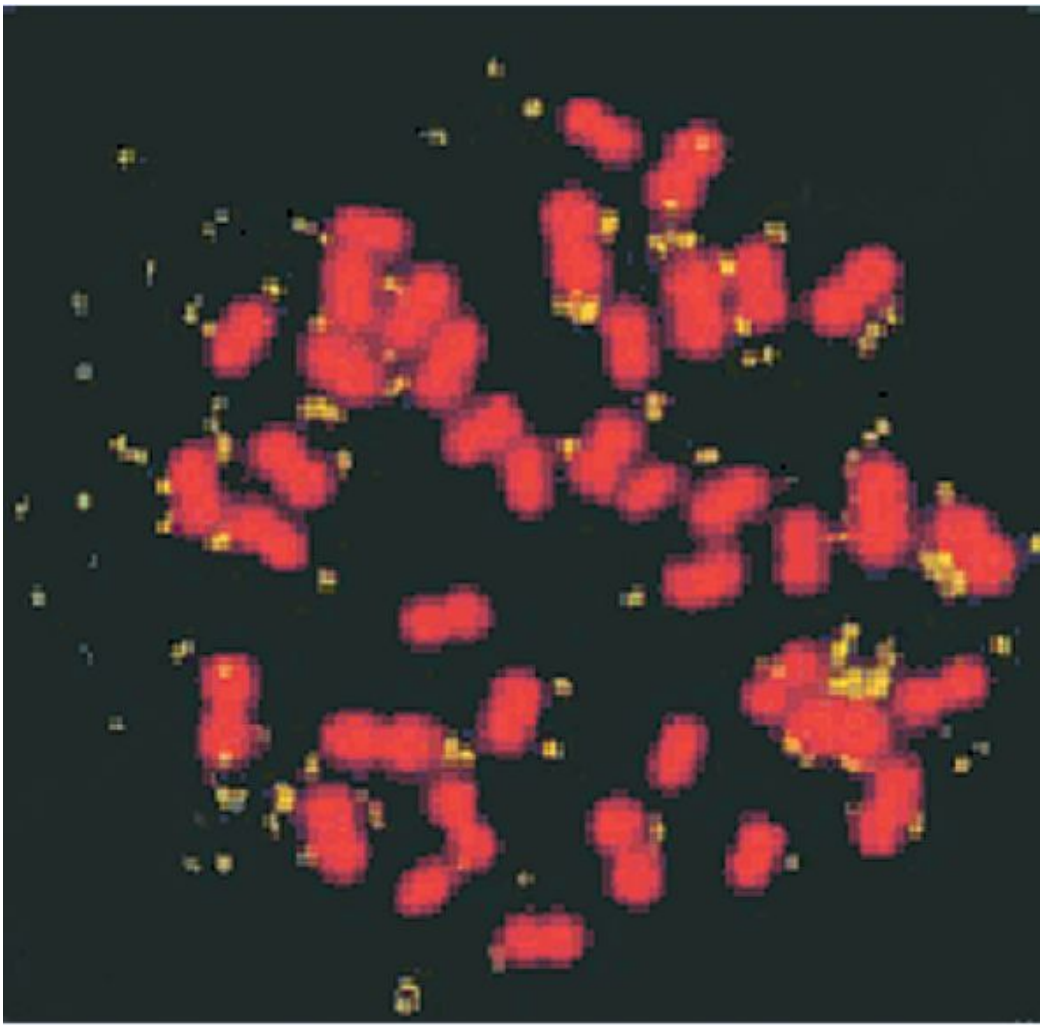
Alternatively, chromosomes may undergo changes in their structure. A segment may be broken off one chromosomal arm and become fused to the arm of another chromosome, resulting in a chromosomal translocation (see Figure 1.8C). Moreover, chromosomal segments may be exchanged between chromosomes from different chromosome pairs, resulting in reciprocal translocations. A chromosomal segment may also become inverted, which may affect the regulation of genes that are located near the breakage and fusion points (see Figure 1.8D).

A segment of a chromosome may be copied many times over, and the resulting extra copies may be fused head-to-tail in long arrays within a chromosomal segment that is termed an HSR (homogeneously staining region; **Figure 1.9A**). A segment may also be cleaved out of a chromosome, replicate as an autonomous, extrachromosomal entity, and increase to many copies per nucleus, resulting in the appearance of subchromosomal fragments termed DMs (double minutes; Figure 1.9B). These latter two changes cause increases in the copy number of genes carried in such segments, resulting in gene amplification. Sometimes, both types of gene amplification coexist in the same cell. In general, gene amplification can favor the growth of cancer cells by increasing the copy number of growth-promoting genes.



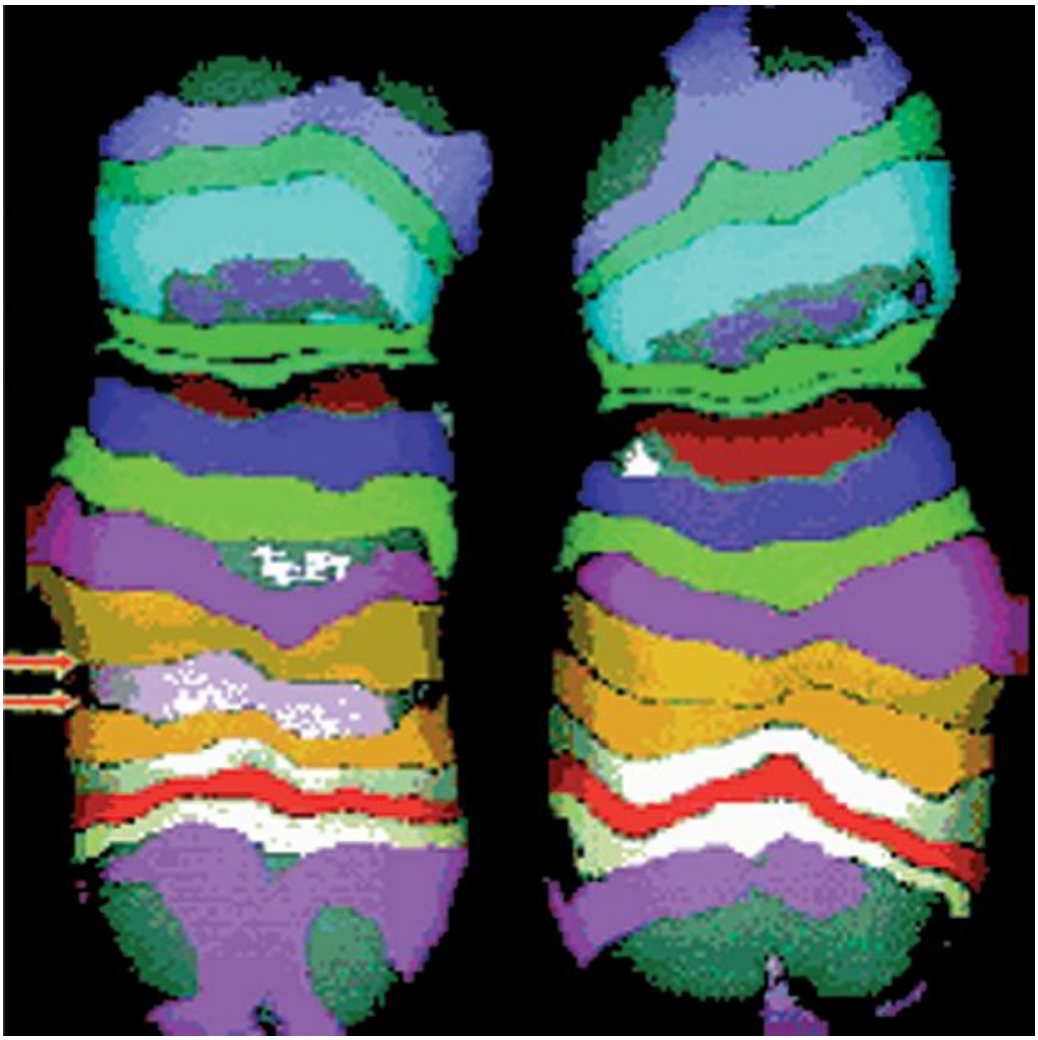
A black-and-white image of what should be 22 numbered human chromosome pairs, plus an X-Y pair. In most cases, which should be a pair appears as three or four chromosomes. The Y chromosome is absent. Most chromosomes shown visible banding, but a segment labeled h s r has a long middle section that is white. Also shown are eight pieces of chromosome labeled as markers.

(A)



Several dozen peanut-shaped objects appear bright red against a black background. Interspersed are small, yellow, grainlike flecks.

(B)



Two versions of a short segment of human chromosome. Colored stripes reveal that, as two small arrows indicate, a pale purple stripe present in the lef version is missing from an otherwise similar pattern of stripes on the right version.

(C)

Figure 1.9 Increases and decreases in copy number of chromosomal segments
(A) The amplification in the gene copy number of the *myc* oncogene (that is, a cancer-causing gene; see Section 4.3) in a human neuroendocrinal tumor, arising via end-to-end assembly of multiple copies of the oncogene, has caused an entire stretch of chromosome to stain *white* (*rectangle*), creating a homogeneously staining region (HSR). Almost all other chromosomes are present in multiple copies, many with structural abnormalities. (B) Double-minute chromosomes (DMs) derive from chromosomal segments that have broken loose from their original sites and have been replicated repeatedly as extrachromosomal genetic

elements; like normal chromatids, these structures are doubled during metaphase of mitosis. FISH reveals the presence of amplified copies of the *HER2/neu* oncogene borne on DMs (*yellow dots*) in a mouse breast cancer cell. (C) The use of multicolor FISH (mFISH) revealed that a segment within normal human Chromosome 5 (*paired arrows, light purple segment, left*) has been deleted, yielding an interstitial deletion in which this segment is absent (*right chromosome*) following extensive exposure to radiation from plutonium. (A, from J.-M. Wen et al., *Cancer Genet. Cytogenet.* 135:91–95, 2002. With permission from Elsevier. B, from C. Montagna et al., *Oncogene* 21:890–898, 2002. With permission from Nature. C, from M.P. Hande et al., *Am. J. Hum. Genet.* 72:1162–1170, 2003. With permission from Elsevier.)

On some occasions, certain growth-inhibiting genes may be discarded or inactivated by cancer cells during their development. For example, when a segment in the middle of a chromosomal arm is discarded and the flanking chromosomal regions are joined, this can result in an interstitial deletion (Figure 1.9C), which liberates the incipient cancer cell from the inhibitory actions of the now-deleted gene or genes.

These descriptions of copy-number changes in genes, involving both amplifications and deletions, might suggest widespread chaos in the genomes of cancer cells, with gene amplifications and deletions occurring randomly. However, as the karyotypes and genomes of human tumors have been examined more intensively, it has become clear that certain regions of the genome tend to be lost characteristically in certain tumor types but not in others; this non-random activation or inactivation of a particular gene in a number of independently arising human tumors is termed a recurrent mutation and points to a critical role played by the altered gene and encoded protein in specific steps of tumor development. This suggests a theme that we will pursue in great detail throughout this book—that the gains and losses of particular genes favor the proliferation of specific types of tumors.

The normal configuration of chromosomes is often termed the euploid karyotypic state. Euploidy implies that each of the autosomes is present in normally structured pairs and that the X and Y chromosomes are present in the numbers appropriate for the sex of the individual carrying them. Deviation from the euploid karyotype—the state termed aneuploidy—is seen, as mentioned above, in many cancer cells. Indeed, the cells of perhaps 90% of human solid tumors carry aneuploid karyotypes (see Figure 1.9); often this aneuploidy is merely a consequence of the general chaos that reigns within a cancer cell. However, this connection between aneuploidy and malignant cell proliferation also hints at a theme that we will return to repeatedly in this book: the acquisition of extra copies of one chromosome or the loss of another can create a

genetic configuration that somehow benefits the cancer cell and its agenda of runaway proliferation.

OceanofPDF.com

Glossary

translocation
: (1) Rearrangement of chromosomes that results in the fusion of two chromosomal segments that are not normally attached to one another, often resulting in a microscopically visible alteration of karyotype. (2) Movement of a physical entity from one part of the cell to another. (3) Movement of a ribosome down an mRNA being translated.

reciprocal translocation
: Exchange via a process resembling recombination of chromosomal segments between two chromosomes from different (i.e., usually nonhomologous) chromosome pairs, resulting in the conservation of all participating chromosomal segments.

homogeneously staining region
: A region of a chromosome consisting of amplified copies of a chromosomal segment that have become fused end to end; because each copy contains a characteristic sequence of DNA, the region as a whole appears homogenous following staining.

gene amplification
: *See* **amplification**: Genetic mechanism by which the copy number of a gene is increased above its normal level in the diploid genome.

interstitial deletion
: Genetic alteration, often observed through analysis of karyotype, that causes deletion of an internal segment of a chromosomal arm.

recurrent mutation
: Somatic mutations of a particular gene or nucleotide sequence that is observed in the genomes of a number of independently arising tumors, providing strong indication that mutations of this gene or sequence confer selective advantage to the cells that sustain them. *See also* **driver mutation**.

euploid
: (1) Referring to a collection of chromosomes that corresponds precisely in number and structure to the array present in normal, wild-type cells. (2) Describing a karyotype having such a complement of chromosomes. *See also* **karyotype.**

double-minute

A chromosomal segment that becomes separated from the chromosome in which it normally resides and is able to perpetuate itself as an extrachromosomal particle unlinked to a centromere, so termed because it is visualized at metaphase as small spots that are doubled like the chromatids prior to anaphase.

aneuploid

(1) Describing a karyotype that deviates from diploid because of increases or decreases in the numbers of certain chromosomes. (2) Less commonly, describing a karyotype that carries structurally abnormal chromosomes.

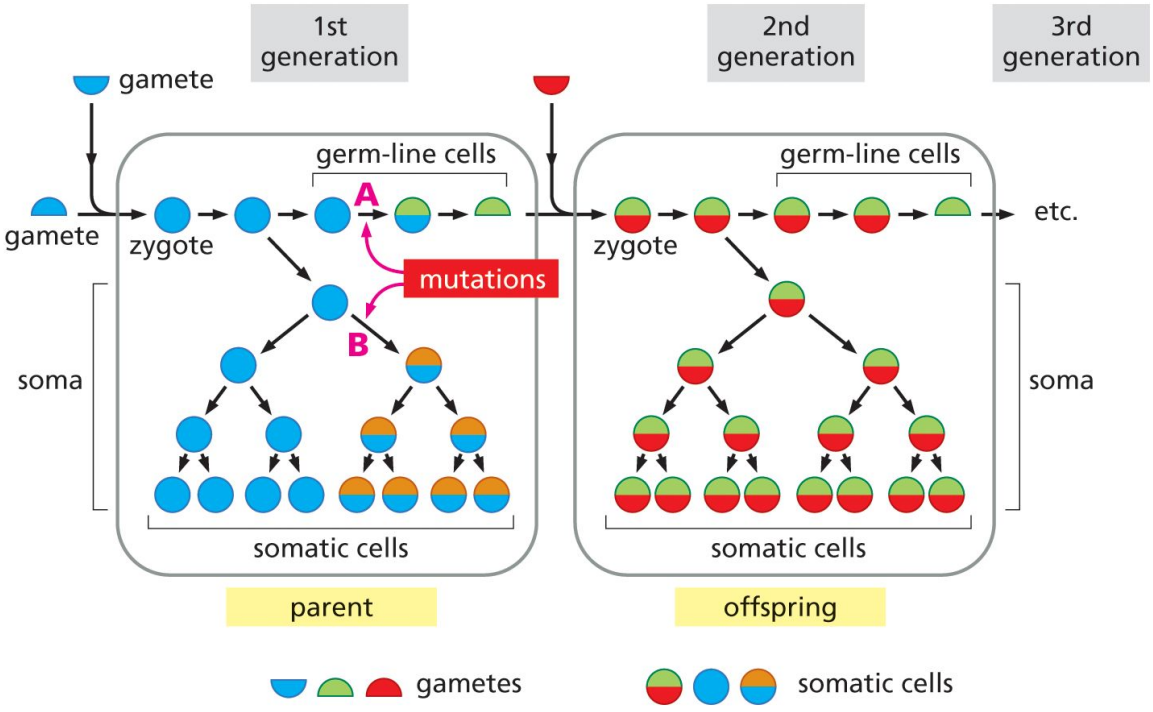
1.5 Mutations causing cancer occur in both the germ line and the soma

Mutations alter the information content of genes, and the resulting mutant alleles of a gene can be passed from parent to offspring. This transmission from one generation to the next, made possible by the germ cells (sperm and egg), is said to occur via the germ line (**Figure 1.10**). Importantly, the germ-line transmission of a recently created mutant allele from one organism to its offspring can occur only if a precondition has been met: the responsible mutation must strike a gene carried in the genome of sperm or egg (**gametes**) or in the genome of one of the cell types that are immediate precursors of the sperm or egg within the gonads. Mutations affecting the genomes of cells everywhere else in the body—which constitute the soma—create somatic mutations. The resulting mutant alleles have no prospect of being transmitted to the offspring of an organism, because they are not incorporated into the vehicles of generation-to-generation genetic transmission—the chromosomes of sperm or eggs.



A comparison of the effects of germ-line and somatic mutations. A parent individual begins with the uniting of two gametes to form a zygote. Multiplication of the zygote produces the cells of the soma and also germ cells. Mutation B in a somatic cell is passed on only to the descendants of that cell within the same individual. Mutation A in a germ cell, by contrast, produces a gamete that can pass the mutation on to an offspring by uniting with another gamete. The resulting zygote carries the mutation, and therefore so does every somatic cell and germ cell descended from it. The mutated gamete may then be passed on to a third generation, as well.

Figure 1.10 Germ-line versus somatic mutations The fate of the novel allele created by a mutation depends upon the particular cell in which the mutation strikes. Mutation A, which occurs in the genome of a germ-line cell in the gonads, can be passed from parent (*above left*) to offspring via gametes —sperm or egg (*green half circles*). Once incorporated into the fertilized egg (zygote), the mutant alleles can then be transmitted to all of the cells in the body of the offspring (2nd generation) outside of the gonads, i.e., its soma, as well as being transmitted via germ-line cells and gametes to a third generation (*not shown*). However, mutation B (*left*), which strikes the genome of a somatic cell in the parent, can be passed (*light brown half circles*) only to the lineal descendants of that mutant cell within the body of the parent and cannot be transmitted to offspring. (Adapted from B. Alberts et al., Essential Cell Biology, 5th ed. New York: W. W. Norton & Company, 2019.)

Somatic mutations are of central importance to the process of cancer formation. As described repeatedly throughout this book, a somatic mutation can affect the behavior of the cell in which it occurs and, through repeated rounds of cell growth and division, can be passed on to all descendant cells within a tissue. These direct descendants of a single progenitor cell, which may ultimately number in the millions or even billions, are said to constitute a cell clone, in that all members of this group of cells trace their lineage directly back to the single ancestral cell in which the mutation originally occurred.

An elaborate repair apparatus within each cell continuously monitors the cell's genome and, with great efficiency, eradicates mutant sequences, replacing them with appropriate wild-type sequences and eliminating cells with inappropriate karyotype. (We will examine this repair apparatus in depth in Chapter 12.) This apparatus maintains genomic integrity by minimizing the number of mutations that strike the genome and, in the absence of proper repair, are then perpetuated

by transmission to descendant cells. The challenge that the repair apparatus confronts is suggested by the fact that as many as 10^{16} cells are formed in the human body during a single lifetime, each created following the replication of cell genomes and the proper segregation of chromosomes; the occasional errors made by these processes must be detected and resolved, lest mutant genomes be perpetuated and transmitted to descendant cells. One stunning indication of the efficiency of genome repair comes from the successes of organismic cloning: the ability to generate an entire organism from the nucleus of a differentiated cell (prepared from an adult tissue) indicates that the genome of this adult cell is essentially a faithful replica of the genome of a fertilized egg, which existed many years and many cell generations earlier (**Supplementary Sidebar 1.2**).

OceanofPDF.com

Glossary

germ line
: (1) The collection of genes that is transmitted from one organismic generation to the next. (2) The cells within a multicellular organism that are responsible for carrying and transmitting genes from one organismic generation to its offspring.

soma
: All the tissues in the body outside of the germ cells (sperm and egg) and the immediate precursors of the germ cells.

somatic mutation
: Mutation that strikes the genome of a cell outside of the germ line; such a mutation cannot, by definition, be transmitted to the next organismic generation. *See also* **germ line**.

clone
: (adj., **clonal**) (1) Copy of a gene that has been isolated by recombinant DNA procedures and amplified into a large number of identical copies. (2) Population of cells, all of which descend from a common progenitor cell. (3) Offspring of a procedure of asexual reproduction in which the genome of a somatic diploid cell of an organism is used to form a cell that functions equivalently to a fertilized egg that may itself develop thereafter into an entire organism.

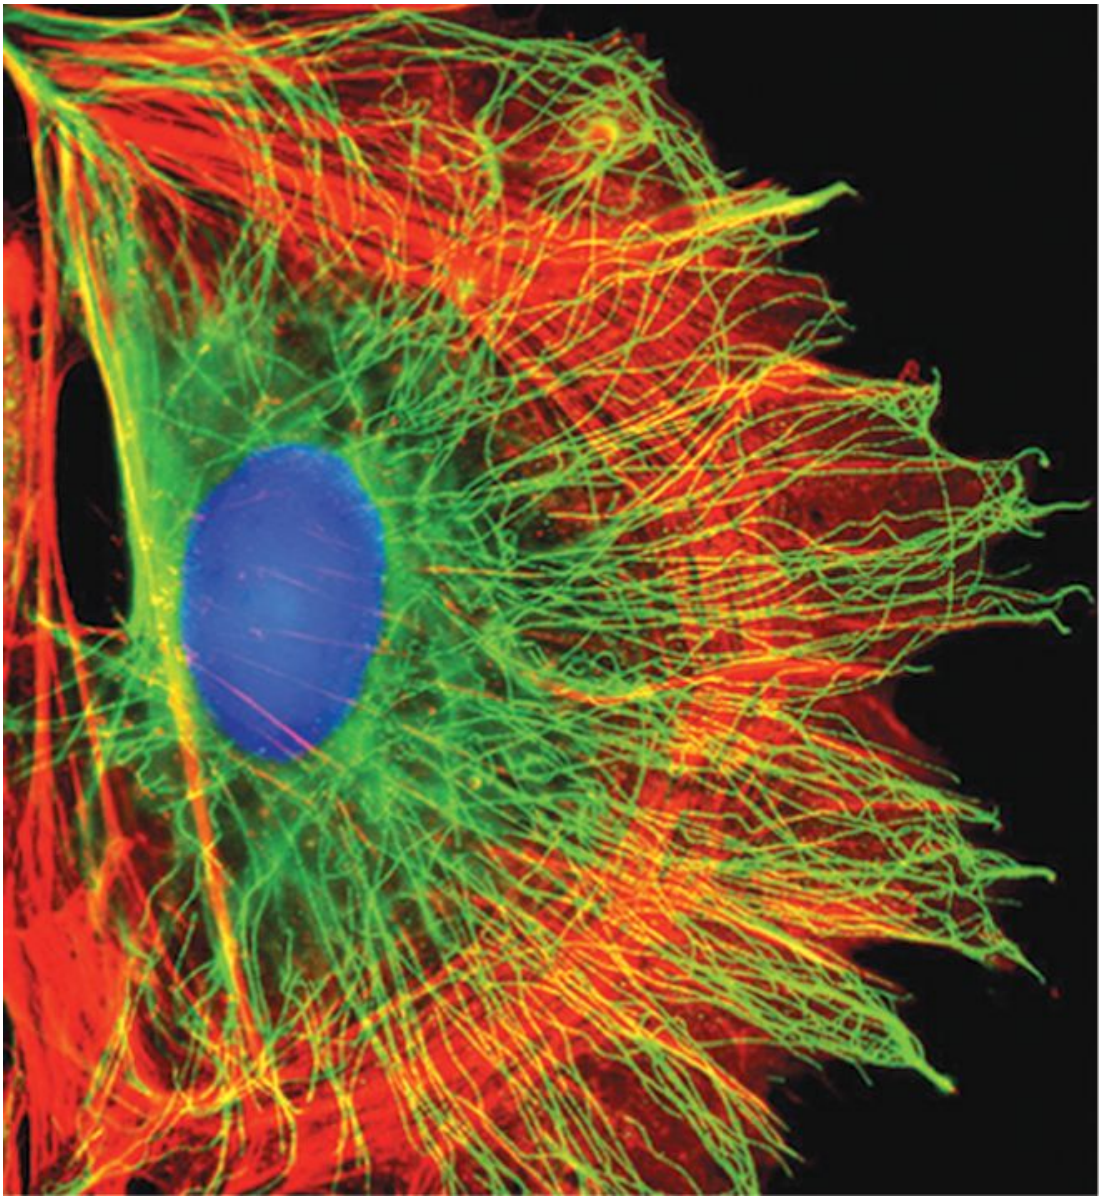
1.6 Genotype embodied in DNA sequences creates phenotype through proteins

The genes studied in Mendelian genetics are essentially mathematical abstractions. Mendelian genetics explains their transmission, but it sheds no light on how genes create cellular and organismic phenotypes. Phenotypic attributes can range from complex, genetically templated behavioral traits to the morphology (shape, form) of cells and subcellular organelles to the biochemistry of cell metabolism. This mystery of how genotype creates phenotype represented the major problem of twentieth-century biology. Indeed, attempts at forging a connection between these two became the obsession of many molecular biologists during the second half of the twentieth century and continue as such into the twenty-first, if only because we still possess an incomplete understanding of how genotype influences phenotype.

Molecular biology has provided the basic conceptual scaffold for understanding the connection between genotype and phenotype. In 1944, DNA was proven to be the chemical entity in which the genetic information of cells is carried. Nine years later, Watson and Crick elucidated the double-helical structure of DNA. Eleven years after that, in 1964, it became clear that the sequences in the bases of the DNA double-helix determine precisely the sequence of amino acids in proteins. The unique structure and function of each type of protein in the cell is determined by its sequence of amino acids. Therefore, the specification of amino acid sequence, which is accomplished by base sequences in the DNA, provides almost all the information that is required to construct a protein.

Once synthesized within cells, proteins proceed to create phenotype, doing so in a variety of ways. Some proteins assemble within the cell to create intracellular structure —the components of the cytoarchitecture, or, more specifically, the cytoskeleton (**Figure 1.11A and B**). When secreted into the space between cells, other proteins form the extracellular matrix (ECM), which ties cells together, enabling them to form complex, physically robust tissues (Figure 1.11C and D). As we will see later, the structure of the ECM is often disturbed by malignant cancer cells, enabling them to migrate to sites within a tissue and organism that are usually forbidden to them. Examples of how individual protein molecules can assemble to form the cytoskeleton and the ECM can be found in **Figure 1.12**.

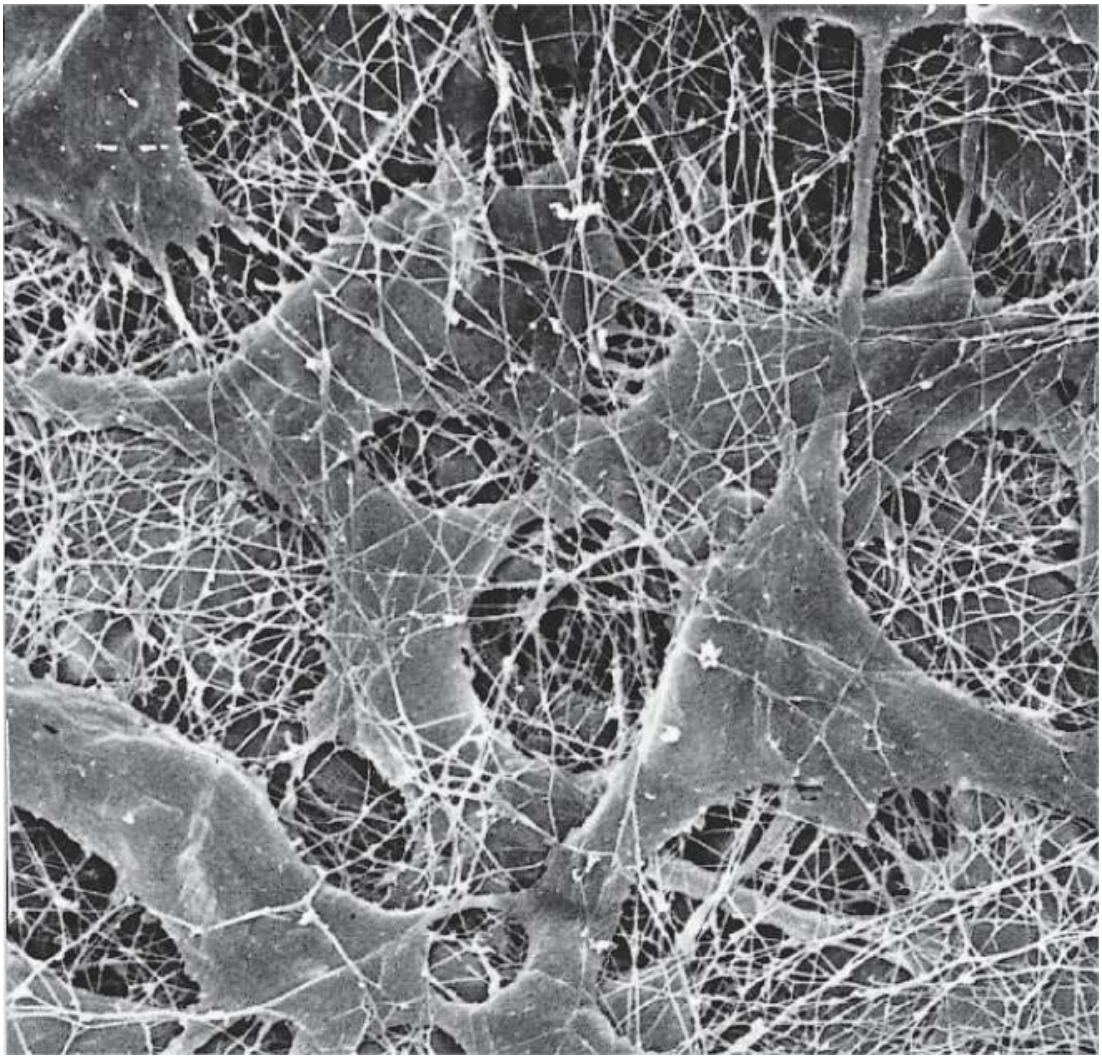


A cell is shown in color with a bright blue nucleus surrounded by a capsule of orange filaments. Green filaments radiate outward from the nucleus and penetrate the capsule to reach the cell exterior.

(A)

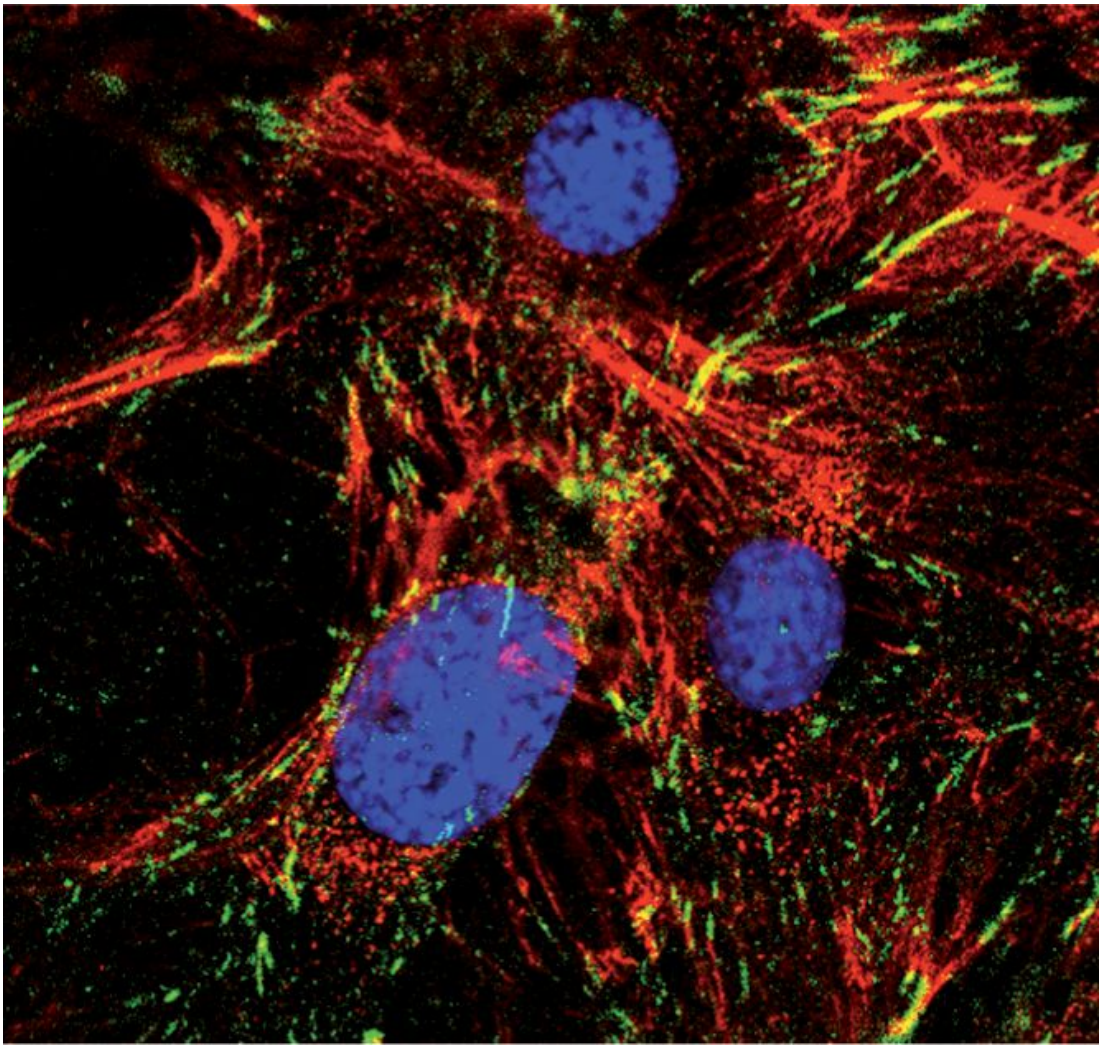
An epithelial cell is shown in color. The center, shown in bright blue and almost gemlike in appearance, is surrounded by a yellow, spongy mass of hairlike fibers.

(B)



A black-and-white electron micrograph shows a dense network of crisscrossing fibers. Most are very thin, but a few are thick, like tree trunks amidst branches, viewed from above.

(C)

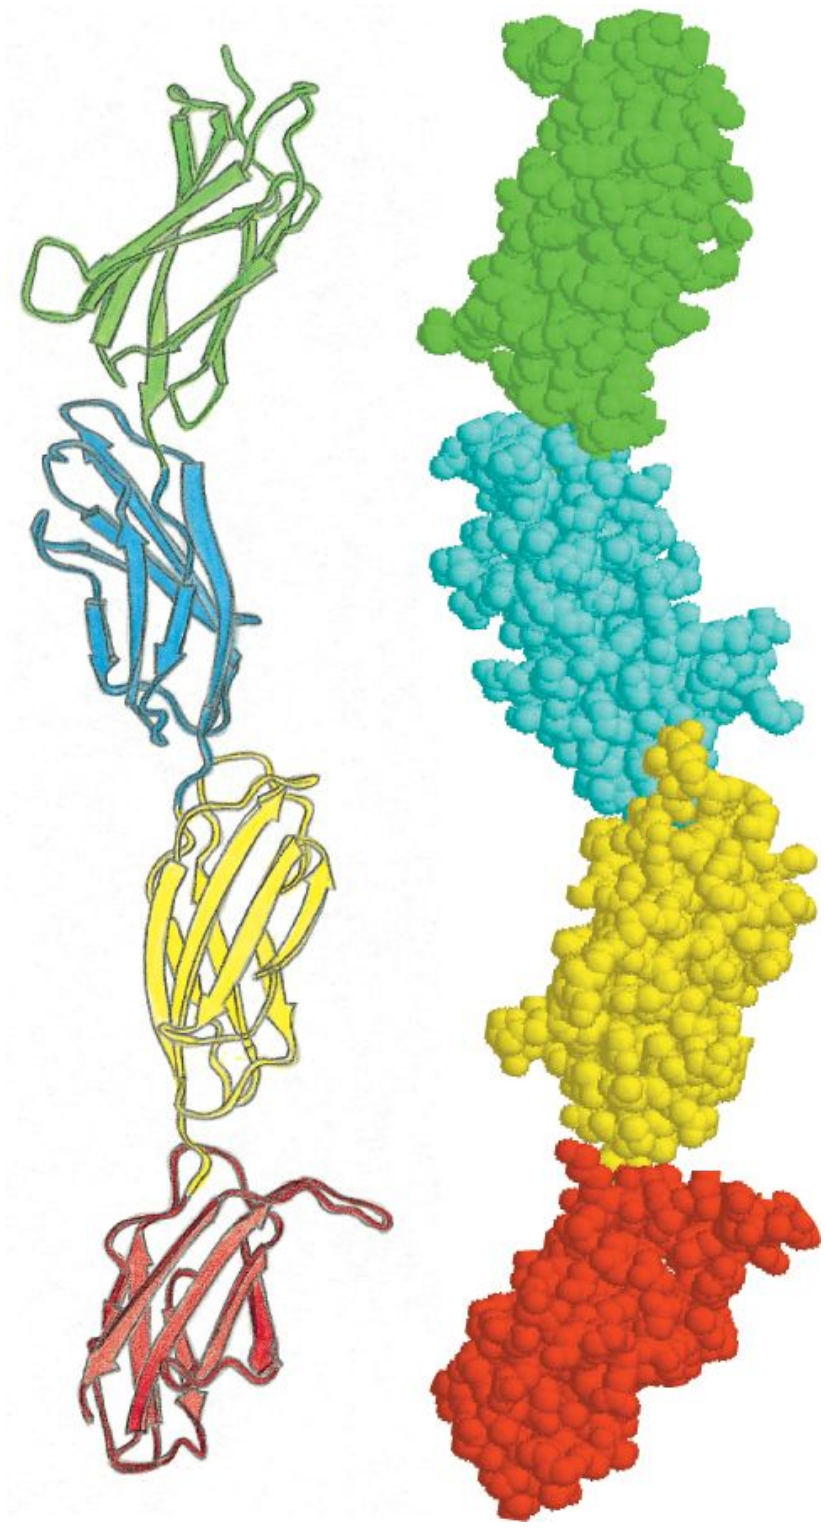


Three deep blue ovals are surrounded by seemingly random streaks of red, with a streaks of yellow and green also visible.

(D)

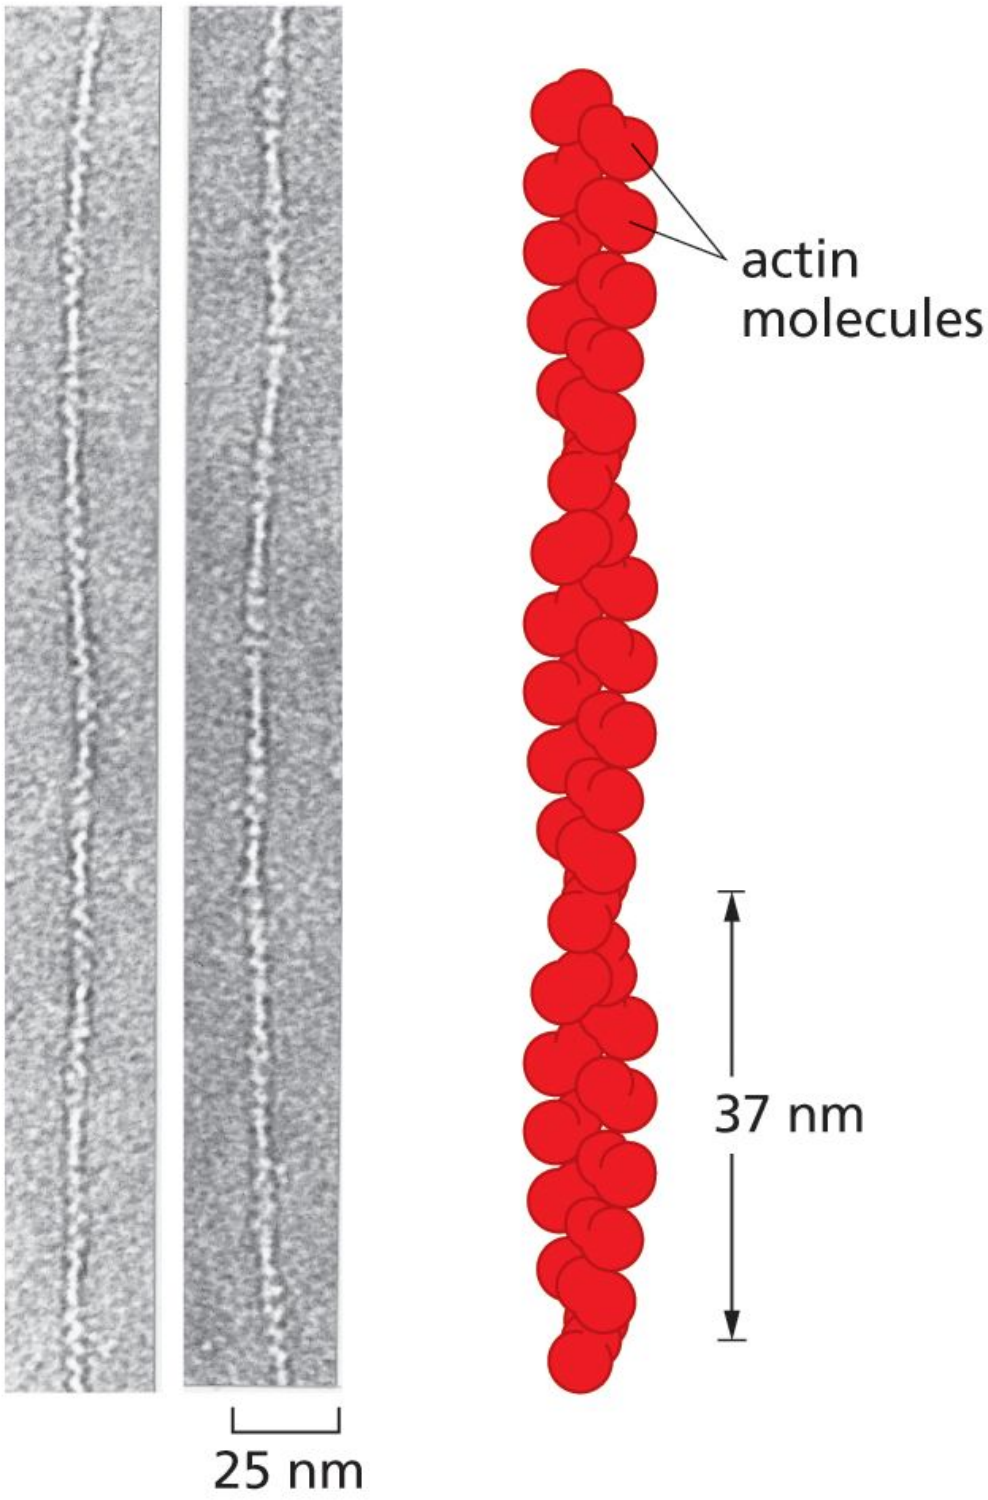
Figure 1.11 Intracellular and extracellular scaffolding The cytoskeleton is assembled from complex networks of intermediate filaments, actin microfilaments, and microtubules. Together, they generate the shape of a cell and enable its motion. (A) In this cultured cell, microfilaments composed of actin (*orange*) form bundles that lie parallel to the cell surface while microtubules composed of tubulin (*green*) radiate outward from the nucleus (*blue*). Both types of fibers are involved in the formation of protrusions from the cell surface. (B) Here, important intermediate filaments of epithelial cells—cytokeratins—are detected through use of hybrid proteins in which a fluorescent reporter protein (eYFP, *light yellow*) has been fused to both cytokeratins 8 and 18. (This is achieved through the creation of hybrid mRNAs in which the corresponding

reading frames have been fused to one another using recombinant DNA techniques that insert eYFP-encoding DNA segments into the two cytokeratin genes.) (C) Cells secrete a diverse array of proteins that are assembled into the extracellular matrix (ECM). A scanning electron micrograph reveals the complex meshwork of collagen fibers, glycoproteins, hyaluronan, and proteoglycans, in which fibroblasts (connective tissue cells) are embedded in the rat cornea. (D) Mouse breast cancer cells propagated in a monolayer on the bottom surface of a Petri dish are attached to the dish via fibronectin molecules that they have secreted (*red*). Points of physical contact with the ECM formed by the fibronectin are achieved by integrin molecules (*green*; see Section 5.9) displayed on the surface of these cells that form *focal adhesions* that physically tether the cells to the fibronectin of the ECM. Nuclei are stained in *blue*. (A, courtesy of A. Tousson, High-Resolution Imaging Facility, University of Alabama at Birmingham. B, courtesy of Bram van den Broek and Kees Jalink. C, courtesy of T. Nishida. D, courtesy of Tsukasa Shibue.)



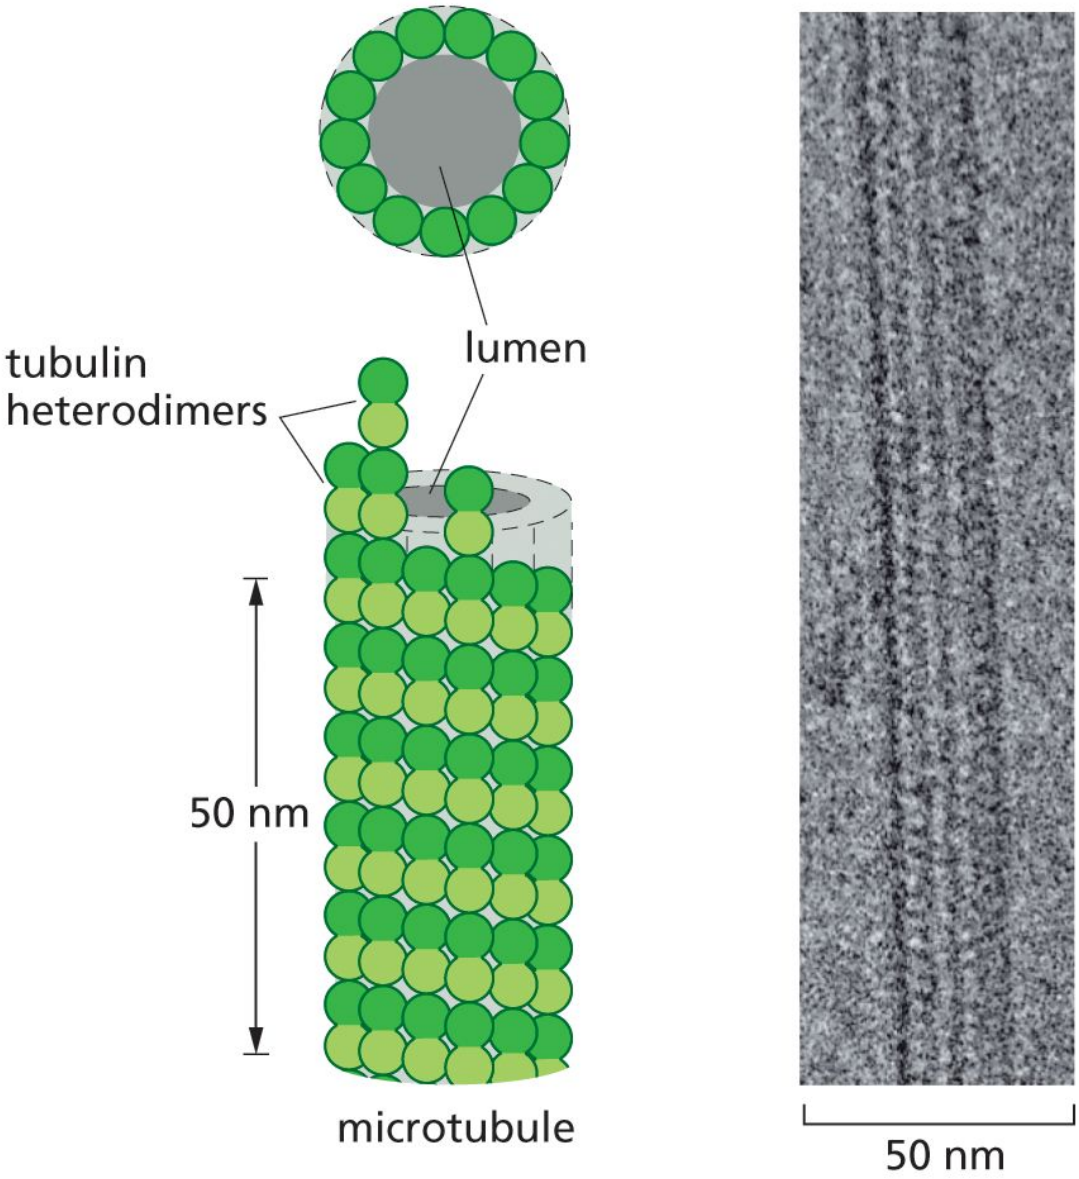
A segment of protein is shown, top to bottom, as a green mass connected to a blue mass connected to a yellow mass connected to a red mass. The same structure appears as a ribbon diagram on the left and as a space-filling

diagram on the right. In the ribbon diagram, most sections are made of antiparallel beta sheets connected by looping strands.
(A)



Two micrographs of twisted fibers roughly 4.5 nanometers thick appear next to a model of a chain of actin molecules showing that a 180 degree twist occurs ever 37 nanometers of length.

(B)



A micrograph of a microtubule roughly 23 nanometers thick appears next to a model showing that the hollow center, called the lumen, is surrounded by a helical arrangement of peanut-shaped structures called tubulin heterodymers, oriented with their long axis parallel to the tubule axis.

(C)

Figure 1.12 Structures of proteins and multiprotein assemblies (A) The three-dimensional structure of part of fibronectin, an important extracellular matrix protein (see Figure 1.11C and D), is depicted as a ribbon diagram (*left*), which illustrates the path taken by its amino acid chain; alternatively, the space-filling model (*right*) shows the positions of the individual atoms. One portion of fibronectin is composed of four distinct, similarly structured domains, which are shown here with different colors. (B) The actin fibers (*left*), which constitute an important component of the cytoskeleton (see Figure 1.11A), are composed of assemblies of individual protein molecules, each of which is illustrated here as a distinct two-lobed body (*right*). (C) Microtubules are assembled as hollow tubes made from heterodimers of two types of tubulin (*light green*, *dark green*); in addition to helping form the microskeleton, they form the fibers of the mitotic apparatus and the spines of flagella and cilia. (A, adapted from D.J. Leahy, I. Aukhil and H.P. Erickson, *Cell* 84:155–164, 1996. With permission from Elsevier. B, left, courtesy of Roger Craig; right, from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015. C, left, from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015; right, courtesy of R. Wade.)

Many proteins function as enzymes that catalyze the thousands of biochemical reactions that together are termed intermediary metabolism; without the active intervention of enzymes, few of these reactions would occur spontaneously. In recent years, it has become apparent that the metabolism of cancer cells is often quite different from that of corresponding normal cells. Proteins can also contract and create cellular movement as well as muscle contraction. Cellular motility, described in more detail in Chapter 14, plays an important role in cancer development by allowing cancer cells to spread through tissues and migrate to distant organs.

And most important for the process of cancer formation, proteins can convey signals between cells, thereby enabling complex tissues to maintain the appropriate numbers of constituent cell types. Within individual cells, certain proteins receive signals from an extracellular source, process these signals, and pass them on to other proteins within the cell; such signal-processing functions, often termed signal transduction, are also central to the creation of cancers, since many of the abnormal-growth phenotypes of cancer cells are the result of aberrantly functioning intracellular signal-transducing molecules.

The functional versatility of the countless proteins within a cell (**Sidebar 1.3**) makes it apparent that almost all aspects of cell and organismic phenotype can be created by their actions. Once we realize this, we can depict genotype and phenotype in the simplest of molecular terms: genotype resides in the sequences of bases in DNA, while phenotype derives from the actions of proteins. (In fact, this depiction is simplistic,

because it ignores the important role of RNA molecules as intermediaries between DNA sequences and protein structure and the abilities of some RNA molecules to function as enzymes and others to act as regulators of the expression of certain genes.)

Sidebar 1.3 How many distinct proteins can be found in the human body, and how are the encoding mRNAs produced?

It is difficult to extrapolate from the number of human genes (~20,000) to the total number of distinct proteins encoded in the human genome. The simplest estimate comes from the assumption that each gene encodes the structure of a single protein. But this assumption is naive, because it ignores the fact that the pre-mRNA transcript deriving from a single gene may be subjected to several *alternative splicing* patterns, yielding multiple, distinctly structured mRNAs, many of which may in turn encode distinct proteins (see Figure 1.13).

In more detail, flanking each intron are two retained sequences, the exons, which are fused together during this process of splicing. The initially synthesized RNA molecule and its derivatives found at various stages of splicing, together with nuclear RNA transcripts being processed from thousands of other genes, collectively constitute the hnRNA (heterogeneous nuclear RNA). The end product of these post-transcriptional modifications may be an RNA molecule that is only a small fraction of the length of its initially synthesized hnRNA precursor. This final, mature RNA molecule may be exported into the cytoplasm, where, as an mRNA (messenger RNA) molecule, it serves as the template on which ribosomes assemble the amino acids that form the proteins. (The term pre-mRNAs is often used to designate those hnRNAs that are precursors of cytoplasmic mRNAs.) The complexity of post-transcriptional modifications of RNA yields an enormous array of distinct protein species within the cell.

In some cells, splicing may include certain exons in the final mRNA molecule made from a pre-mRNA, while in other cells, these exons may be absent (Figure 1.13B). Such alternative splicing patterns can generate mRNAs having greatly differing structures and protein-encoding sequences. In one admittedly extreme case, a single *Drosophila* gene has been found to be capable of generating 38,016 distinct mRNAs and thus proteins through various alternative splices of its pre-mRNA; genes having similarly complex alternative splicing patterns are likely to reside in our own genome.

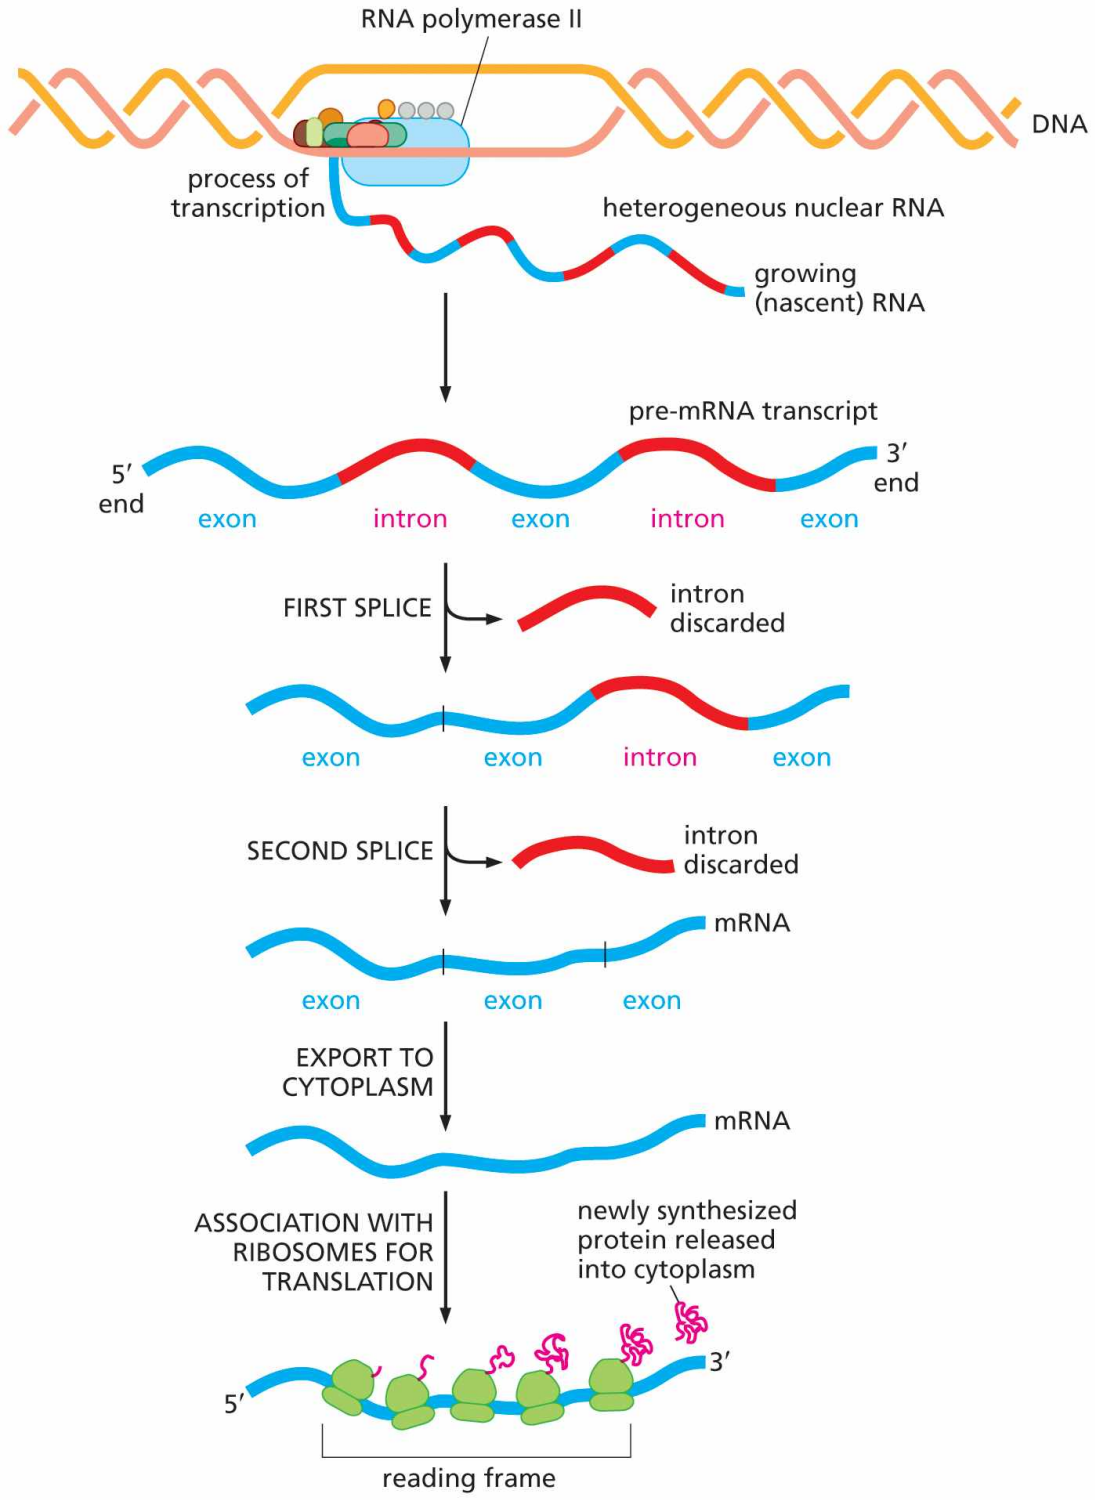
An additional dimension of complexity derives from the post-translational modifications of proteins. The proteins that are exported to the cell surface or secreted in soluble form into the extracellular space are usually modified by the covalent attachment of complex trees of sugar molecules—usually attached to asparagine side chains of proteins—during the process of glycosylation. Intracellular proteins often

undergo other types of chemical modifications. Thus, proteins involved in transducing the signals that govern cell proliferation often undergo phosphorylation through the covalent attachment of phosphate groups to serine, threonine, or tyrosine amino acid residues. Many of these phosphorylations affect some aspect of the functioning of these proteins. Similarly, the histone proteins that wrap around DNA and control its access by the RNA polymerases that synthesize hnRNA are subject to methylation, acetylation, and phosphorylation, as well as more complex post-translational modifications.

The polypeptide chains that form proteins may also undergo cleavage at specific sites following their initial assembly, often yielding small proteins showing functions that were not apparent in the uncleaved precursor proteins. Later, we will describe how certain signals may be transmitted through the cell via a cascade of the protein-cleaving enzymes termed proteases. In these cases, protein A may cleave protein B, activating its previously latent protease activity; thus activated, protein B may cleave protein C, and so forth. Taken together, alternative splicing and post-translational modifications of proteins generate vastly more distinct protein molecules than are apparent from counting the number of genes in the human genome.

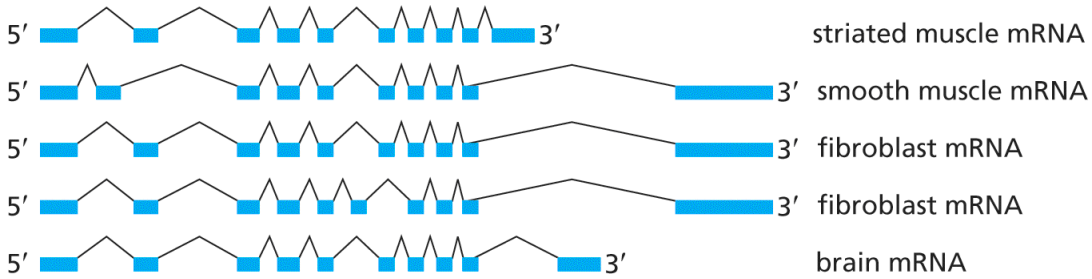
In the complex eukaryotic (nucleated) cells of animals, as in the simpler prokaryotic cells of bacteria, DNA sequences are copied into RNA molecules in the process of transcription; a gene that is being transcribed is said to be actively expressed, while a gene that is not being transcribed is often considered to be repressed. In its simplest version, the transcription of a gene yields an RNA molecule of length comparable to the gene itself. Once synthesized, the base sequences in the RNA molecule are translated by the protein-synthesizing factories in the cell, its ribosomes, into a sequence of amino acids. The resulting macromolecule, which may be hundreds, even thousands of amino acids long, folds up into a unique three-dimensional configuration and becomes a functional protein.

In eukaryotic cells—the main subject of this book—the synthesis of RNA is itself a complex process. An RNA destined to become a messenger RNA (mRNA) molecule (often termed a pre-mRNA), when transcribed from its parent gene in the nucleus, may initially be almost as long as that gene. However, while it is being elongated, segments of the pre-mRNA molecule, some very small and others enormous, may be cleaved out of the growing RNA molecule. These segments, termed introns, are soon discarded and consequently have no impact on the subsequent coding ability of the RNA molecule (**Figure 1.13**). The retained portions of the initial RNA transcript, termed exons, once fused together to form a mature mRNA, are exported to the cytoplasm (see Sidebar 1.3). The entire process of editing pre-mRNA molecules via deletion of introns and fusion of exons is termed splicing.



A top-to-bottom flowchart that starts with D N A and ends with protein synthesis. On a stretch of D N A that has been untwisted to separate the two strands, R N A polymerase 2 transcribes the information on one of the strands onto a heterogeneous nuclear R N A strand it generates, consisting of

alternating blue and red segments. The result is a pre m R N A transcript with a 5 prime end and a 3 prime end, between which two red intron segments alternate with three blue exon segments. Through successive splices, the intron segments are removed, leaving m R N A consisting entirely of blue exon segments. This m R N A is exported to the cytoplasm, where it associates with ribosomes that attach to it and read its information to synthesize proteins and release them into the cytoplasm.
(A)



Five different patterns of alternating exons and introns in a pre-mRNA molecule: one for striated muscle, one for smooth muscle, two for fibroblasts, and one for brain tissue. The exons and introns vary in length but there are the same number per molecule. The smooth muscle and fibroblast types conclude on the 3 prime end with a long intron followed by a long exon.

(B)

Figure 1.13 Processing of pre-mRNA (A) By synthesizing a complementary RNA copy of one of the two DNA strands of a gene, RNA polymerase II creates a molecule of heterogeneous nuclear RNA (hnRNA; *red and blue*). The subset of hnRNA molecules that are processed into mRNAs are termed pre-mRNA. The progressive removal of the introns (*red*) leads to a processed mRNA containing only exons (*blue*). (B) A given pre-mRNA molecule may be spliced in a number of alternative ways, yielding distinct mRNAs that may encode distinct protein molecules. Illustrated here are the tissue-specific alternative splicing patterns of the α-tropomyosin pre-mRNA molecule, whose mRNA products specify important components of cell (and thus muscle) contractility. In this case, the introns are indicated as *black carets* while the exons are indicated as *blue rectangles*. (B, adapted from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015.)

Of note, an initially transcribed pre-mRNA may be processed through alternative splicing into a series of distinct mRNA molecules that retain different combinations of exons (see Figure 1.13B). Indeed, the pre-mRNAs arising from ~93% of the genes in

our genome are subject to alternative splicing. The resulting alternatively spliced mRNAs may carry altered reading frames, explaining, for example, the distinctive isoforms of certain proteins that are found in cancer cells but not in their normal counterparts. Alternatively, these splicing events may affect untranslated regions of mRNAs, such as those targeted by microRNAs (miRNAs; Section 1.9); these interactions with miRNAs can alter the function of an mRNA, by regulating either its translation or its stability. Alternative splicing events are currently estimated to generate mRNAs encoding ~70,000 distinct proteins arising from ~20,000 human genes. Importantly, the order of exons in the mature, spliced mRNA reflects the order of these segments in the initial unprocessed primary pre-mRNA transcript.

Interestingly, a protein that orchestrates an alternative splicing pattern of certain pre-mRNAs has been reported, when expressed in excessively high levels in cells, to favor their transformation (conversion) from a normal to a cancerous growth state. In certain hematopoietic malignancies described in the next chapter, the genes encoding several other splicing factors (SFs) have been found to have suffered missense mutations in specific codons, suggesting that these tumors gained proliferative advantage from the resulting subtle changes in protein structure (**Sidebar 1.4**). These findings are surprising, since one might imagine that proteins that regulate splicing would mediate the processing of many or all pre-mRNAs within the cell rather than affecting only a subset of genes involved in a specific cell-biological function, such as cell transformation. Moreover, a 2008 survey of alternatively spliced mRNAs found 41 that showed a distinct pattern of alternative splicing in human breast cancer cells compared with normal mammary cells; indeed, these alternatively spliced mRNAs could be used as diagnostic markers of the cancerous state of these cells. Even more dramatic, in 2010 as many as 1000 pre-mRNAs were found to undergo alternative splicing as cells passed through an epithelial–mesenchymal transition (EMT), an important transdifferentiation step that carcinoma cells utilize in order to acquire traits of high-grade malignancy, as will be discussed in Chapters 13 and 14. And a year later, the genes encoding three splicing factors were found to be targets of recurrent mutations in a number of independently arising cases of myelodysplastic syndrome (MDS)—a pre-neoplastic condition of the bone marrow that is sometimes termed a "pre-leukemia."

Sidebar 1.4 Splicing factors and cancer

Splicing, (including alternative splicing) is regulated by a large cohort of splicing factors (SFs) that function by recognizing and binding specific oligonucleotide segments in pre-mRNA, thereby guiding the general splicing machinery to the appropriate sites of cleavage and fusion of segments within the individual pre-mRNA molecules. When portrayed most simply, all splicing factors would seem to be dedicated to monitoring the processing of all the pre-mRNAs produced within a cell.

However, the truth is more interesting: some appear to be specialized to process specific pre-mRNAs, including some SFs ostensibly involved in the control of cell proliferation. In addition to the observation that overexpression of at least one of these has been found to transform normal cells in culture into tumor cells, three other SFs have been found to appear repeatedly in mutant form in the genomes of various types of cancer cells, indicating that their alteration favors tumor development. Hence, certain SFs may be specialized to control the processing of genes with highly specialized cell-biological functions, including in this case the control of cell growth and proliferation.

Post-translational modification of the initially synthesized protein may result in the covalent attachment of certain chemical groups to the side chains of amino acid residues in a protein chain; included among these modifications are, notably, phosphates, complex sugar chains, and methyl, acetyl, succinyl, and lipid groups, as well as ubiquitin and SUMO groups. In the case of certain critical cellular proteins, this can lead to an extraordinary complexity: thus, histone H3, which is associated with chromosomal DNA and is involved in the regulation of transcription, has been estimated to exist in perhaps 1000 distinct isoforms, each defined by a different combination of post-translational modifications (PTMs). Some PTMs are almost universal: cell-surface proteins and those secreted in soluble form into the extracellular space almost invariably display carbohydrate side chains that are attached via the process of glycosylation, as cited in Sidebar 1.3; proteins of the Ras family, which are located in the cytoplasm and play important roles in cancer development, contain lipid groups attached to their carboxy termini. An equally important post-translational modification involves the cleavage of one protein by a second protein termed a protease, which has the ability to cut amino acid chains at certain sites, also mentioned in Sidebar 1.3. Accordingly, the final, mature form of a protein chain may include far fewer amino acid residues than were present in the initially synthesized protein. Following their synthesis, many proteins are dispatched to specific sites within the cell or are exported from the cell through the process of secretion; these alternative destinations are specified in the newly synthesized proteins by short amino acid (oligopeptide) sequences that function, much like postal addresses, to ensure the diversion of these proteins to specific intracellular sites.

With the passage of time, subtleties in the molecular biology of cells continue to be discovered. One of these discoveries involves long noncoding RNAs, discussed in more detail in Section 1.9. Yet another involves ribosomes, which have traditionally been depicted as workshops that are highly flexible in being able to translate essentially all mRNAs in the cytoplasm. Of late, ribosomes have been found to have physically associated proteins that specialize them to translate certain mRNAs but not others. Such specialization could not have been imagined by those who first articulated the DNA → RNA → protein paradigm more than half a century ago. The discovery of

these specialized ribosomes leaves open the possibility that the formation of some of them is favored in certain types of cancer cells.

OceanofPDF.com

Glossary

morphology
: Shape and form of a cell, tissue, or organism.

cytoarchitecture
: Physical structure of a cell.

cytoskeleton
: Network of filamentous proteins in the cell cytoplasm that provides it with structure and rigidity enables it to exhibit motile behavior and is formed from polymerized actin, tubulin, and intermediate filament proteins such as cytokeratins.

extracellular matrix
: Meshwork of secreted proteins, largely glycoproteins and proteoglycans, that surrounds most cells within tissues and creates a structural scaffold in the intercellular space.

intermediary metabolism
: The collection of biochemical reactions within a cell that allow the interconversion of various molecular species into one another, involving both anabolic and catabolic reactions. *See* **anabolic, catabolic**.

motility
: (adj., **motile**) Tendency for movement, such as that of individual cells, from one location to another.

transduction
: (1) Process whereby a signaling element, such as a protein, receives a signal and, in response, processes the signal and emits another signal. (2) Process by which a gene is introduced into a cell, usually by a vector such as a viral vector.

heterogenous nuclear RNA (hnRNA)
: The collection of primary transcripts synthesized by pol II and derived processed intermediates arising from the actively transcribed genes of a cell.

messenger RNA (mRNA)
: The transcript of a gene that has been processed by splicing and exported to the cytoplasm where it serves as the template for protein synthesis conducted by ribosomes.

pre-mRNA
: The class of nuclear RNA molecules that are destined to become mRNA following their processing via splicing and export to the cytoplasm.

alternative splicing
: Process whereby a pre-mRNA may be spliced in several alternative ways, resulting in mRNAs composed of different combinations of exons.

alternative splicing
: Process whereby a pre-mRNA may be spliced in several alternative ways, resulting in mRNAs composed of different combinations of exons.

glycosylation
: Covalent attachment of a carbohydrate side chain, usually a covalently linked branched network of monosaccharides, to a second molecule, e.g., to the side chain of an asparagine residue of a protein; such attachment occurs in concert with or following initial synthesis of the polypeptide backbone of a protein.

glycosylation
: Covalent attachment of a carbohydrate side chain, usually a covalently linked branched network of monosaccharides, to a second molecule, e.g., to the side chain of an asparagine residue of a protein; such attachment occurs in concert with or following initial synthesis of the polypeptide backbone of a protein.

phosphorylation
: Covalent attachment of a phosphate group to a substrate, often the side chain of an amino acid residue of a protein. *See also* **phosphoprotein**.

protease
: An enzyme that cleaves protein substrates.

protease
: An enzyme that cleaves protein substrates.

eukaryotic
: Referring to the large, complex, nucleated cells of metazoa, metaphyta, and many protozoa. *See also* **prokaryotic.**

prokaryotic
: Referring to the relatively small, nonnucleated cells of bacteria and archaea. *See also* **eukaryotic**.

transcription
: Copying of DNA sequences into RNA molecules mediated by RNA polymerases.

repressed
: Referring to a gene that is not being expressed and therefore is not being transcribed.

ribosome
: The ribonucleoprotein complex that operates in the cytoplasm to translate the coding information of an mRNA to which it is bound into an amino acid sequence that yields as an end product a complete protein molecule.

intron
: Portion of a primary RNA transcript that is deleted during the process of splicing. *See also* **exon**.

exon
: Portion of a primary RNA transcript that is retained in the RNA product of splicing. *See also* **intron**.

splicing
: (1) Process that causes the deletion of a defined internal segment of a primary RNA transcript and the subsequent fusion of the two RNA segments flanking the deleted RNA segment. (2) Process occurring in the nucleus whereby a pre-mRNA precursor is converted into an mRNA through the deletion of introns and the fusion of remaining exons.

isoform
: Protein that is functionally and structurally similar but not identical to another protein. Multiple distinct isoforms of a protein are usually encoded either by a single gene (via alternative splicing of a pre-mRNA) or by closely related paralogous genes. *See* **paralog**.

transformation
: (1) Process of converting a normal mammalian cell into a cell having some or many of the attributes of a cancer cell. (2) Alteration of a cell through the introduction of a genetic element, usually referring to a process occurring in prokaryotic cells.

epithelial–mesenchymal transition
: Cell-biological program enabling acquisition by epithelial cells of some of the phenotypes of mesenchymal cells such as fibroblasts.

Compare **mesenchymal–epithelial transition**.

pre-neoplastic

Referring to a tissue that has acquired certain features of a frank tumor but has itself not yet developed into a neoplasia. *See also* **neoplastic**.

post-translational modification

Covalent alteration of a protein occurring concomitantly with or after the initial polymerization of the polypeptide backbone of the protein, including cleavage of the initially synthesized polypeptide and covalent modification of its amino-acid side chains.

ubiquitin

A polypeptide composed of 76 amino acid residues that undergoes covalent attachment to a substrate protein, often signaling that the resulting ubiquitylated protein is destined for degradation and usually present as a linear or branched polyubiquitylated modification of the substrate protein.

SUMO

One of a group of four ubiquitin-like polypeptides that, like ubiquitin, are attached covalently to substrate proteins, thereafter affecting intracellular localization and functions of the modified proteins but not their degradation.

expression

(1) Transcription of an active gene or synthesis of a protein from its encoded mRNA. (2) Forced release of interstitial fluid from a tissue caused by contraction of cells and/or extracellular matrix in that tissue. *See also* **repression**.

translation

Synthesis of proteins by ribosomes in which the amino acid sequences of the synthesized proteins are dictated by the nucleotide sequences of the ribosome-associated mRNA molecules. *See also* **ribosome**.

hematopoiesis

(adj., - **poietic**) Process that results in the formation of all of the cells in the blood, including its red and white cells, the latter including various cells of the immune system.

splicing factor

Protein involved in regulating the process of splicing including the recognition of appropriate splice sites in the RNA molecule serving as the substrate of the splicing. *See also* **splice site**, **splicing**.

missense codon

A triplet codon in the genetic code, often created by a point mutation, that specifies an amino acid residue different from that specified by the codon that it replaces. *See also* **nonsense codon**.

splicing factor

Protein involved in regulating the process of splicing including the recognition of appropriate splice sites in the RNA molecule serving as the substrate of the splicing. *See also* **splice site**, **splicing**.

transformation

(1) Process of converting a normal mammalian cell into a cell having some or many of the attributes of a cancer cell. (2) Alteration of a cell through the introduction of a genetic element, usually referring to a process occurring in prokaryotic cells.

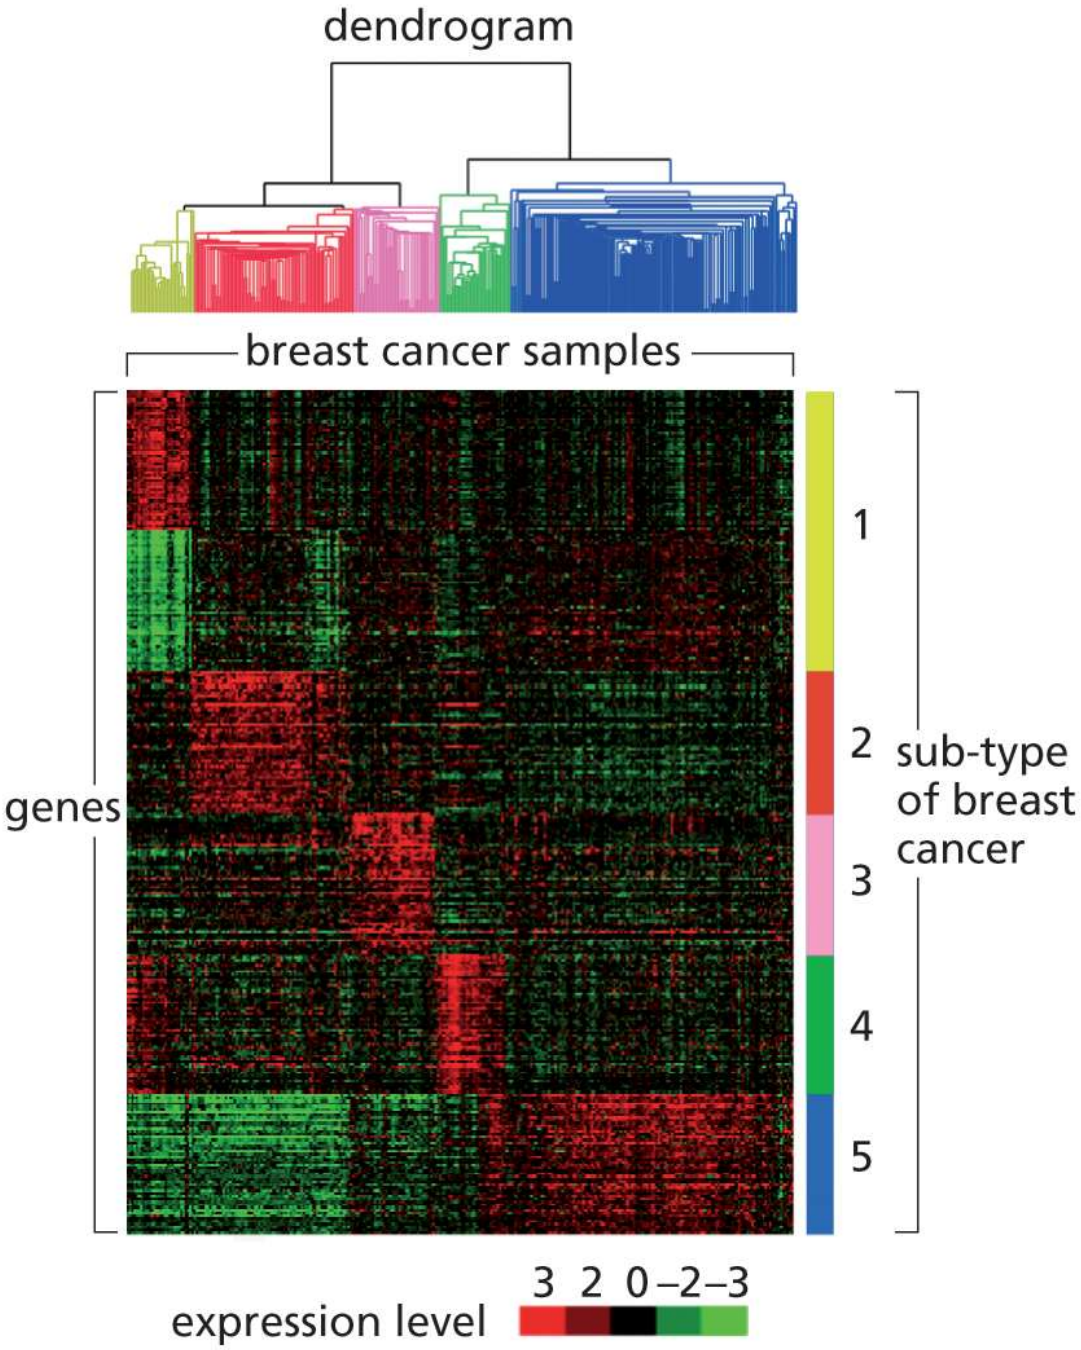
1.7 Gene expression patterns also control phenotype

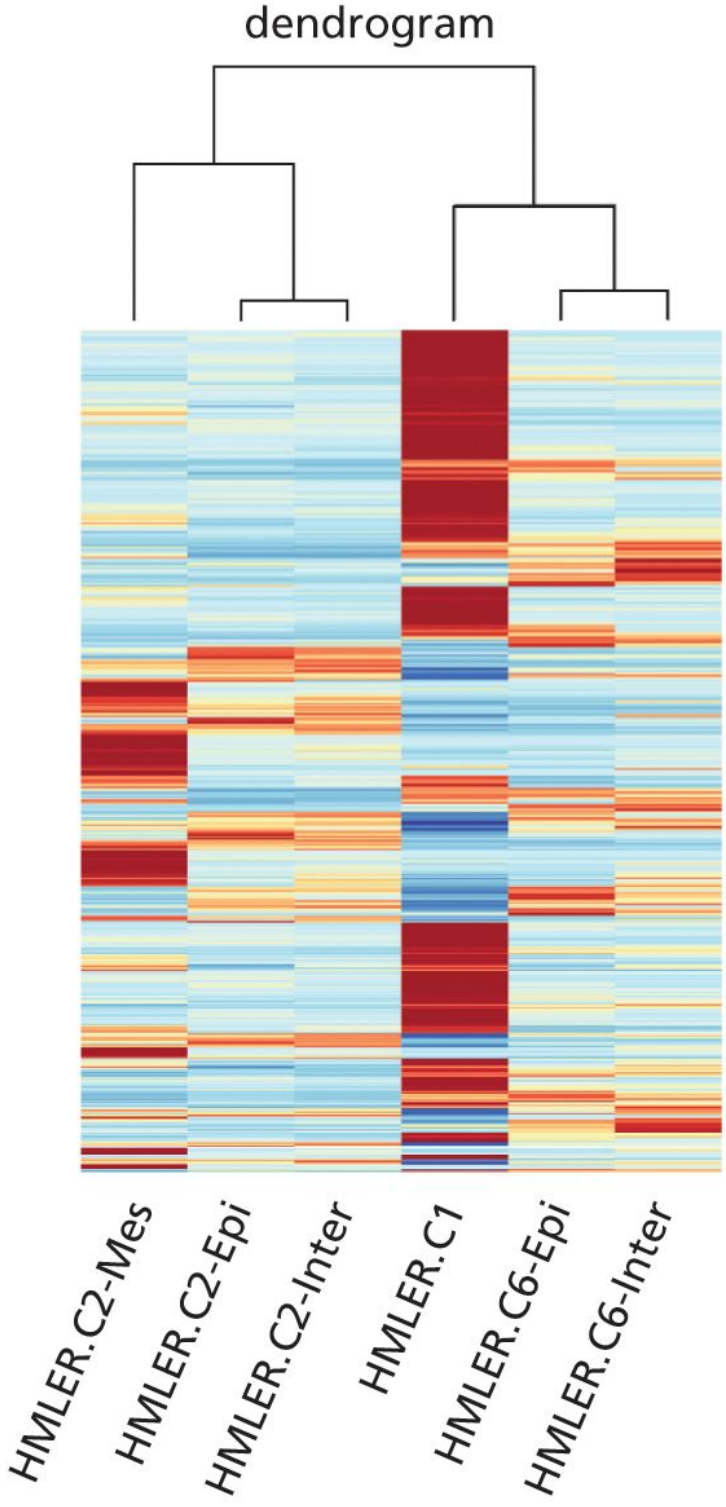
Approximately 20,000 genes in the mammalian genome, acting combinatorially within individual cells, are able to create the extraordinarily complex organismic phenotypes of the mammalian body. A central goal of twenty-first-century biology is to relate the functioning of this large repertoire of genes to organismic physiology, developmental biology, and disease development. The complexity of this problem is illustrated by the fact that there are at least several hundred distinct cell types within the mammalian body, each with its own behavior, its own distinct metabolism, and its own physiology. Indeed, as the collections of RNA transcripts are surveyed in individual cells throughout the body, more and more cell types are uncovered, so that this number may eventually grow into many hundreds, possibly even several thousand.

This complexity is acquired during the process of organismic development, and its study is the purview of developmental biologists. They wrestle with a problem that is inherent in the organization of all multicellular organisms. All of the cells in the body of an animal are the lineal descendants of a fertilized egg. Moreover, almost all of these cells carry genomes that are reasonably accurate copies of the genome that was initially present in this fertilized egg (see **Supplementary Sidebar 1.2**). The fact that cells throughout the body are phenotypically quite distinct from one another (for example, a skin cell versus a brain cell) while being genetically identical creates a central problem of developmental biology: how do these various cell types acquire distinct phenotypes if they all carry identical genetic templates? The answer, documented in thousands of ways over the past four decades, lies in the selective reading of the genome by different cell types. Newer technologies, notably the recently gained ability to analyze the transcriptional programs (often termed the transcriptomes) of individual cells, have been confirming existing classifications of distinct differentiated cell types, while revealing that certain of these cell types, previously thought to represent a single homogeneous population, actually include a variety of distinct subtypes as mentioned above (**Figure 1.14**).



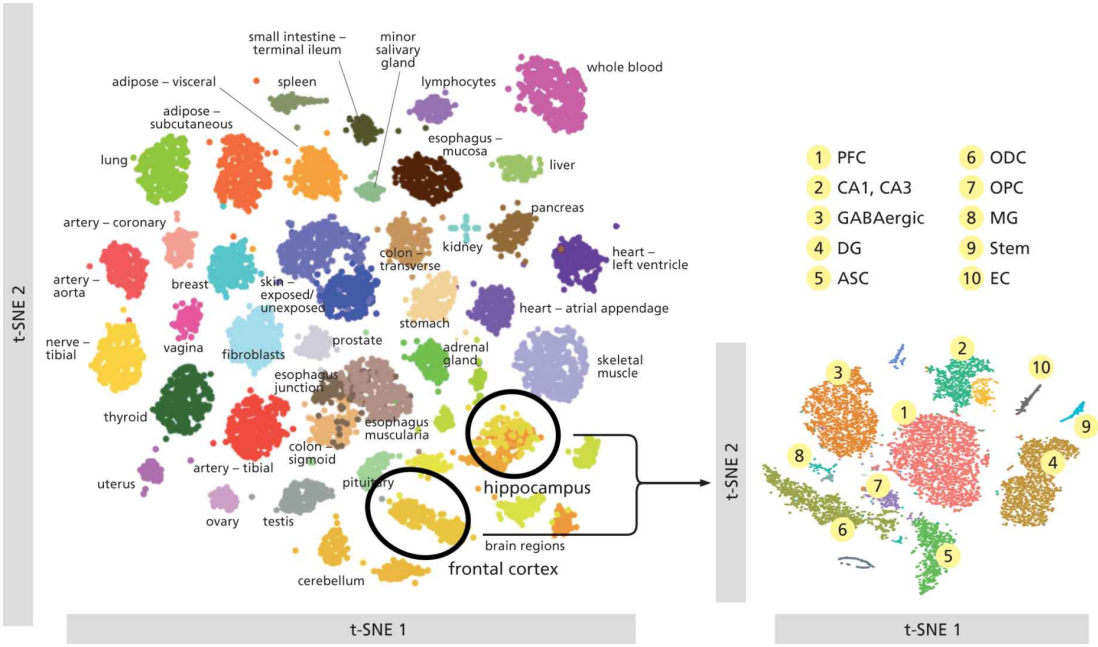
A rectangle with shades of red and green on a black background. Across the top, breast cancer tissue samples are organized into a dendrogram. The vertical axis is labeled genes on the left. Within the rectangle, red represents especially strong gene expression, white green represents especially weak gene expression. The patterns of red and green form six distinct horizontal bands, each characterized by a distinct left-to-right pattern of red and green. Down the right side, the top two bands are associated with breast cancer sub-

type 1, and the remaining four bands with sub-types 2, 3, 4 and 5, respectively.
(A)



A rectangle with six vertical bands, each characterized by a particular pattern of thin horizontal stripes in various shades of blue, orange, and red. Across the bottom, the stripes are labeled, left to right, H M L E R.C2-Mes, H M L E R.C2-Epi, H M L E R.C2-Inter, H M L E R.C1, H M L E R.C6-Epi, and H M L E R.C6-Inter. Across the top, a dendrogram groups the three C2 bands together and groups the C1 and C6 bands together. Within the each group of three, the Epi and Inter bands form a subgroup.

(B)



Two sets of axes, each with a horizontal t S N E 1 axis and a vertical t S N E 2 axis. The main set of axes displays many clusters of dots, each cluster representing a certain type of tissue: lung, liver, prostate, uterus, and so on. The clusters in the lower right corner are all associated with different types of brain tissue. The second set of axes displays the clustering of hippocampal and frontal lobe cells in finer detail, revealing ten subtypes, named P F C, C A 1 C A 3, GABA ergic, D G, A S C, O D C, O P C, M G, Stem, and E C.

(C)

Figure 1.14 Global surveys of gene expression arrays Multiple experimental strategies are available to survey the gene expression programs of cells. (A) One procedure makes it possible to survey the expression levels of thousands of genes within a given type of cell (i.e., its transcriptome) using sequence-specific probes immobilized in a *microarray* to register the expression of cognate mRNAs. In this image, the most highly expressed genes and the most weakly expressed genes in

each of the five major subtypes of breast cancer were used to choose DNA probes for stratification (*ordinate*). Hierarchical clustering was used to generate the *dendrogram* (*above*), which plots the degrees of similarity of the transcriptomes of these five groups of cells, doing so by clustering similar transcriptomes together on individual branches of the larger tree. In this image, higher-than-average levels of RNA expression are indicated as *red* pixels, while lower-than-average levels are indicated by *green* pixels. Average-level expression is indicated by *black* pixels. This analysis reveals that breast cancers, which at one level appear to be superficially similar, can actually be stratified into at least five distinct subtypes indicated by the five vertical colored bars on the right. Subsequent work has used such stratification to develop specific therapies for each subtype, in part based on information in this microarray. (B) In 2015, the newer RNA-seq technology overtook microarray analysis as the most common method for analyzing transcriptomes. It depends on the reverse transcription of a large collection of mRNAs, followed by sequencing of resulting cDNAs to measure the presence and abundance of the reverse transcripts. In this figure, the mRNAs from six different human breast cancer cell lines residing in different phenotypic states along the epithelial-to-mesenchymal spectrum (see Chapter 14) have been analyzed by RNA-seq. The 525 genes analyzed (*vertical axis*) were chosen because of their variability between two of these cell lines. Genes that are expressed at average levels are indicated in *yellow*, and overexpressed genes in *red*; while relatively underexpressed genes are in *blue*. Hierarchical clustering (*above*) has been used to organize these six samples, placing those with greater similarity closer to one another in the dendrogram tree. (C) RNA-seq was used to quantify gene expression across a variety of human tissues (*left panel*). The gene expression profiles (transcriptomes) obtained from each tissue sample were projected onto a two-dimensional space, using a statistical approach that groups samples with similar transcriptomes close to one another. This approach, termed the T-distributed Stochastic Neighbor Embedding (t-SNE) machine learning algorithm, takes a high-dimensional dataset and reduces it to a two-dimensional projection of the data (indicated here by the t-SNE 1 and t-SNE 2 axes of the two scatter plots presented here). A similar approach was applied to the transcriptomes of individual cells (*right panel*), measured using the more recently developed technology of single-cell sequencing (scRNA-seq). In this case, two of the tissues examined by conventional RNA-seq—hippocampus and frontal cortex—were subjected to scRNA-seq analysis, revealing that these two tissues, when mixed, actually together harbor ten distinct subtypes of cells (indicated by the acronyms). These images provide a direct visual validation of the fact that various differentiated cell types and the tissues that they form express distinct sets of transcripts, which presumably underlie their distinct tissue-specific functions. (Such single-cell RNA-seq reveals that the number of distinct subtypes of cells within many tissues is far larger than deduced from previous analyses of the

transcriptomes of pooled cells prepared from various tissues.) (A, Charles M. Perou. B, Courtesy of Yun Zhang. C, left from F. Aguet and K.G. Ardlie, *Curr. Genet. Med. Rep.* 4:163–169, 2016. With permission from Springer. Right, from N. Habib, I. Avraham-Davidi, A. Basu et al., *Nat. Methods* 14:955–958, 2017. With permission from Nature.)

As cells in the early embryo pass through repeated cycles of growth and division, the cells located in different parts of the embryo begin to assume distinct phenotypes, this being the process of differentiation. Differentiating cells become committed to form one type of tissue rather than another, for example, gut as opposed to nervous system. All the while, they retain the same set of genes. This discrepancy leads to a simplifying conclusion: sooner or later, differentiation must be understood in terms of the sets of genes that are expressed (that is, transcribed) in some cells but not in others.

By being expressed in a particular cell type, a suite of genes dictates the synthesis of a cohort of proteins and RNA molecules that collaborate to create a specific cell phenotype. Accordingly, the phenotype of each kind of differentiated cell in the body should, in principle, be understandable in terms of the specific subset of genes that is expressed in that cell type.

The genes within mammalian cells have been grouped into two broad functional classes—the housekeeping genes and the tissue-specific genes. Many genes encode proteins that are universally required among all cell types throughout the body and maintain cell viability by carrying out certain biological functions common to all of them. These commonly expressed genes are classified as housekeeping genes. The size of the repertoire of human housekeeping genes is of more than passing interest to cancer biologists (**Supplementary Sidebar 1.3**).

A minority of expressed genes within a differentiated cell—the tissue-specific genes—are dedicated to the production of proteins and thus phenotypes that are associated specifically with this and a number of other specialized cell types in the body. It may be, for example, that 6000 housekeeping genes are expressed by a cell while far fewer than 3000 differentiation-specific genes are responsible for the distinguishing, differentiated characteristics of the cell. By implication, in each type of differentiated cell, a significant proportion of the 20,000 or so genes in the genome are unexpressed, since they are not required either for the cell's specific differentiation program or for general housekeeping purposes. As detailed sequencing of the mRNAs expressed by various tissues proceeds, the distinctions between housekeeping genes and tissue-specific genes have blurred, rendering these classifications more difficult to justify. The census of proteins co-expressed in the average differentiated mammalian cell using the analytical tools of proteomics reveals about 10,000 concomitantly expressed proteins; on its own, this census does not account for the diversification of protein

structures that results from post-translational modifications such as phosphorylation, glycosylation, and proteolysis (see Section 1.6).

OceanofPDF.com

Glossary

transcriptome
: (1) The assembly of all of the transcripts that are produced by one cell or cell type. (2) More commonly, the assembly of all of the mRNAs produced by one cell or cell type.

differentiation
: Process whereby a cell acquires a specialized phenotype, such as a phenotype characteristic of cells in a particular tissue.

housekeeping gene
: A gene that is used universally in all cells throughout the body independent of their differentiated state and is assumed to be essential for their continuing viability.

tissue-specific gene
: Gene that is expressed only in cells of certain individual tissue types.

proteomics
: (1) Technologies by which systematic analyses are made of large numbers of distinct protein species in a biological sample, such as a cell lysate or a biological fluid. (2) Enumeration of the set of proteins synthesized by a cell or tissue.

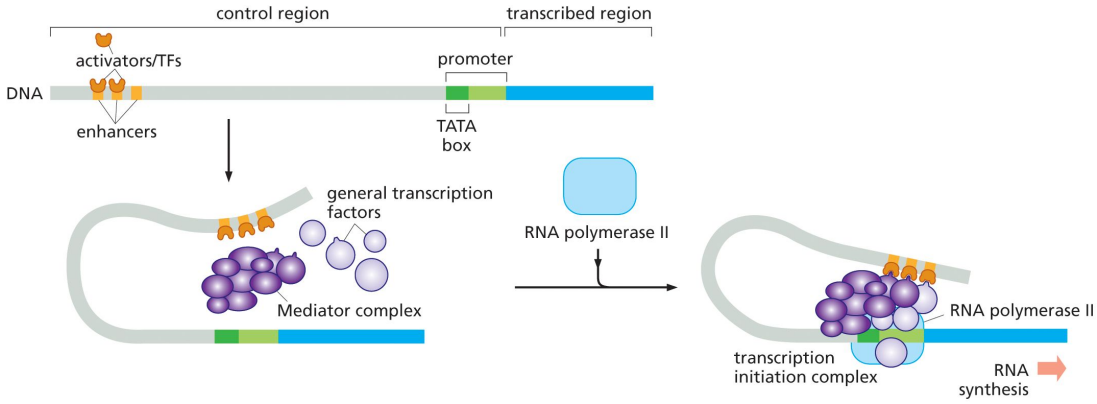
1.8 Modification of chromatin proteins and DNA controls gene expression

The foregoing description of differentiation makes it clear that large groups of genes must be coordinately expressed while other genes must be repressed in order for cells to display complex, tissue-specific phenotypes. Such coordination of expression is the job of proteins called transcription factors (TFs; **Figure 1.15**). Multiple transcription factors associated with a gene each bind to a specific DNA sequence in the control region of the gene and determine whether or not the gene will be transcribed. The specific stretch of nucleotide sequence to which each TF binds, often called a sequence motif, is usually quite short, typically 5–10 nucleotides long. In ways that are still incompletely understood at the molecular level, some TFs operate to provide the RNA polymerase enzyme (RNA polymerase II in the case of pre-mRNAs) with access to a gene. Yet other TFs may block such access and thereby ensure that a gene is transcriptionally repressed.



A sequence depicting the regulation of gene expression. At the start, a stretch of D N A has a long, gray control region and a somewhat shorter, blue transcribed region. The end of the control region that connects to the transcribed region is shown in green and labeled promoter. A section on the left end of the promoter is labeled T A T A box. At the other end of the control region, away from the transcribed region, is a short series of segments called enhancers. Free-floating u-shaped structures called activators or transcription factors attach to these, one per enhancer. Next, the control region folds over, bringing the enhancers with attached activators near the promoter. The space inside the fold is populated by general transcription factors, which are generally spherical, and by a complex protein

cluster called a mediator complex. Finally, R N A polymerase 2 has attached to the promoter, the mediator complex and the general transcription factors have attached to the R N A polymerase 2, and specific binding sites on the mediator complex and the general transcription factors have attached to the transcription factors on the enhancers, locking the loop into place. Transcription can now begin.
Figure 1.15 Regulation of gene transcription RNA polymerase II (pol II) is responsible for generating the transcripts that in turn are processed to become mRNAs in the cytoplasm. The control region of a gene transcribed by pol II includes specific segments of DNA, termed *enhancers*, to which gene regulatory proteins, known as transcription factors (TFs, *light brown*; also termed *activators*) bind in a sequence-specific manner, the latter often forming multiprotein complexes; the *enhancer* segments (*orange*) are often located many kilobases upstream of the *promoter*. The bound TFs influence the structure of chromatin (notably the histone proteins that package DNA; see Figure 1.16), creating a localized chromatin environment that enables pol II to produce an RNA transcript (*orange-red arrow, right*). In addition, the bound TFs interact with the transcription initiation complex via the Mediator complex (of ∼30 protein subunits). The promoter of the gene (*dark, light green*) contains sequences to which RNA polymerase II (pol II) and associated proteins can bind in order to initiate transcription of a gene; within the promoter of regulated genes is a short AT-rich sequence (TATA Box) that helps, together with associated proteins, to ensure proper localization of the start site of transcription. (The general TFs are involved in initiating the transcription of thousands of genes throughout the genome, while the specialized TFs bound to enhancers, as described above, regulate the expression of specific subsets of genes.) Although in general a gene can be separated into two functionally significant regions—the nontranscribed control sequences and the transcribed sequences represented in pre-mRNA and mRNA molecules—some of the regulatory sequences (enhancers) may be located within the transcribed region of a gene, often in introns. (From B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton & Company, 2015.)

Transcription factors can exercise great power, since a single type of TF can simultaneously affect the expression of a large cohort of downstream responder genes, each of which carries the recognition sequence that allows this TF to bind its promoter (see Figure 1.15). This ability of a single master regulator, such as a TF, to elicit multiple changes within a cell or organism is often termed pleiotropy. In the case of cancer cells, a single malfunctioning, pleiotropically acting TF may simultaneously orchestrate the expression of a large cohort of responder genes that together proceed to create major components of the cancer cell phenotype. A 2018 enumeration of the genes in the human genome that are likely to encode TFs has listed 1639 distinct genes

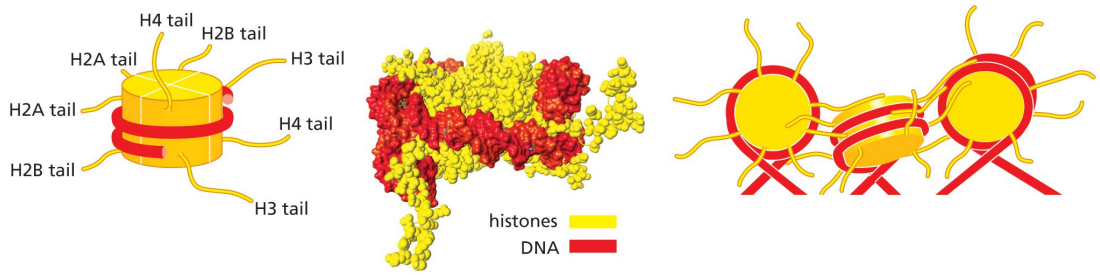
(about 8% of the total protein-coding genes). Not included in this list were variant versions of these proteins arising through alternative splicing of pre-mRNAs.

The transcription of most genes is dependent upon the actions of several distinct TFs that must sit down together, each at its appropriate sequence site (that is, enhancer) in or near the gene promoter, and collaborate to activate gene expression (see Figure 1.15). This means that the expression of a gene is most often the result of the combinatorial actions of several TFs. Therefore, the coordinated expression of multiple genes within a cell, often called its gene expression program, is dependent on the actions of multiple TFs acting in combination on large numbers of gene promoters. In a variety of differentiated human cells, large clusters of multiple distinct TFs (each binding to its own enhancer sequence) assemble together with general transcription factors to drive high-level transcription of nearby non-housekeeping genes; these clusters of TFs, which may number in the hundreds within a given cell type, are termed super-enhancers (even though, more appropriately, the term should refer to the DNA sequences to which the component TFs bind). Some have proposed that the DNA sequences in the human genome responsible for regulating transcription, such as the enhancers, exceed those sequences encoding protein structure.

Figure 1.15 implies that modulation of gene expression is achieved by controlling initiation of transcription by RNA polymerase II (pol II) and that transcription proceeds in one direction. In fact, for many genes, possibly the majority, pol II molecules initially sit down on the promoter of a gene and proceed to transcribe the DNA in both directions. After extending nascent RNA transcripts for 20–60 nucleotides, pol II halts—the process termed transcriptional pausing or **promoter-proximal pausing**. A subset of the stalled polymerase complexes that have initiated in the appropriate transcriptional direction are then induced by physiologic signals to resume elongation, resulting in full-length pre-mRNA transcripts, while other pol II complexes remain stalled and never resume transcription. The factors that permit stalled pol II to proceed with elongation of transcripts are incompletely understood but would seem to be as important as the conventionally defined TFs in regulating gene expression. One important cancer-causing protein, termed Myc, has been found to act as an anti-pausing protein whose actions permit thousands of cellular genes to be fully transcribed.

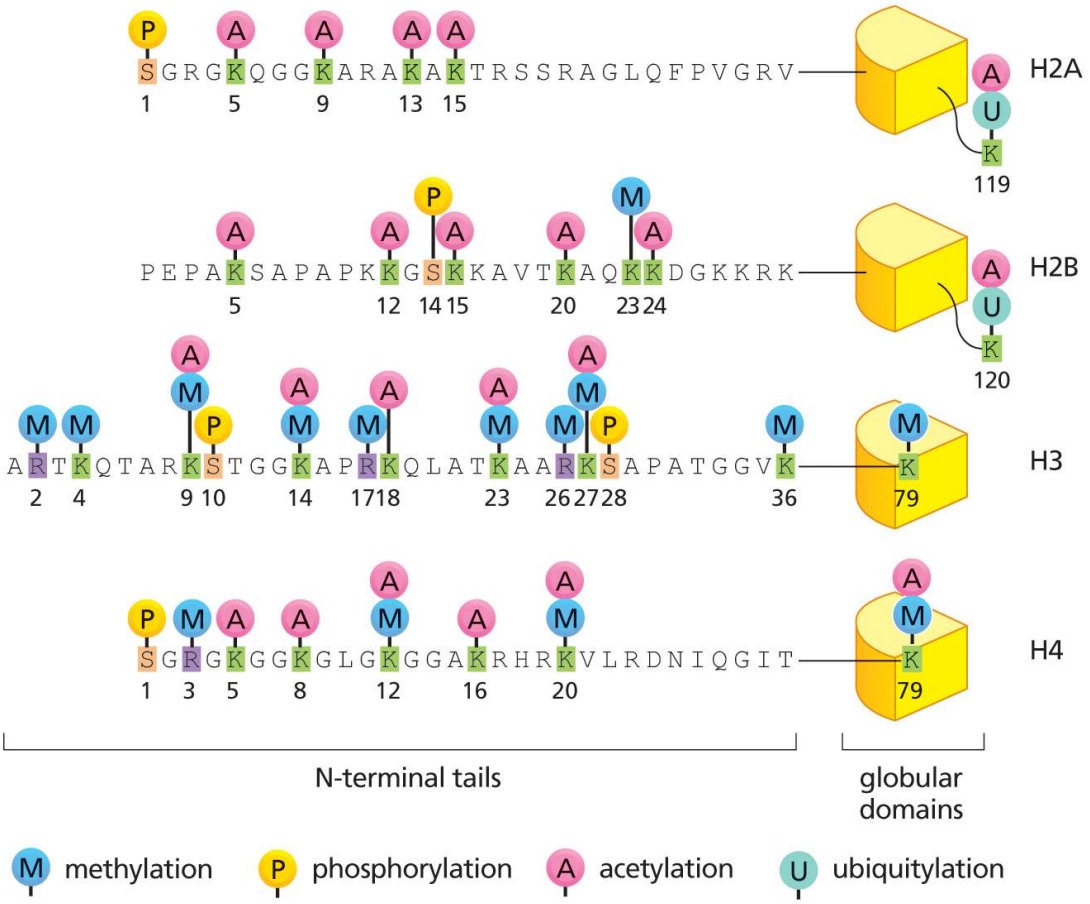
Figure 1.15 also implies that both TFs and RNA polymerase interact only with DNA. In fact, in eukaryotic cells, DNA is packaged in a complex mixture of proteins that, together with the DNA, form the chromatin (**Figure 1.16**). The chromatin proteins are responsible for controlling the interactions of TFs and RNA polymerases with DNA and therefore play critical roles in governing gene expression. The core of chromatin is formed by DNA bound to nucleosomes, the latter being octamers consisting of two copies of each of four standard histone species (H2A, H2B, H3, and H4) with a fifth histone species—H1—bound to some but not all nucleosome octamers. This basic

organization of chromatin structure, which resembles beads on a string, is found throughout the chromosomes. Altogether, about 30 million nucleosomes package the genomic DNA in the nucleus of each human cell.



In a schematic diagram, a red coil is wrapped around a short yellow cylinder with long, eight hairlike projections labeled H3 tail, H4 tail, H2A tail and H2E tail. Each projection is attached to an octant of the cylinder. The same structure is also shown, more realistically, as a space-filling molecular model. Finally, a schematic diagram shows three such structures locked together in a row.

(A)



The detailed structure of each type of N-terminal histone tail. The structure of the H2A tail is S G R G K Q G G K A R A K A K T R S S R A G L Q F P V G R V. The S in position 1 has an attached phosphate group. The kays in positions 5, 9, 13 and 15 have attached acetyl groups. Also, within the main body a K in position 119 has an attached ubiquitil group, which in turn has an attached acetyl group. The structure of the H2B tail is P E P A K S A P A P K K G S K K A V T K A Q K K D G K K R K. The kays in positions 5, 12, 15, 20 and 24 have attached acetyl groups. The S in position 14 has an attached phosphate group. The K in position 24 has an attached methyl group. Also, within the main body a K in position 120 has an attached ubiquitil group, which in turn has an attached acetyl group. The structure of the H3 tail is A R T K Q T A R K S T G G K A P R K Q L A T K A A R K S A P A T G G V K. The ars in positions 2, 17 and 26 and the kays in positions 4, 36, and also 79 within the main body all have attached methyl groups. The esses in positions 10 and 28 have attached phosphate groups. The kays in positions 9, 14, 23 and 27 each have an attached methyl group, which in turn has an attached acetyl group. The structure of the H4 tail is S G R G K G G K G L G K G G A K R H R K V L R D N I Q G I T. The kays in positions 5, 8, and 16 have attached acetyl groups. The S in position 1 has an attached phosphate group. The R in

position 3 has an attached methyl group. The kays in positions 12, 20, and also 79 within the main body each have an attached methyl group, which in turn has an attached acetyl group.
(B)

Figure 1.16 Organization of chromatin structure Examination of chromatin prepared in the proper way reveals that it appears like beads on a string (*not shown*). We now understand this structure in molecular detail. (A) The DNA double-helix (*red*) is wrapped ∼1.67 times around each nucleosome, which consists of a core (*yellow*) formed as an octamer of four different histone molecules, each present in two copies (*left*); the N-terminal tail of each of the histones protrudes from the core nucleosome. X-ray crystallography has revealed (*middle*) that the core of the nucleosome (*yellow*) is disc-shaped; the N-terminal histone tails are not clearly revealed in this space-filling molecular model. The N-terminal tails of the histones (*right, yellow*) regulate the degree of compaction of chromatin, in part through their role in mediating interactions between nucleosomes bound along the DNA. (B) Each of these N-terminal histone tails can be modified by the covalent attachment of a variety of chemical groups, most commonly methyl, acetyl, phosphate, and ubiquitin groups. These post-translational modifications (PTMs) are attached by histone "writers," enzymes that alter the structure and the function of the chromatin proteins and determine whether or not a given segment of chromatin will be transcribed or not. (A, Adapted from Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015. PDB code: 1KX5. B, from H. Santos-Rosa and C. Caldas, *Eur. J. Cancer* 41:2381–2402, 2005. With permission from Elsevier.)

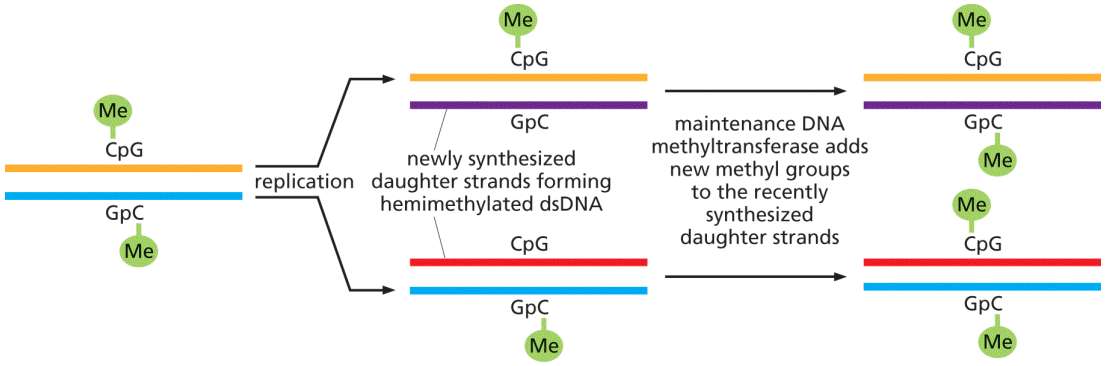
The globular core of the nucleosome represents the basic scaffold of chromatin that is modified in two ways. First, some of the standard histones (sometimes termed canonical histones), such as histones H2A and H3, may be replaced in a minority of nucleosomes by variant forms that are specified by genes distinct from those encoding the standard histones. Indeed, there are several dozen variant histones scattered here and there throughout the chromatin; the precise contributions of most of these to the regulation of chromatin structure and function remain poorly understood. One exception to this rule is the much-studied H2AX, which represents 10–15% of the H2A molecules in the nucleosomes. As discussed in Chapter 12, the phosphorylation of H2AX occurs in the nucleosomes that flank sites of double-strand DNA breaks, facilitating subsequent DNA repair. Yet another variant of histone H2A, termed H2A.Z, operates specifically to activate genes encoding epithelial functions and to repress those specifying mesenchymal functions; the resulting shifts in transcription are responsible for the programming of malignant cell traits that we will encounter in detail in Chapter 14.

Second, chromatin structure and transcription are strongly affected by covalent modifications of the standard four histones that occur after these histones assemble into nucleosomes. Most of these modifications affect lysine and arginine residues in the N-terminal tails of the core histones (see Figure 1.16B), which extend outward from the globular core of each nucleosome. Included here are modifications such as methylation, acetylation, phosphorylation, and ubiquitylation; other, less common modifications have also been observed, including biotinylation and sumoylation. A minority of this bewildering array of modifications have been associated with specific cell-biological programs, such as meiosis, apoptosis, and X-chromosome inactivation. During the cell growth-and-division cycle, one type of histone phosphorylation is associated with the condensation of chromatin that occurs during mitosis and the related global shutdown of gene expression. At other times in the cell cycle, acetylation of core histones is generally associated with active gene expression, while methylation is generally correlated with gene repression. Certain histone-modifying enzymes are specialized to elicit specific phenotypic changes in cells, doing so by altering transcriptional programs in ways that favor cancer cell growth and survival and, in turn, the outgrowth of tumors. [Recent measurements have suggested that various combinations of post-translational modifications (PTMs) generate as many as 1000 distinct isoforms of the H3 proteins present within individual human cells.]

Decades of research have revealed that the phenotypes and thus transcriptional programs of cells are transmitted stably over dozens, even hundreds of successive cycles of cell growth and division. For example, the descendants of a fibroblast are highly likely to preserve and exhibit a fibroblastic phenotype. This implies that specific states of histone modification are also transmitted faithfully from mother cells to their daughters in order to ensure the perpetuation of phenotypic states over many cell generations. However, the biochemical mechanisms responsible for the transmission of histone modification states are incompletely understood. This fidelity and associated heritability of cell-biological phenotypes is also critical to cancer biology, since many of the specific phenotypes of cancer cells are inherited from normal ancestral cells (often termed cells-of-origin) and resist disruption by the actions of activated oncogenes and inactivated tumor suppressor genes. Since the perpetuation of specific cellular phenotypes over multiple cell generations does not depend on specific changes in nucleotide sequence, this transmission of phenotype is considered a product of **epigenetic inheritance**.

Importantly, histone modifications, acting on their own, represent only one mechanism to ensure the stable intergenerational transmission of gene expression programs. In fact, a second key mechanism that enables epigenetic inheritance depends on covalent modification of DNA, specifically by DNA methyltransferases—enzymes that attach methyl groups covalently to cytosine bases of CpG dinucleotides in the DNA double helix. (The designation CpG indicates that the sequence is a cytidine positioned 5′ immediately before a guanosine.) The affected CpG dinucleotides are often located

near transcriptional promoters, and the resulting methylation generally causes repression of nearby genes. The biochemical mechanism of maintenance methylation is well understood: maintenance DNA methyltransferase enzymes recognize hemi-methylated segments of recently replicated DNA and proceed to methylate any unmethylated CpG dinucleotides that are complementary to already-methylated CpGs in the other DNA strand (**Figure 1.17**). Extensive CpG methylation in the vicinity of a gene promoter often results in its repression and, in turn, in the continuing repression of this gene in descendant cells. As might be concluded from the previous paragraph, the mechanisms of transcriptional repression operate through close coordination between DNA methylation and enzymes responsible for histone modification. The mechanisms of CpG methylation assume a major role in ensuring that certain tumor suppressor genes are transcriptionally repressed, as will be discussed in more detail in Chapter 7.



A three-stage diagram. In the first stage, a D N A double helix has a C p G dinucleotide on one side directly opposite a G p G on the other side. Both cees are methylated. After replication, each daughter D N A also has a C p G dinucleotide on one side directly opposite a G p G on the other side, but only the C in the strand that came from the parent is methylated. The newly synthesized daughter strands are hemimethylated d s D N A. Finally, maintenance D N A methyltransferase adds new methyl groups to the recently synthesized daughter strands. Now both daughter strands are replicas of the original parent strand, methylated on both cees of the dinucleotides.

Figure 1.17 Maintenance of DNA methylation following replication When a DNA double helix that is methylated (*green* Me groups, *left*) at CpG sites undergoes replication, the newly formed daughter helices will initially lack methyl groups attached to CpGs in the recently synthesized daughter strands (*purple*, *red*) and will therefore be *hemi-methylated*. Shortly after their synthesis, however, a maintenance DNA methyltransferase will detect the hemi-methylated DNA and attach methyl groups (*green*) to these CpGs, thereby regenerating the same configuration of methyl groups that existed in the parental helix prior to replication. CpG sites that are unmethylated in the parental helix (*not shown*) will

be ignored by the maintenance methyltransferase and will therefore remain so in the newly synthesized strands.

OceanofPDF.com

Glossary

transcription factor
: Protein that is involved in regulating the transcription of a gene, often by associating with specific sequences in the promoter region of the gene. *See also* **general transcription factor**.

sequence motif
: (1) Short oligonucleotide sequence in DNA that is characteristically associated with one or another biological function including recognition and binding by sequence-specific transcription factors. (2) Amino acid sequence that is characteristically associated with a structural or functional aspect of a protein.

pleiotropy
: Ability of a gene or protein to concomitantly evoke multiple distinct downstream responses within a cell or organism.

enhancer
: A relatively short sequence of nucleotides near or within a gene to which a transcription factor may bind in a sequence-specific manner and in turn influence the transcription of this gene. *See also* **super-enhancer, transcription factor**.

expression program
: The coordinated expression of a series of genes.

general transcription factor
: A protein that associates with sequence-specific transcription factors throughout the genome to enable transcription to occur; general transcription factors usually do not possess sequence-specific DNA-binding domains and are presumed to be responsible for regulating the expression of large numbers of genes, possibly in certain cases all of the actively transcribed genes in a cell. *See also* **transcription factor**.

super-enhancer
: A large cohort of transcription factors, each bound to its cognate enhancer sequence, that assemble in a physical complex and drive the high-level expression of a nearby gene. *See also* **enhancer**.

transcriptional pausing
: The process causing an RNA polymerase II molecule that has initiated transcription of a gene to halt at a downstream site relatively close to

the transcriptional start site; formation of a full-length transcript depends on release of the polymerase from the site of pausing.

chromatin
: Complex of DNA, RNA, and protein molecules that together constitute chromosomes.

canonical
: Referring to the most widely accepted representation of an entity or process, often the one that is initially discovered and characterized. *See also* **non-canonical**.

hemi-methylated
: Referring to a DNA molecule in which only one of the two complementary strands of a particular DNA segment is methylated, usually at the deoxycytidine moiety of a CpG dinucleotide sequence.

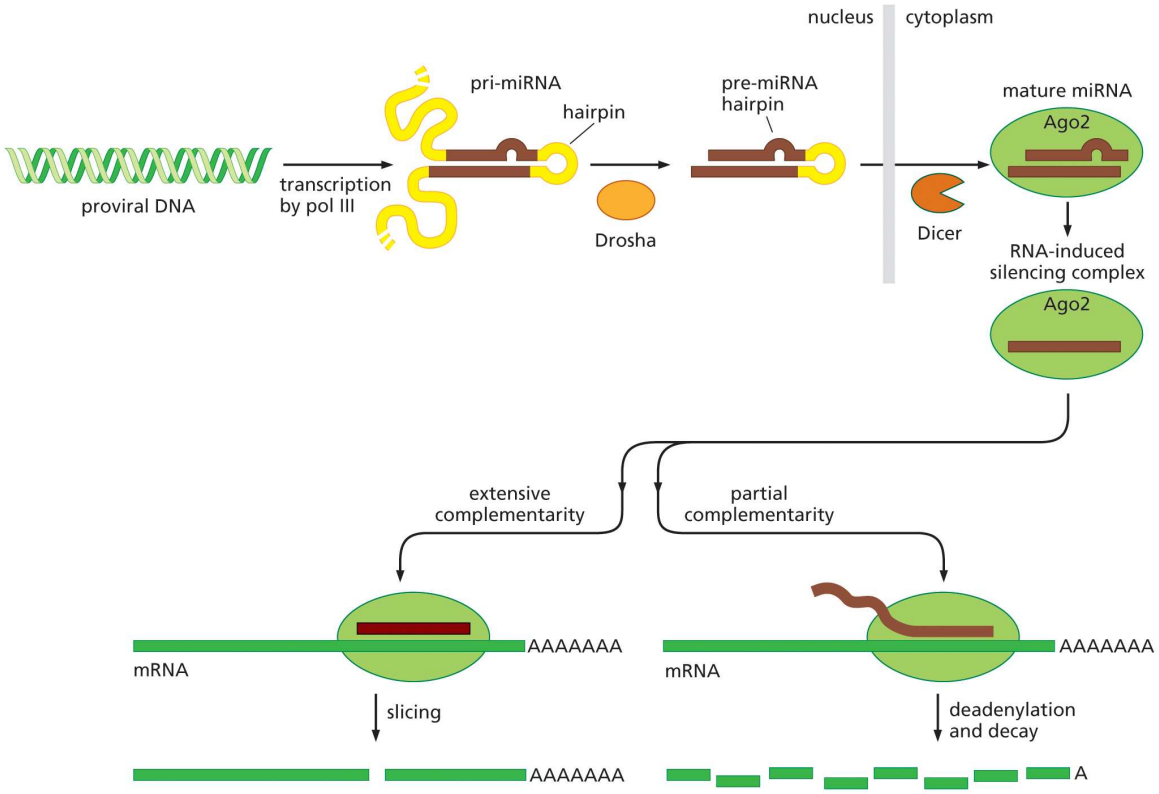
cell-of-origin
: The fully normal cell that serves as the ancestor of all the neoplastic cells within a tumor, i.e., their last common normal ancestor.

OceanofPDF.com

1.9 Unconventional RNA molecules also affect the expression of genes

The Central Dogma of molecular biology, developed in the decade after the 1953 discovery of the DNA double helix, proposed that information flows in cells from DNA via mRNA to proteins. In addition, non-informational RNA molecules—ribosomal and transfer RNAs—were implicated as components of the translational machinery, and small nuclear RNAs were found to play key roles in the splicing and maturation of pre-mRNAs. In the 1980s, the view of RNA's functions was expanded through the discovery that certain RNA species can act as enzymes, thereby taking their place alongside proteins as catalysts of certain biochemical reactions.

The 1990s revealed an entirely new type of RNA molecule that functions to control either the levels of certain mRNAs in the cytoplasm, the efficiency of translating these mRNAs, or both. These microRNAs (miRNAs) are only ∼22 nucleotides long and are generated as cleavage products of far larger nuclear RNA precursors. As outlined in **Figure 1.18**, the post-transcriptional processing of a primary miRNA transcript results in the formation in the cytoplasm of a miRNA that is part of a RISC (RNA-induced silencing complex) nucleoprotein. This complex associates with a spectrum of mRNA targets that contain, usually in their untranslated region, a sequence that is partially or completely complementary to the miRNA in the complex. Such association can result in either the inhibition of translation of the mRNA or its degradation, or both.



A multi-stage diagram depicting Micro R N As and gene regulation. Within a cell nucleus, a section of proviral D N A double helix is transcribed by pol 3 to produce a primary micro R N A with a section that is folded into a hairpin shape. A Drosha protein enzyme complex excises this hairpin section and it becomes pre-micro R N A, which passes out of the nucleus into the cytoplasm. There, action by the Dicer enzyme generates a mature micro R N A bound to Argonaute, shown as a green capsule labeled Ago2. Discarding of one side of the hairpin produces an R N A-induced silencing complex. The process ends in one of two ways. In the case of extensive complementarity, the R N A-induced silencing complex makes occasional slices in m R N A. In the case of partial complementarity, the R N A-induced silencing complex chops the m R N A into many small segments. This outcome is labeled deadenylation and decay.

Figure 1.18 MicroRNAs and gene regulation A primary microRNA (pri-miRNA) is transcribed from a gene, and an enzyme complex involving the Drosha protein excises a small segment of the pri-miRNA that has formed a double-stranded RNA hairpin because of the self-complementarity of nucleotide sequences. The resulting pre-miRNA is exported to the cytoplasm, where it is further processed by the Dicer enzyme to generate a mature

miRNA of 21 to 25 nucleotides. The resulting double-stranded miRNA is then bound to Argonaute (Ago2), which discards one of the two strands to generate the nucleoprotein complex termed RISC (RNA-induced silencing complex) and associates with mRNAs in the cytoplasm with which it has either precise or partial sequence complementarity, resulting in either degradation of the mRNA or inhibition of its translation. Several dozen miRNAs have been found to regulate various steps of tumor formation, either favoring or blocking critical steps of this process. Mutations of the gene encoding the Dicer enzyme (as well as those encoding other proteins involved in miRNA processing) have been associated with cancer progression, and analyses of miRNA expression patterns, much like expression array analyses of mRNAs (see Figure 1.14), have proved useful in classifying various types of cancer. (Courtesy of P.A. Sharp and D. Bartel.)

More than 500 distinct miRNA species have been found and characterized in human cells. Although it remains unclear precisely how many of these miRNAs are actually involved in regulating the translation and stability of mRNAs, those that do affect mRNA function are thought to regulate expression of more than 60% of all genes in the human genome. Moreover, a single miRNA species can target and thus regulate the functioning of dozens of distinct mRNA species, enabling it to act pleiotropically on a variety of cellular processes.

The potential importance of miRNAs in regulating gene expression is suggested by one survey of mRNAs and corresponding proteins in a group of 76 lung cancers. Only about 20% of the genes studied showed a close correlation between mRNA expression and protein expression levels. Hence, in the remaining 80%, the rate of protein synthesis (which can be strongly influenced by miRNAs) and the post-translational lifetime of proteins strongly influenced actual protein levels. Since proteins, rather than mRNA, are responsible for creating cell phenotypes, this also reveals the limitations of interpreting mRNA levels as reliable indicators of gene activity.

Let-7, a miRNA expressed by the *C. elegans* worm, was one of the first characterized miRNAs. It was found to suppress expression of the *ras* gene in worms and later in mammals. As we will read later (Chapters 4 through 6), the Ras proteins play critical roles in the development of many types of common human cancers. Since this pioneering work, the overexpression or loss of more than a dozen miRNA species has been associated with the formation of a variety of human cancers and the acquisition by tumors of malignant traits. The list of

these miRNAs, which have garnered the term “oncoMiRs,” continues to lengthen. In addition, loss of the Dicer processing enzyme (see Figure 1.18) and of other miRNA-processing enzymes involved in creating mature miRNAs has been found to facilitate the formation of tumors in mice and humans, doing so through still-unknown mechanisms. Interestingly, inheritance of a variant of the *K-ras* gene, which causes a single nucleotide change in the 3′ untranslated region (3′ UTR) of its mRNA, prevents recognition by *Let-7* and is associated with higher levels of the growth-promoting K-Ras protein and as much as a twofold increased risk of certain forms of lung and ovarian cancers.

A decade after the discovery of microRNAs, yet another unusual class of RNAs appeared on the scene: a diverse assay of lncRNA molecules (long noncoding RNAs) were found in the nucleus and cytoplasm and were shown to be involved in still-poorly understood ways in regulating gene expression. The discovery of these molecules came from the realization that 4 to 9% of the human genome is transcribed into relatively long (>200-nucleotide) RNA molecules that have no identifiable protein-coding sequences and thus no readily ascertainable functions. Some lncRNAs are polyadenylated while others are not. The few lncRNAs that have been characterized seem to function by associating with proteins that are involved in one fashion or another in regulating transcription, often by serving as scaffolds to hold certain chromatin-modifying proteins together. There may be several thousand distinct lncRNA species encoded by the human genome, and they are increasingly viewed as key molecular components of the cell’s regulatory machinery.

The role of lncRNAs in cancer development is only beginning to be uncovered. For example, elevated expression of the *HOTAIR* lncRNA has been found to be correlated with metastatic behavior of human breast and colorectal carcinomas. More important, forced expression of *HOTAIR* in carcinoma cells causes localization of a transcription-repressing protein complex, termed PRC2, to certain chromosomal sites, altered methylation of histone H3 lysine 27 (see Figure 1.16B), and increased cancer invasiveness and metastasis. Another lncRNA has been reported to be critically important in enabling melanoma cell invasiveness.

Yet another class of unconventional RNAs came into clear view in the decade after 2010: small circular RNAs (circRNA) that are created as side products of splicing in the nucleus. While more than 10,000 of these have been identified, most may be incidental by-products of splicing, with only a tiny subset playing validated functional roles. One prominent example here is ciRS-7, which contains

∼70 copies of a sequence that enables it to act as a sponge to attract and bind molecules of miR-7, thereby diverting the latter from its usual mRNA targets. miR-7, in turn, is an important tumor-suppressing microRNA for reasons described above.

The actions of miRNAs and lncRNAs provide a glimpse of the complexity of gene expression and its regulation in mammalian cells. Thus, after the transcription of a gene is initiated, a number of mechanisms may then intervene to control the accumulation of its ultimate product—a protein that does the actual work of the gene. Among these mechanisms are (1) promoter-proximal pausing; (2) post-transcriptional processing of pre-mRNA transcripts, including alternative splicing patterns; (3) stabilization or degradation in the cytoplasm of the mRNA product; (4) regulation of mRNA translation; and (5) post-translational modification, stabilization, or degradation of the protein product. These mechanisms reinforce the notion, cited above, that the rate of transcription of a gene often provides little insight into the levels of its protein product within a cell. Hence, as we will see, distinct patterns of mRNA expression may help us to distinguish various neoplastic cells from one another but, on their own, tell us rather little about how these cells are likely to behave.

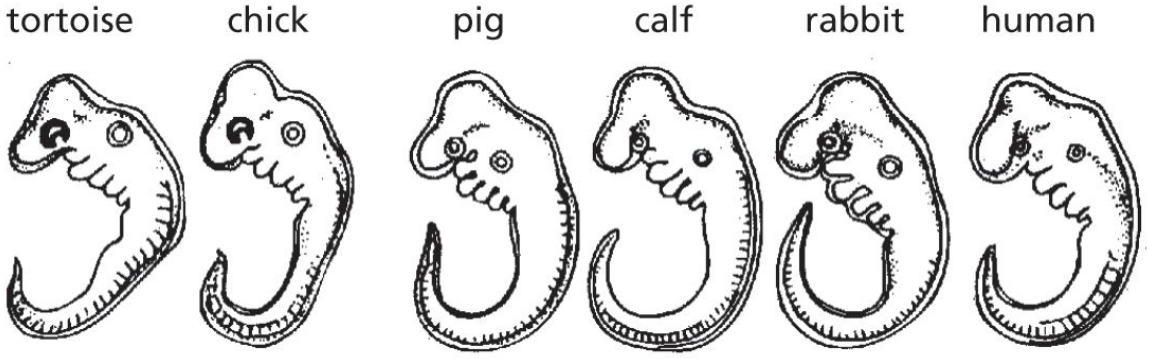
1.10 Metazoa are formed from components conserved over vast evolutionary time periods

The following descriptions of cell biology, genetics, and evolution are informed in part by our knowledge of the history of life on Earth. Metazoa probably arose only once during the evolution of life on this planet, likely more than 650 million years ago. Once the principal mechanisms governing their genetics, biochemistry, and embryonic development were developed, these mechanisms remained largely unchanged in the descendant organisms up to the present (see Figure 1.6). This sharing of conserved traits among various animal phyla and orders has profound consequences for cancer research, since many lessons learned from the study of more primitive but genetically tractable organisms, such as flies and worms, have proven to be directly transferable to our understanding of how mammalian tissues, including those of humans, develop and function.

A survey of the diverse organisms grouped within the mammalian class reveals that the differences in biochemistry and cell biology are minimal (**Figure 1.19**). For this reason, throughout this book we will move effortlessly back and forth between mouse biology and human biology, treating them as if they are essentially identical. On occasion, where species-specific differences are important, these will be pointed out.



Drawings of the embryos of a tortoise, a chick, a pig, a calf, a rabbit, and a human. They all look very similar: a lumpy head, a series of folds that look

like the beginnings of a ribcage, and a long, tail-like projection, curled forward like a fishhook, that will develop into the spine.

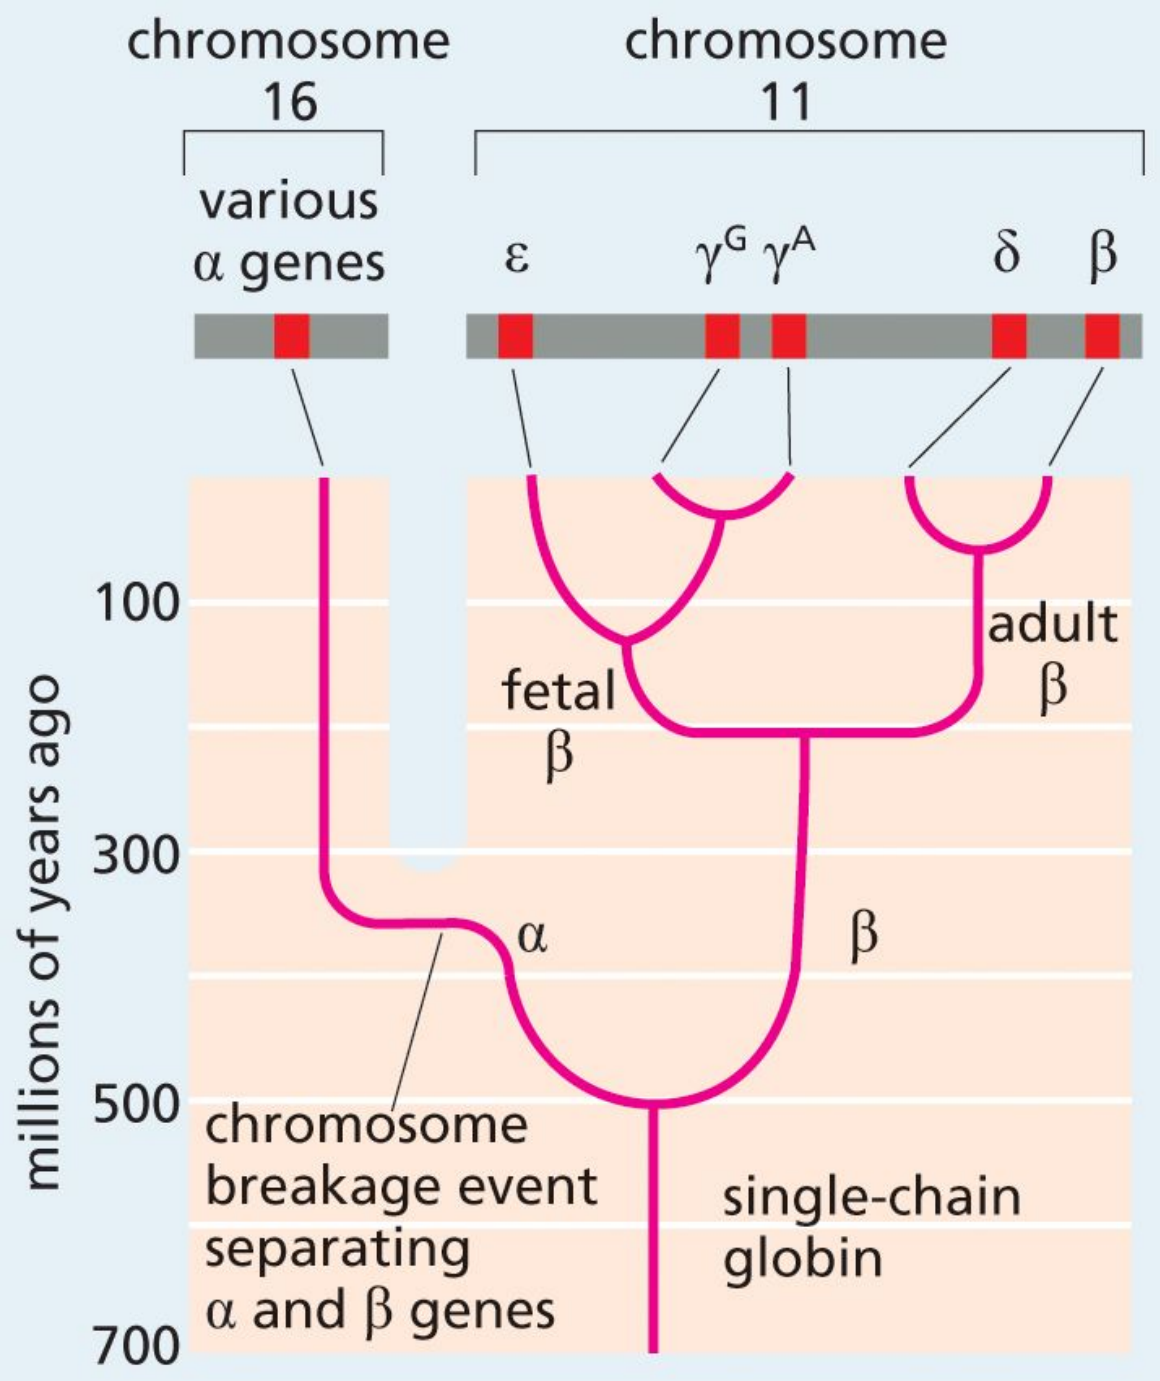
Figure 1.19 Visual evidence of the conservation of vertebrate biological traits A stunning visual demonstration that contemporary metazoa develop through embryonic pathways that have changed little since mammals and reptiles diverged from one another 200+ million years ago comes from an examination of mammalian embryos and one reptile—a tortoise. These morphological similarities do not begin to reveal the underlying biochemical pathways of cells and organisms that are equally well conserved. These 1874 drawings have been criticized for oversimplifying the similarities between these embryos. (In G.J. Romanes, Darwin and after Darwin, London, Vol. 1, 1892, adapted in turn from Haeckel, E., Anthropogenie; oder, Entwickelungsgeschichte des menschen. Keimes- und stammesgeschichte.)

The complex signaling circuits operating within cells seem to be organized in virtually identical fashion in all types of mammals. Even more stunning is the interchangeability of the component parts. It is rare that a human protein cannot function in place of its counterpart *orthologous* protein (**Sidebar 1.5**) in mouse cells. In the case of many types of proteins, this conservation of both function and structure is so profound that proteins can be swapped between organisms that are separated by far greater evolutionary distances. A striking example, noted earlier (see Figure 1.6), is provided by the gene and thus the protein that specifies eye formation in mammals and in flies. Extending even further back in our evolutionary history are the histones and the mechanisms of chromatin remodeling discussed earlier. In fact, the counterparts of many molecules and biochemical mechanisms that operate in mammalian cells are already apparent in protozoa.

Sidebar 1.5 Orthologs and homologs

All higher vertebrates (birds and mammals) seem to have comparable numbers of protein-encoding genes—in the range of 20,000. Moreover, almost every gene present in the bird genome seems to have a closely related counterpart in the human genome. The correspondence between mouse and human genes is even stronger, given the closer evolutionary relatedness of these two mammalian species.

Within the genome of any single species, there are genes that are clearly related to one another in their information content and in the related structures of the proteins they specify. Such genes form a gene family. For example, the group of genes in the human genome encoding globins constitutes such a group. It is clear that these related genes arose at some point in the evolutionary past through repeated cycles of the process in which an existing gene is duplicated followed by the progressive divergence of the two duplicated nucleotide sequences from one another (**Figure 1.20**). More directly related to cancer development are the more than 500 protein kinases encoded by the human genome. The kinase enzymes attach phosphate groups to their protein substrates, and almost all of these enzymes are specified by members of a single gene family that underwent hundreds of cycles of gene duplication and divergence during the course of metazoan evolution (see **Supplementary Sidebar 17.7**).



A branching, bottom-to-top chronology of the evolutionary development of gene families. 700 million years ago, there was a single-chain globin gene. 500 million years ago, there was differentiation into alpha and beta versions. 350 million years ago, there was a chromosome breakage event separating the alpha and beta genes. The alpha branch produced human chromosome 16 with various versions of the alpha gene. The beta branch produced human chromosome 11. A branch 100 million years ago produced, on one side, fetal

beta with the epsilon, G gamma G and A gamma genes, and on the other side adult beta with the delta globin and beta globin genes.
Figure 1.20 Evolutionary development of gene families The evolution of organismic complexity has been enabled, in part, by the development of increasingly specialized proteins. New proteins are "invented" largely through a process of gene duplication followed by diverging evolution of the two resulting genes via incremental changes that ultimately lead to structurally and functionally distinct proteins. Repeated cycles of such gene duplications followed by divergence have led to the development of large numbers of multi-gene families. During vertebrate evolution, an ancestral globin gene, shown here as an example, which encoded the protein component of hemoglobin, was duplicated repeatedly, leading to the α and multiple distinct β-like globin genes in the modern mammalian genome that are present on two human chromosomes. Because these globins have distinct amino acid sequences, each can serve a specific physiologic function. (From B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015.)

Genes that are related to one another within a single species' genome or genes that are related to one another in the genomes of two distinct species are said to be homologous to one another. Often the precise counterpart of a gene in a human can be found in the genome of another species. These two closely related genes are said to be orthologs of one another. Thus, the precise counterpart—the ortholog—of the c-*myc* gene in humans is the c-*myc* gene in chickens. To the extent that there are other *myc*-like genes harbored by the human genome (that is, N-*myc* and L-*myc*), they are members of the same gene family as c-*myc* but are not orthologs of one another or of the c-*myc* gene in chickens; instead, the c-*myc*, N-*myc*, and L-*myc* genes within a mammalian genome are termed paralogs due to their descent from a common ancestral gene.

Throughout this book we will often refer to genes without making reference to the species from which they were isolated. This is done consciously, since in the great majority of cases, the functioning of a mouse gene (and encoded protein) is indistinguishable from that of its human or chicken ortholog.

OceanofPDF.com

Glossary

gene family
: Group of genes all of which are descended evolutionarily from a common ancestral gene. The members of a gene family generally encode distinct, structurally related proteins.

kinase
: Enzyme that removes the γ phosphate from ATP and covalently attaches the phosphate moiety to substrate molecules, often but not exclusively proteins.

homologous
: (1) Referring to the relationship between a pair of chromosomes that carry the same set of genes within a diploid cell or organism. (2) Referring to genes or characteristics that are similar in related organisms because of shared descent from a common precursor. (3) Referring to two nucleic acids having similar or closely related nucleotide sequences. *See also* **analogous**.

ortholog
: (*also* **orthologue**) A gene in one species that is the closest relative of a gene in another species, with the two genes arising from a common ancestral gene in a common ancestral species; usually orthologs represent direct counterparts of one another in the genomes of two species, often retaining very similar functions. *See also* **homolog**, **paralog**.

paralog
: (*also* **paralogue**) A gene or protein that is related to another gene or protein through evolution from a common ancestral precursor; paralogs usually arise via gene duplication followed by sequence divergence of the two resulting genes, often with the development of two distinct functions, with both resulting genes continuing to be present in the genome of a descendant organism. *See also* **homolog, ortholog**.

1.11 Gene cloning techniques revolutionized the study of normal and malignant cells

Until the mid-1970s, the molecular analysis of mammalian genes was confined largely to the genomes of DNA tumor viruses, indeed the viruses described later in Chapter 3. These viruses have relatively simple genomes that accumulate to a high copy number (that is, number of molecules) per cell. This made it possible for biologists to readily purify and study the detailed structure and functioning of viral genes that operate much like the genes of the host cells in which these viruses multiplied. In contrast, molecular analysis of cellular genes was essentially impossible, since there are so many of them (tens of thousands per haploid genome) and they are embedded in a genome of daunting complexity (~3.2 billion base pairs of DNA per haploid cellular genome).

All this changed with the advent of gene cloning (**Supplementary Sidebar 1.4**). Thereafter, cellular genomes could be fragmented and used to create the collections of DNA fragments known as genomic libraries. Various DNA hybridization techniques could then be used to identify the genomic fragments within these libraries that were of special interest to the experimenter, in particular the DNA fragment that carried part or all of a gene under study. The retrieval of such a fragment from the library and the amplification of this retrieved fragment into millions of identical copies yielded a purified, cloned fragment of DNA and thus a cloned gene. Yet other techniques were used to generate DNA copies of the mRNAs that are synthesized in the nucleus and exported to the cytoplasm, where they serve as the templates for protein synthesis. Discovery of the enzyme reverse transcriptase (RT; see Figure 3.12) was of central importance here. Use of this enzyme made it possible to synthesize *in vitro* (that is, in the test tube) complementary DNA copies of mRNA molecules. These DNA molecules, termed cDNAs, carry the sequence information that is present in an mRNA molecule after the process of splicing has removed all introns. While we

will refer frequently throughout this book to DNA clones of the genomic (that is, chromosomal) versions of genes and to cDNAs generated from the mRNA transcripts of such genes, space limitations preclude any detailed descriptions of the cloning procedures *per se*. With segments of cloned gene segments in hand, cancer biologists could begin to suppress or eliminate the function of specific targeted genes through several alternative experimental strategies (**Supplementary Sidebar 1.5**).

For cancer researchers, gene cloning arrived just at the right time. As we will see in the next chapters, research in the 1970s diminished the candidacy of tumor viruses as the cause of most human cancers. As these viruses moved off center stage, cellular genes took their place as the most important agents responsible for the formation of human tumors. Study of these genes would have been impossible without the newly developed gene cloning technology, which became widely available in the late 1970s, just when it was needed by the community of scientists intent on finding the root causes of cancer.

OceanofPDF.com

Glossary

library
: (1) A collection of DNA clones derived from a cell's or an organism's genome or from cDNAs prepared from its expressed mRNAs, in which each component clone ideally derives from a distinct gene in this genome. (2) A collection of chemical compounds such as those synthesized because of their possible therapeutic utility.

reverse transcriptase
: Enzyme capable of making a DNA complementary copy of an RNA molecule using the RNA molecule as template.

complementary DNA
: DNA strand that is produced on an RNA template by reverse transcriptase.

in vitro
: (1) Referring to biochemical processes, notably reactions, that occur outside of living cells, including in cell lysates or under conditions involving purified reactants. (2) Referring to the propagation of living cells in a vessel (e.g., a Petri dish) rather than in living tissues.

clone
: (adj., **clonal**) (1) Copy of a gene that has been isolated by recombinant DNA procedures and amplified into a large number of identical copies. (2) Population of cells, all of which descend from a common progenitor cell. (3) Offspring of a procedure of asexual reproduction in which the genome of a somatic diploid cell of an organism is used to form a cell that functions equivalently to a fertilized egg that may itself develop thereafter into an entire organism.

Supplementary Sidebars

Supplementary Sidebar 1.1 Each female cell can access information only from a single X chromosome

In the simplest depiction of sex chromosome behavior, each male cell relies on the information carried by its single X chromosome, while each female cell is able to consult both of its X chromosomes. Given the large number of genes present on the X chromosome, this disparity would create substantial physiologic differences between male and female cells, since female cells would, in general, express twice as much of each of the products specified by the genes on their X chromosomes. This problem is solved by the mechanism of X-inactivation. Early in embryogenesis, one of the two X chromosomes is randomly inactivated in each of the cells of a female embryo. This inactivation silences almost all of the genes on this chromosome and causes this chromosome to shrink into a small particle termed the Barr body (**Figure S1.1**). Subsequently, all descendants of that cell will inherit this pattern of chromosomal inactivation and will therefore continue to carry the same inactivated X chromosome. Accordingly, the female advantage of carrying redundant copies of X chromosome–associated genes is only a partial one.

Figure S1.1 Physical maps and condensation of human sex chromosomes (A) Shown is a scanning electron micrograph of human X and Y chromosomes. Like the 22 autosomes (non-sex chromosomes), they have been sequenced. (B) This has allowed the *cytologic* maps of these chromosomes. These maps can be generated by microscopically examining stained chromosomes harvested at the metaphase of mitosis, in which, as an example, heterochromatic regions of the chromosome stain darkly. The maps can then be matched with their DNA sequence. Note that the short arm of a human chromosome is the “p” arm, while the long arm is the “q” arm. Each chromosome has been divided into regions on the basis of the observed banding pattern, and distinct genes have been assigned on the basis of the sequence analyses (*histograms to right of each chromosome*). Identified genes are filled bars (*red*), while sequences that appear to encode still-to-be-identified genes are in open bars; in most chromosomal regions the latter

represent a small minority. The human Y chromosome is ∼57 megabases (Mb) long, compared with the X chromosome's ∼155 Mb. (C) One of the two X chromosomes in each cell of an early female embryo is randomly inactivated and remains inactivated in all lineal descendant cells as a Barr body. It is visible in the interphase nuclei of these cells, where it remains condensed and associated with the nuclear membrane (*white arrow*). (A, courtesy of Indigo® Instruments. Supplementary Sidebar 1.2 Organismic cloning and the integrity of the somatic cell genome

A large number of growth-and division cycles intervene between the formation of the fertilized egg (that is, the zygote) and the formation of specific differentiated cells. These cycles, which may number in the many dozens, involve processes that may go awry, notably DNA replication and chromosome segregation. This provokes the question of the intactness of the genome of somatic cells; that is, How closely do they correspond in sequence and organization to the genome of their ancestral zygote? The efficiency of the complex apparatus that repairs DNA (see Chapter 12), the resulting suppression of somatic mutations, and the consequent integrity of the genomes of somatic cells were all illustrated dramatically in the much-celebrated case of the sheep Dolly. In experiments performed in Scotland in 1996, nuclei from cells taken from the breast tissue of Dolly's "mother" were removed and implanted in egg cells (oocytes) whose own nuclei had previously been eliminated. The resulting cells, containing donor nuclei and recipient egg cytoplasm, were then induced to proliferate and to form embryos. The fact that an essentially normal sheep (Dolly) was born many months later, having developed from one of these embryos, demonstrated that the genome in one of her mother's mammary gland cells carried no mutations that compromised normal embryologic development. The success of organismic cloning demonstrated directly that the somatic genome, as gauged through its ability to orchestrate proper organismic development, is largely if not entirely intact (**Figure S1.2**).

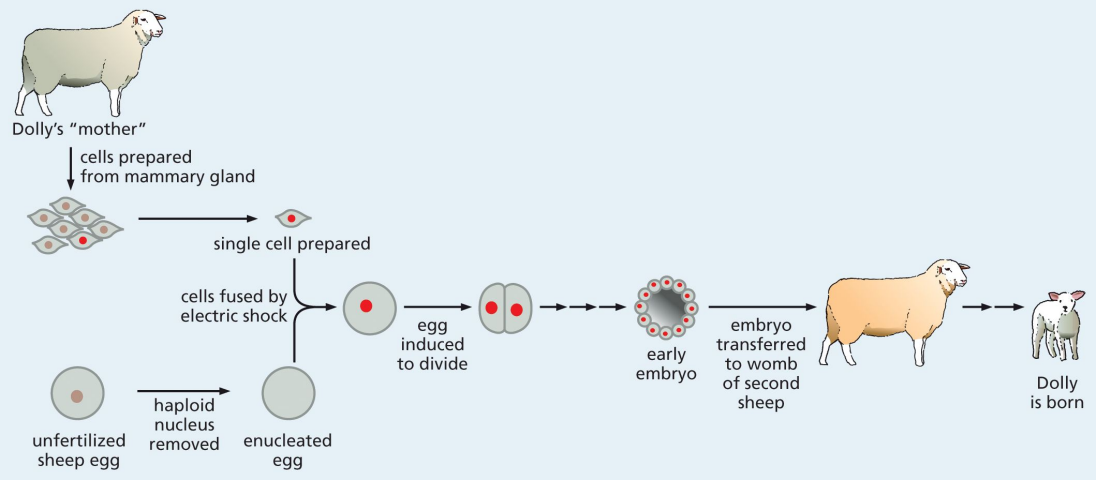

Figure S1.2 Reproductive cloning and genomic integrity In the first reported reproductive cloning procedure, the nucleus of an unfertilized egg was removed and the nucleus from a somatic cell—a mammary gland cell from Dolly's "mother"—was introduced via cell fusion into the enucleated egg. The resulting cell was diploid, having received its entire genetic complement from the mammary gland cell originating with Dolly's "mother." Being diploid, it was genetically equivalent to a fertilized egg. This reconstituted egg cell was induced to divide by chemical means and proceeded to generate an embryo that could then be implanted in the womb of a foster "pseudo-pregnant" ewe—a ewe whose physiologic state was comparable to that of a naturally pregnant ewe but had been induced in this case by hormonal treatment. This implanted embryo could then develop into a newborn, albeit at low efficiency. Successful generation of a healthy newborn led to several conclusions, the most immediate of which was that the nuclear chromosomal DNA originating in the mammary epithelial cells of Dolly's "mother" could be re-programmed, shedding its existing program of mammary gland differentiation and assuming the very different program of a recently fertilized egg; this re-programming clearly came from biochemical signals that were present in the cytoplasm of the enucleated oocyte into which the mammary gland nucleus had been introduced. More important for the present discussion, the birth of a relatively normal lamb indicated that the nucleus of the donor somatic cell prepared from Dolly's "mother's" mammary gland carried the genome of the species in an essentially intact, functional form. This donor mammary gland cell was formed after many successive cell divisions during the development of Dolly's "mother" from a natural fertilized egg. The ability of this cell's genome to generate Dolly indicated that these many successive cell divisions—those intervening between the fertilization of the egg that led to Dolly's mother and the formation of her mammary gland cell—did not affect its functional integrity.

Supplementary Sidebar 1.3 The size of the human essentialome

It is very unclear precisely how many genes and proteins are required to maintain human cell viability. Such critical genes have been considered as forming an "essentialome," for want of a better term. The numbers of genes required for viability are very different for an individual human cell being propagated in culture and for a comparable cell residing in a tissue. Moreover, some genes but not others must be present in two copies in order to ensure optimal functioning, since loss of only one copy will compromise phenotypic fitness—the phenomenon of haploinsufficiency. Given these uncertainties, there is little consensus at present about numbers: such essential genes have been found to range between 1000 and 4000, depending on the experimental conditions. (On the other hand, a set of as many as 10,000 genes may be expressed in virtually all tissues in the body—far more than experimental tests show to be necessary for cell viability.)

These numbers are of great interest to cancer biologists, since they dictate the outer boundaries of genetic variability that may be generated as cells undergo random somatic mutations including the losses of chromosomal segments of significant size. For example, the chromosomal region carrying the *RB1* tumor suppressor gene on Chromosome 13 (see Chapters 7 and 8) may be deleted homozygously in certain cancer cells (**Figure S1.3**). However, the ends of this deleted region and thus its overall size are likely to be limited by the locations to the left and right along Chromosome 13 of essential genes that cannot be discarded homozygously because their continued functions are critical to ongoing cell viability.

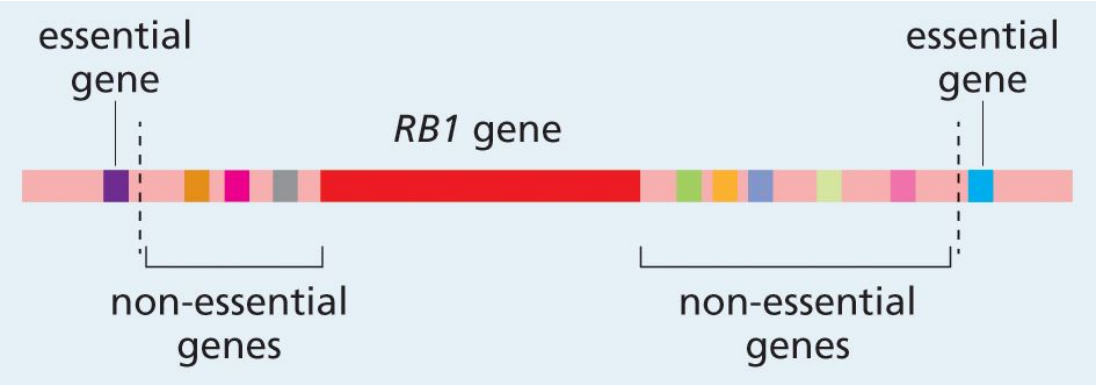

Figure S1.3 Loss of genomic regions during cancer formation As will be described in Chapter 7, tumor suppressor genes (TSGs) represent an important class of cellular proliferation–controlling genes that operate to constrain cell proliferation in various ways and are often shed during the formation of a variety of human tumor cells. Often both copies of a TSG gene, such as the *RB1* gene depicted here, are lost through interstitial deletions, leading to homozygous loss of the gene and often adjacent chromosomal regions (see Figure 1.9C). When

examining the genomes of a series of independently arising tumors, it becomes clear that the boundaries of the homozygously deleted flanking regions are found at random locations to the left and right of the *RB1* TSG—the only thing shared in common among the deletions mapped in different independently arising tumors being the loss of the TSG itself (a loss that confers proliferative advantage on a pre-neoplastic cell). In addition to homozygous deletions of the TSG itself, additional nearby cellular genes flanking the TSG on both sides are often lost homozygously, because their loss during tumor formation has no effect on cell viability and is therefore compatible with the subsequent outgrowth of robustly proliferating cancer cells. The outside boundaries of the chromosomal segment that can be deleted homozygously (*vertical dashed lines*) are defined by the locations along the chromosome of nearest genes to the left and the right of the TSG that are essential for continued cell viability, must therefore be retained in at least single copy number in a cancer cell, and therefore cannot be deleted homozygously. Accordingly, any pre-neoplastic cell that deletes an overly large chromosomal segment carrying this *RB1* gene (or entire chromosomal arm) homozygously will be lost from the population of cells that could serve as precursors of full-blown tumor cells.

Supplementary Sidebar 1.4 Gene cloning strategies

Gene cloning strategies first became practical in the late 1970s, and since that time a diverse array of technical strategies have been developed. **Figure S1.4** illustrates the logic of gene cloning that is common to many of these strategies.

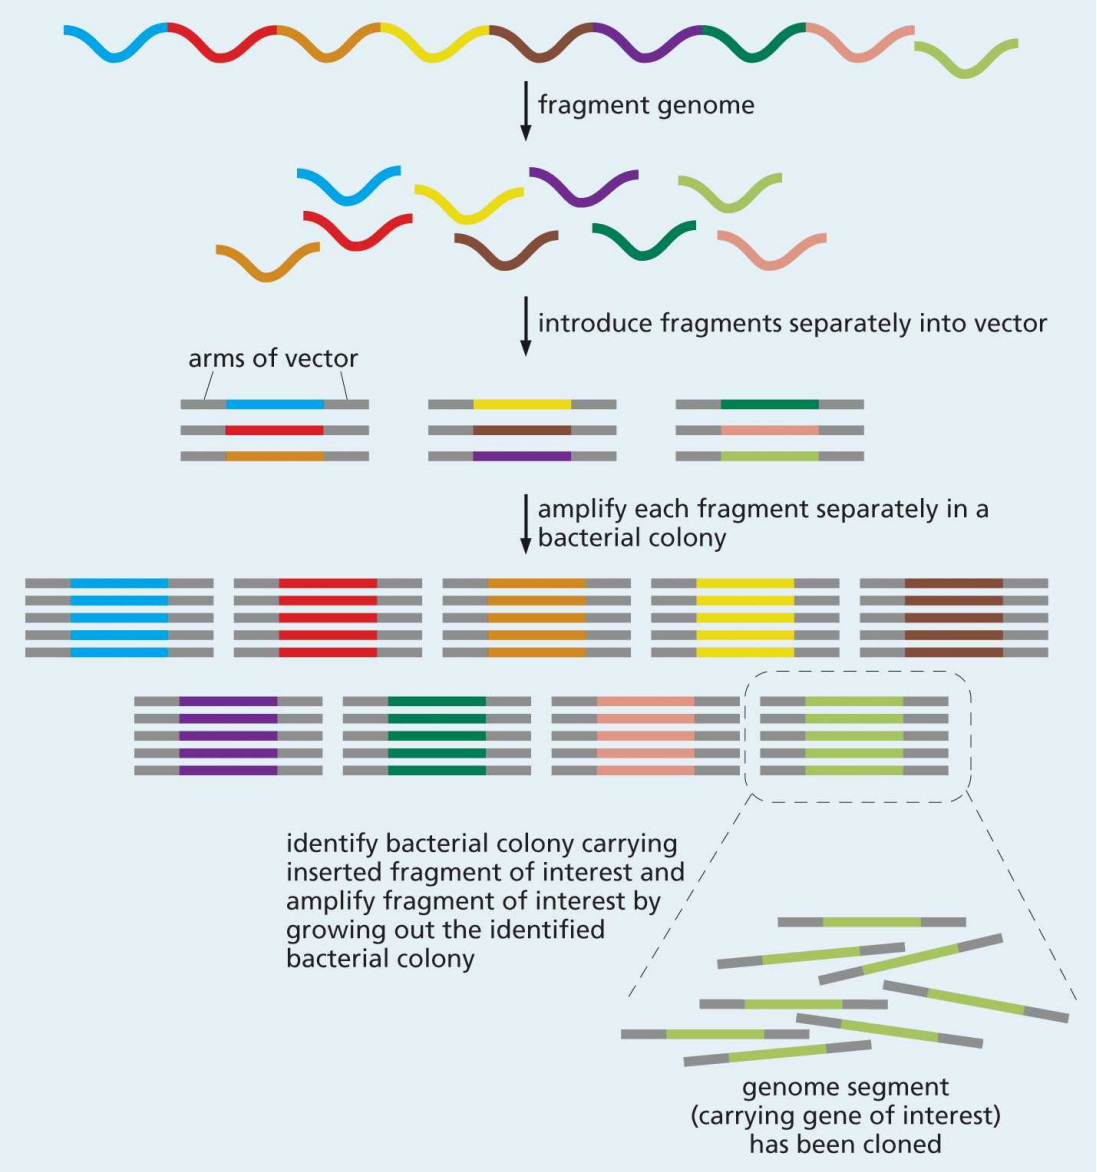

Figure S1.4 Molecular cloning of genes Many versions of the gene cloning procedure have been developed since this technology was first invented in the 1970s. Pictured is an outline of one version. The genome from an organism (e.g., human) is fragmented into relatively small segments, often several tens of kilobases long (*top*); each DNA segment is linked (i.e., experimentally recombined) to the DNA of a vector (*gray arms*), yielding a recombinant vector. Each recombinant vector is then inserted independently into a bacterium, which is expanded into a colony containing many thousands of bacteria. The bacterial colony bearing the vector with the gene of interest is identified and the vector is retrieved, yielding millions of copies of this genomic fragment (*bottom right*).

Supplementary Sidebar 1.5 Suppressing gene expression with shRNAs, siRNAs, and CRISPR/Cas9

The discovery of microRNAs (miRNAs), as described in Section 1.9, led to an understanding of the complex molecular machinery that allows their processing from primary transcripts in the nucleus and their dispatch into the cytoplasm, where they inhibit the functioning of thousands of cellular mRNA species. At the same time, these discoveries enabled the development of novel experimental strategies in which exogenous miRNAs could be introduced into cells through the use of viral vectors or transfection, whereupon these introduced RNAs exploit the cellular miRNA-processing machinery to produce mimics of endogenously synthesized miRNAs; the mimics then proceed to shut down the operations of targeted mRNA species, partly by blocking translation and partly by driving the degradation of these mRNA molecules (**Figure S1.5A**). This ability to shut down the expression of proteins of expressed genes within cells has become an invaluable tool for cancer researchers who wish to demonstrate the essential role that one or another protein plays in a cell-biological process under study. One often used procedure is often termed gene “knockdown.”

Figure S1.5 Strategies for reducing or eliminating the expression of a gene
Two major strategies have been employed over the past decade in order to shut down the expression of a gene. (A) The process of gene "knockdown" achieved via RNA interference (RNAi) operates normally in cells to produce microRNAs (miRNAs) that suppress mRNA function, as described in Section 1.9 and Figure 1.18. This process can be exploited experimentally to suppress targeted mRNAs. Two major strategies can be used. In the first, a viral vector (in this case derived either from a retrovirus genome or from the genome of a retrovirus-related lentivirus vector; see **Supplementary Sidebar 3.6**) is constructed that uses an RNA polymerase III promoter to drive expression of a transcript that serves as precursor of an shRNA; this hybrid gene is inserted via recombinant DNA procedures into the DNA proviral genome of the viral vector. The resulting pre-shRNA is processed by the Dicer enzyme into an siRNA of 19–21 nucleotides, which is reduced to a single-stranded RNA (ssRNA). The ssRNA associates with the Argonaut protein (Ago2) and other proteins to form a RISC (RNA-induced

silencing complex), which anneals to partially homologous target sequences that are usually located in the 3′ untranslated region (3′ UTR) of certain mRNAs. This results either in the cleavage of the mRNA or inhibition of its translation (see Figure 1.18), blocking in both cases expression of the mRNA and thus the gene encoding this mRNA. Because the retroviral or lentiviral provirus is integrated into the cell chromosome and is transmitted heritably to the progeny of an initially infected cell, the expression of a targeted mRNA can be suppressed stably over many subsequent cell generations. As an alternative strategy, an siRNA of a particular configuration can be chemically synthesized and transfected directly into a cell (*not shown*). While this is easier than the procedure described above, the targeted mRNA will be suppressed only transiently, since there is no mechanism to ensure the continued synthesis of the siRNA in the descendants of the initially transfected cell. (B) The more recent CRISPR/Cas9 strategy yields gene "knockout," in that the targeted gene is cleaved in a fashion that yields a dsDNA break and usually the total inactivation of gene function. Thus, the broken DNA may be repaired by cellular repair enzymes albeit in a fashion that does not restore the reading frame of the targeted gene, resulting in gene inactivation. Alternatively, a "donor DNA" chosen by an investigator may be inserted into the cleaved DNA in a fashion that also employs cellular repair enzymes (see Chapter 12). Because gene knockdown, as described above, usually results in incomplete suppression of gene function, the newer CRISPR/Cas9 knockout technology and variants of it have increasingly been employed by cancer researchers to eliminate gene function, as will be discussed in more detail in Chapter 7.

For example, knockdown of the expression of a certain pro-apoptotic protein may protect a cell from apoptosis, demonstrating the essential role that the protein plays in orchestrating apoptosis in such a cell. Similarly, knockdown of the expression of a growth factor receptor may render a cell unresponsive to that factor, demonstrating the receptor's key role in conferring such responsiveness.

While highly useful in principle, in practice the application of this technique has proven challenging in the case of certain genes being targeted for knockdown. Thus, a targeted mRNA may not respond significantly, for reasons that are unclear, necessitating the screening of multiple vectors, each targeting a distinct nucleotide segment in the 3′ untranslated region of an mRNA under study; in some cases, four, five, or even six alternative siRNAs (small interfering RNAs) or shRNAs (small hairpin RNAs) must be tested before an experimenter discovers one that can reduce protein expression by 90% or more.

Independent of these difficulties in achieving significant knockdown is the opposite problem: some siRNAs and shRNAs have been found to affect far more mRNAs than their intended target—the phenomenon of "off-target effects." Off-target effects often

make it impossible to draw rigorous conclusions from the results of these experiments because of the confounding effects on other mRNAs and proteins operating in unrelated signaling pathways.

The newer CRISPR/Cas9 technology usually enables the total elimination of a gene's function (Figure S1.5B).

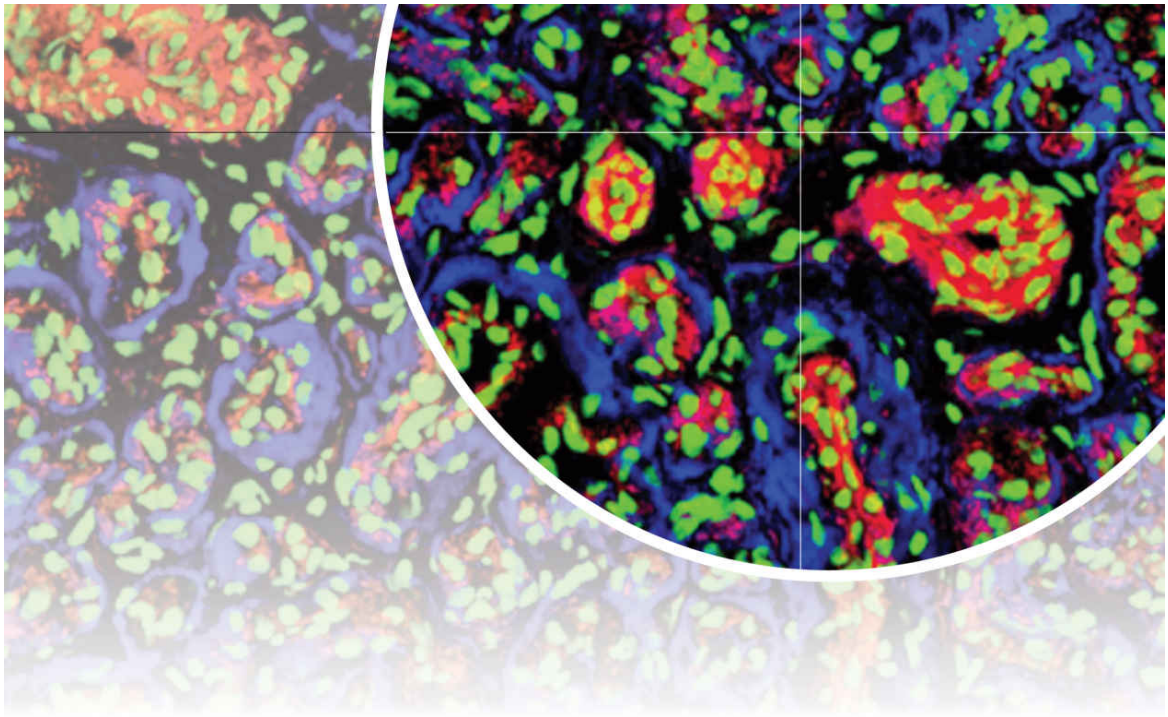
Chapter 2
The Nature of Cancer



A fluorescence microscopy image with blue, green, and red staining. The green spots are smaller and cover the intermixed red and blue streaks.

When I published the results of my experiments on the development of double-fertilized sea-urchin eggs in 1902, I added the suggestion that malignant tumors might be the result of a certain abnormal condition of the chromosomes, which may arise from multipolar mitosis. . . . So I have carried on for a long time the kind of experiments I suggested, which are so far without success, but my conviction remains unshaken.

Theodor Boveri, pathologist, 1914

Tumors destroy man in a unique and appalling way, as flesh of his own flesh which has somehow been rendered proliferative, rampant, predatory and ungovernable. They are the most concrete and formidable of human

> maladies, yet despite more than 70 years of experimental study they remain the least understood.
>
> Francis Peyton Rous, tumor virologist, Nobel lecture, 1966

The cellular organization of metazoan tissues has made possible the evolution of an extraordinary diversity of anatomical designs. Much of this plasticity in design can be traced to the fact that the building blocks of tissue and organ construction —individual cells—are endowed with great autonomy and versatility. Most types of cells in the metazoan body carry a complete organismic genome—far more information than any one of these cells will ever require. And many cells retain the ability to grow and divide long after organismic development has been completed. This retained ability to proliferate and to participate in tissue morphogenesis (the creation of shape) makes possible the maintenance of adult tissues throughout the life span of an organism. Such maintenance may involve the repair of wounds and the replacement of cells that have suffered attrition after extended periods of service.

At the same time, this versatility and autonomy pose a grave danger, in that individual cells within the organism may gain access to information in their genomes that is normally denied to them and assume roles that are inappropriate for normal tissue maintenance and function. Moreover, their genomic sequences are subject to corruption by various mechanisms that alter the structure and hence information content of the genome. The resulting mutated genes may divert cells into acquiring novel, often highly abnormal phenotypes. Such changes may be incompatible with the normally assigned roles of these cells in organismic structure and physiology. Among these inappropriate changes may be alterations in cellular proliferation programs, and these in turn can lead to the appearance of large populations of cells that no longer obey the rules governing normal tissue construction and maintenance.

When portrayed in this way, the renegade cells that form a tumor are the result of normal development gone awry. In spite of extraordinary safeguards taken by the organism to prevent their appearance, cancer cells somehow learn to thrive. Normal cells are carefully programmed to collaborate with one another in constructing the diverse tissues that make possible organismic survival. Cancer cells have a quite different and more focused agenda. They appear to be motivated by only one consideration: making more copies of themselves.

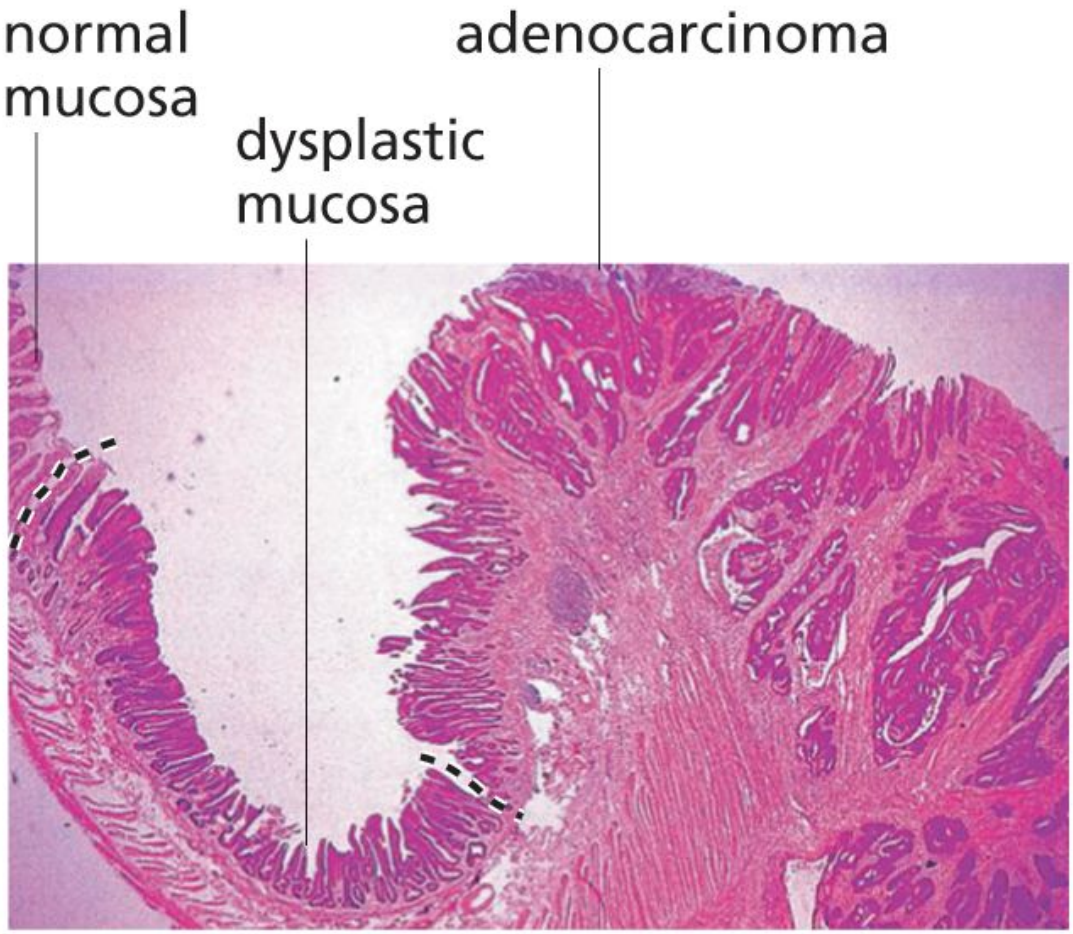
2.1 Tumors arise from normal tissues

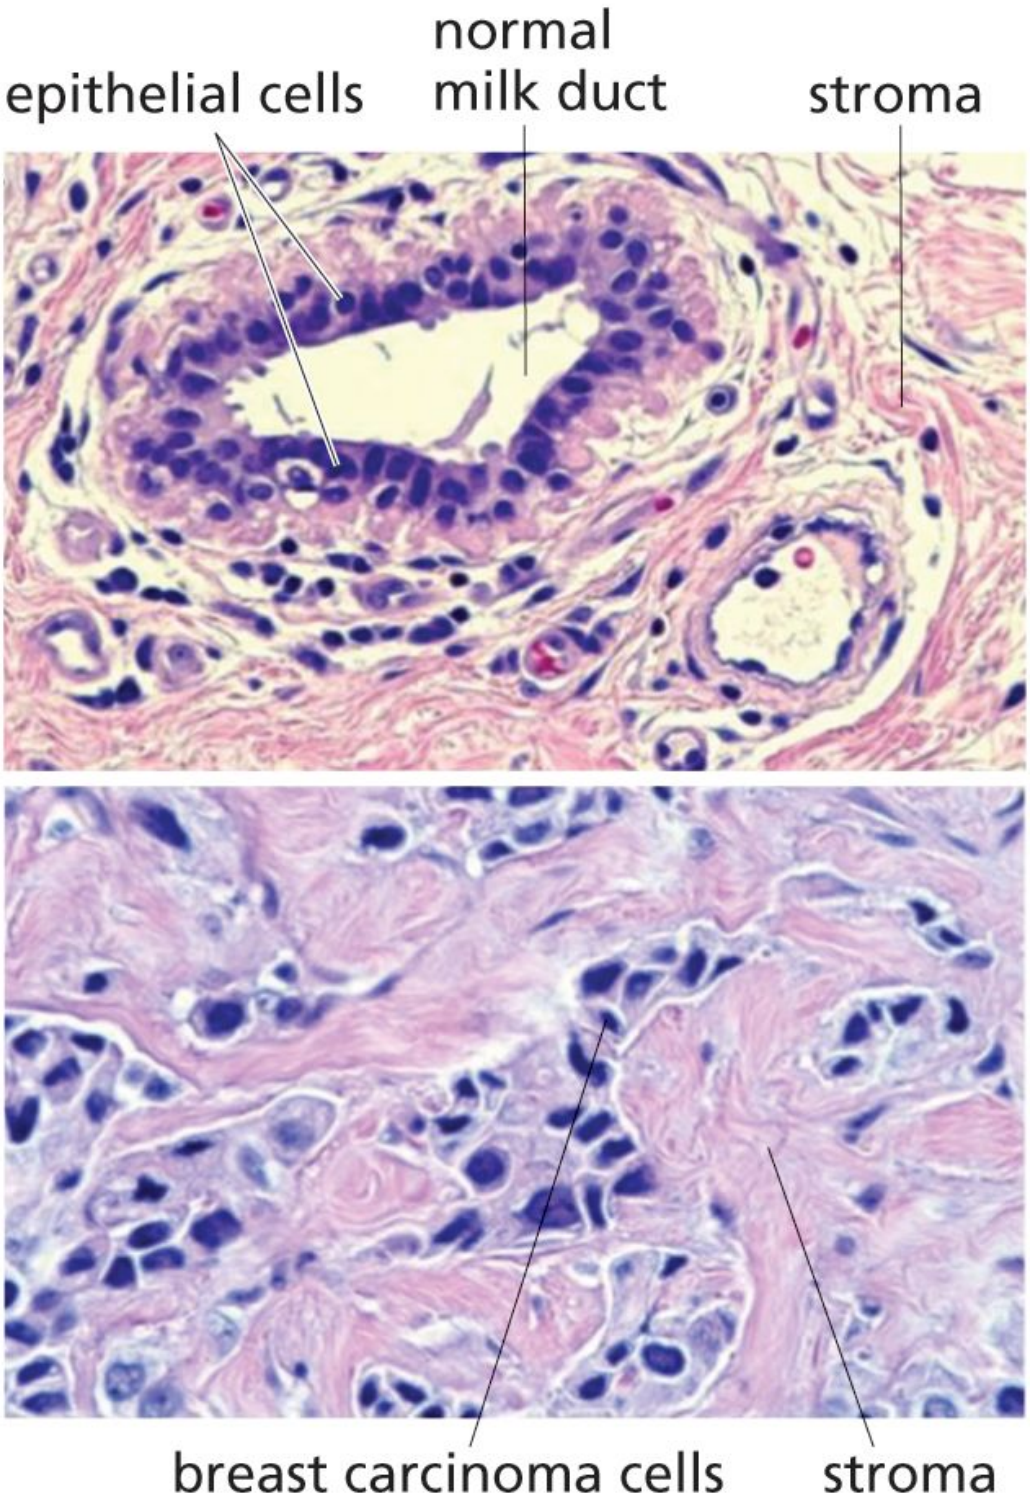
A confluence of discoveries in the mid- and late nineteenth century led to our current understanding of how tissues and complex organisms arise from fertilized eggs. The most fundamental of these was the discovery that all tissues are composed of cells and cell products, and that all cells arise through the division of preexisting cells. Taken together, these two revelations led to the deduction, so obvious to us now, that all the cells in the body of a complex organism are members of cell lineages that can be traced back to the fertilized egg. Conversely, the fertilized egg is able to spawn all the cells in the body, doing so through repeated cycles of cell growth and division.

These realizations had a profound impact on how tumors were perceived. Previously, many had portrayed tumors as foreign bodies that had somehow entered and taken root in an afflicted person. Now, tumors, like normal tissues, could be examined under the microscope by researchers in the then-new science of histology. These examinations of tissue sections (slices) revealed that tumors, like normal tissues, were composed of masses of cells (**Figure 2.1**). Contemporary cancer research makes frequent use of a variety of histological techniques; the most frequently used of these are illustrated in **Supplementary Sidebar 2.1**.



A cross section of cancerous small intestine, stained pink. On the far left is a section labeled normal mucosa. In the middle is a section labeled dysplastic mucosa. These two sections are relatively thin and uniform along their length. On the right is a section labeled adenocarcinoma. This section is greatly thickened, and the structure is more chaotic-looking.

(A)



Two specimens of mammary gland tissue. In the normal tissue, a milk duct is lined with epithelial cells, which appear dark due to the many dark purple nuclei. The duct structure is surrounded by lighter-colored tissue labeled stroma. In the cancerous tissue, cancerous epithelial cells with large, dark

purple nuclei run irregularly through stroma tissue. No well-defined duct structure is visible.
(B)

Figure 2.1 Normal versus neoplastic tissue (A) This histological section of the lining of the ileum in the small intestine, viewed at low magnification, reveals the continuity between normal and cancerous tissue. At the far left is the normal epithelial lining, the mucosa. In the middle is mucosal tissue that has become highly abnormal, or "dysplastic." To the right is an obvious tumor—an adenocarcinoma—which has begun to invade underlying tissues. (B) This pair of sections, viewed at high magnification, shows how normal tissue architecture becomes deranged in tumors. In the normal human mammary gland (*upper panel*), a milk duct is lined by epithelial cells (*dark purple nuclei*). The ducts are surrounded by mesenchymal tissue (termed "stroma"), which consists of connective tissue cells, such as fibroblasts and adipocytes, and collagen matrix (*pink*). In an invasive ductal breast carcinoma (*lower panel*), the cancer cells, which arise from the epithelial cells lining the normal ducts, exhibit abnormally large nuclei (*purple*), no longer form well-structured ducts, and have invaded the stroma (*pink*). (A, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier. B, Courtesy of A. Orimo.)

Evidence accumulated that tumors of various types, rather than invading the body from the outside world, often derive directly from the normal tissues in which they are first discovered (see Figure 2.1A). However, certain tumors did seem to be capable of moving within the confines of the human body: in many patients, multiple tumors were discovered at anatomical sites quite distant from where their disease first began, a consequence of the tendency of cancers to spread throughout the body and to establish new colonies of cancer cells (**Figure 2.2**). These new settlements, termed metastases, were often traceable directly back to the site where the disease of cancer had begun—the founding or primary tumor.

A cancerous liver, sectioned to show many cauliflower-like tumors within the dark liver tissue.

(A)

A brain hemisphere infiltrated by cancer. Multiple white nodules of varying size, which look like lumps of fatty tissue, protrude from the surface.

(B)

Figure 2.2 Metastasis of cancer cells to distant sites Many types of tumors eventually release cancer cells that migrate to distant sites in the body, where they form the secondary tumors known as metastases. (A) Metastases (*white*) in the liver often arise in patients with advanced colon carcinomas. The portal vein, which drains blood from the colon into the liver, provides a route for metastasizing colon cancer cells to migrate directly into the liver, where they are trapped in large numbers in microvessels. (B) Breast cancer often metastasizes to the brain. Here, large metastases are revealed post mortem in the right side of a brain where the dura (membrane covering; shown intact at *right*) of the brain has been removed. (A, courtesy of Peter Isaacson. B, from H. Okazaki and B.W. Scheithauer, Atlas of Neuropathology. New York: Gower Medical Publishing, 1988. With permission of Mayo Foundation for Medical Education and Research.)

Invariably, detailed examination of the organization of cells within tumor masses gave evidence of a tissue architecture that was less organized than the architecture of nearby normal tissues (see Figure 2.1). These histopathological comparisons provided the first seeds of an idea that would take the greater part of the twentieth century to prove: tumors are composed of cells that have lost the ability to assemble and create tissues of normal form and function. Stated more simply, cancer came to be viewed as a disease of malfunctioning cells, and all of the properties of individual tumors must derive, directly or indirectly, from the behavior of the cancerous cells within such tumors.

While the microarchitecture of tumors differed in obvious ways from that of normal tissue, tumors nevertheless exhibited certain histological features that resembled those of normal tissue. This suggested that all tumors should, in principle, be traceable back to the specific tissue or organ site in which they first arose, using the histopathological analyses of tumor sections to provide critical clues. This simple idea led to a new way of classifying these growths, which depended on their presumed tissues of origin. The resulting classifications often united under one roof cancers that arise in tissues and organs that have radically different functions in the body but share common types of tissue organization.

The science of histopathology also made it possible to understand the relationship between the clinical behavior of a tumor (that is, the effects that the tumor had on the patient's body) and its microscopic features. Most important here were the criteria that segregated tumors into two broad categories depending on their degree of aggressive growth. Those that grew locally without invading adjacent tissues were classified as benign, while others that invaded nearby tissues and possibly spawned metastases were termed malignant.

In fact, the great majority of primary tumors arising in humans are benign and are harmless to their hosts, except in the rare cases where the expansion of these localized

masses causes them to press on vital organs or tissues. Some benign tumors, however, may cause clinical problems because they release dangerously high levels of hormones that create physiologic imbalances in the body. For example, thyroid adenomas (premalignant epithelial growths) may cause excessive release of thyroid hormone into the circulation, leading to hyperthyroidism; pituitary adenomas may release growth hormone into the circulation, causing excessive growth of certain tissues—a condition known as acromegaly. Nonetheless, deaths caused by benign tumors are relatively uncommon. The vast majority of cancer-related mortality derives from malignant tumors. More specifically, it is the metastases spawned by these tumors that are responsible for some 90% of deaths from cancer.

Glossary

histology
: Study of tissue structure at the microscopic level. *See also* **histopathology**.

histopathology
: Study of tissue structure at the microscopic level, often with reference to abnormal tissue. *See also* **pathology**.

section
: A slice, e.g., through a tissue.

primary tumor
: Tumor growing at the anatomical site where tumor formation began and proceeded to yield this mass. *See also* **metastasis**.

benign
: (1) Describing a growth that is confined to a specific site within a tissue and gives no evidence of invading adjacent tissue. (2) Referring to an epithelial growth that has not penetrated through the basement membrane.

malignant
: Describing a growth that shows evidence of being locally invasive and possibly even metastatic.

adenoma
: (adj., **- omatous**) Any of a series of premalignant, noninvasive growths in various epithelial tissues, many of which have the potential to progress further to carcinomas. *See also* **polyp**.

hyperthyroidism
: Condition in which the thyroid gland releases inappropriately high levels of thyroid hormone into the circulation, leading to an elevated metabolic rate and multiple secondary effects on the body.

acromegaly
: Pathological condition of excessive growth of certain tissues, notably the hands, feet, and face, usually due to the elaboration of excessive growth hormone by a pituitary tumor.

metastasis
: (pl., **- es**; adj., **metastatic**; v. **metastasize**) A neoplastic growth forming at one site in the body, the cells of which derive from a

malignancy located elsewhere in the body, such as the site of primary tumor formation. (2) The process leading to the formation of metastases. *See also* **primary tumor**.

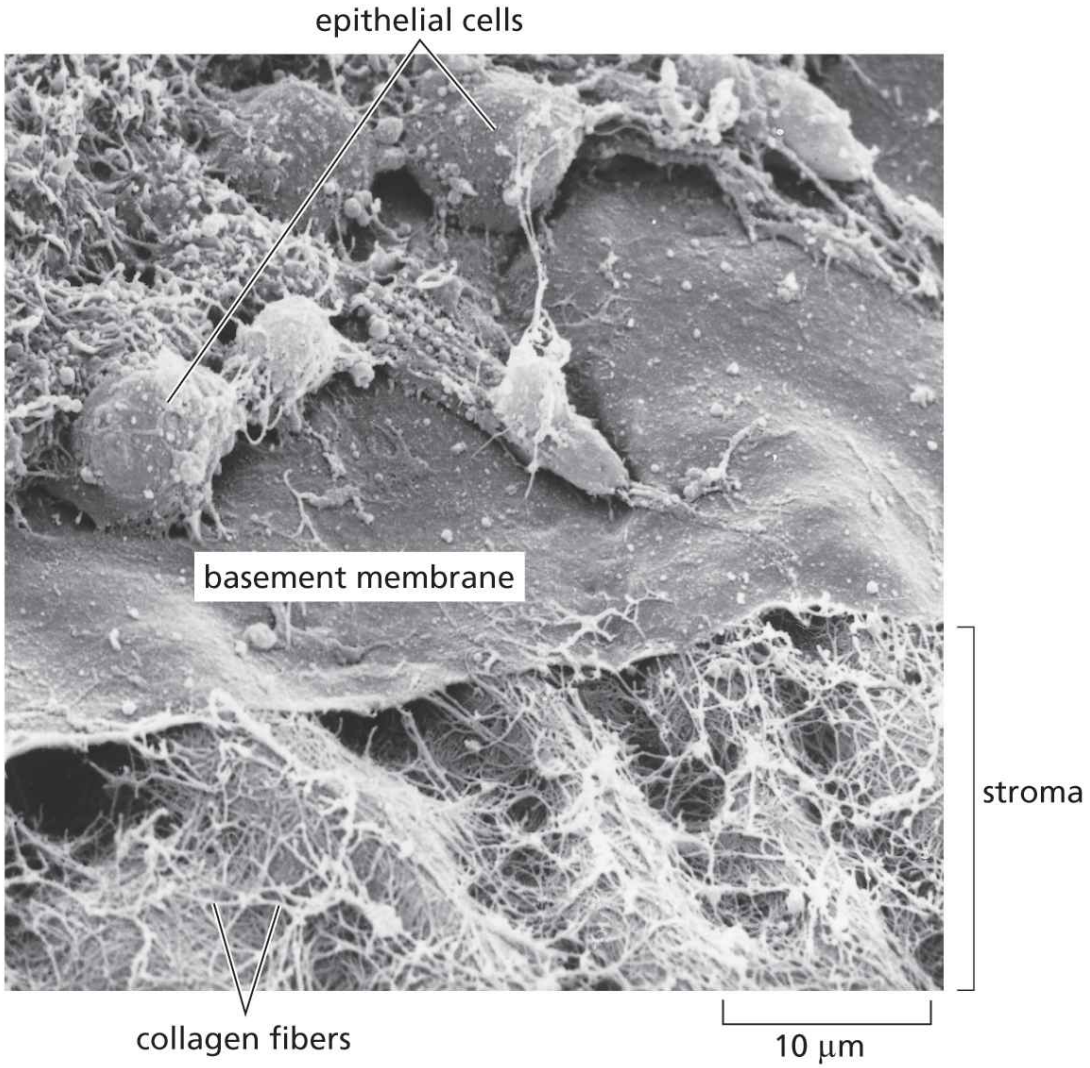
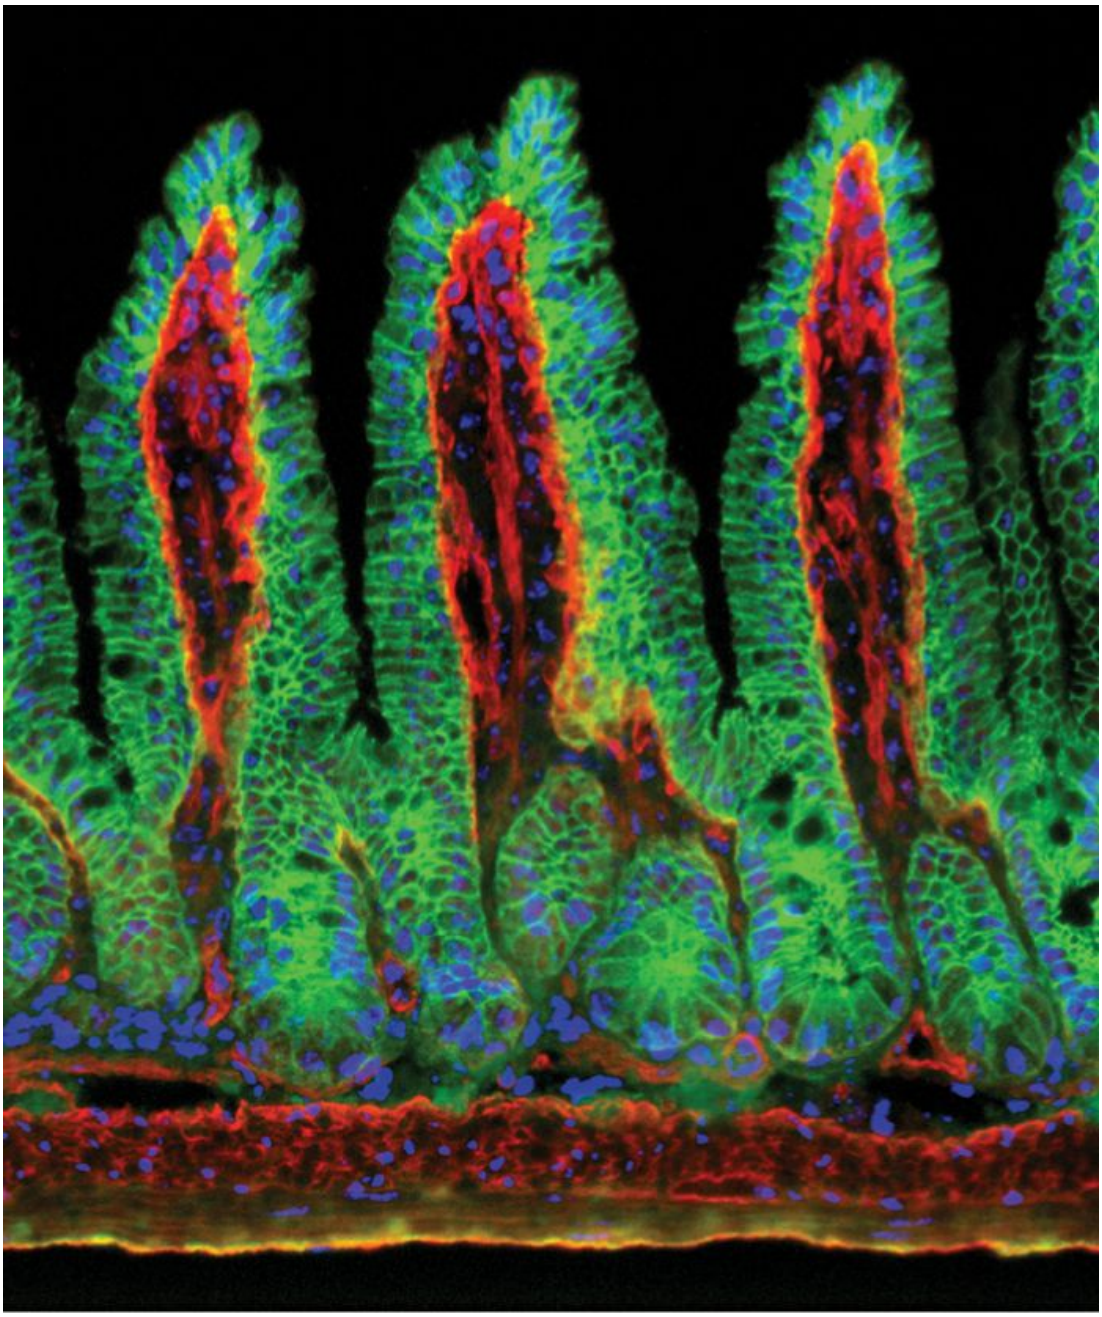
2.2 Tumors arise from many specialized cell types throughout the body

The majority of human tumors arise from epithelial tissues. Epithelia are sheets of cells that line the walls of cavities and channels or, in the case of skin, serve as the outside protective covering of the body. By the first decades of the twentieth century, detailed histological analyses had revealed that normal tissues containing epithelia are all structured similarly. Thus, beneath the epithelial cell layers in each of these tissues lies a basement membrane (sometimes called a basal lamina); it separates the epithelial cells from the underlying layer of supporting connective tissue cells, termed the stroma (**Figure 2.3**).



A black-and-white electron micrograph representing a section of tissue about 50 microns wide. An undulating surface labeled basement membrane lies over stroma tissue that is crisscrossed by a dense, irregular network of collagen fibers. Nodules lying on top of the basement membrane are labeled epithelial cells.

(A)



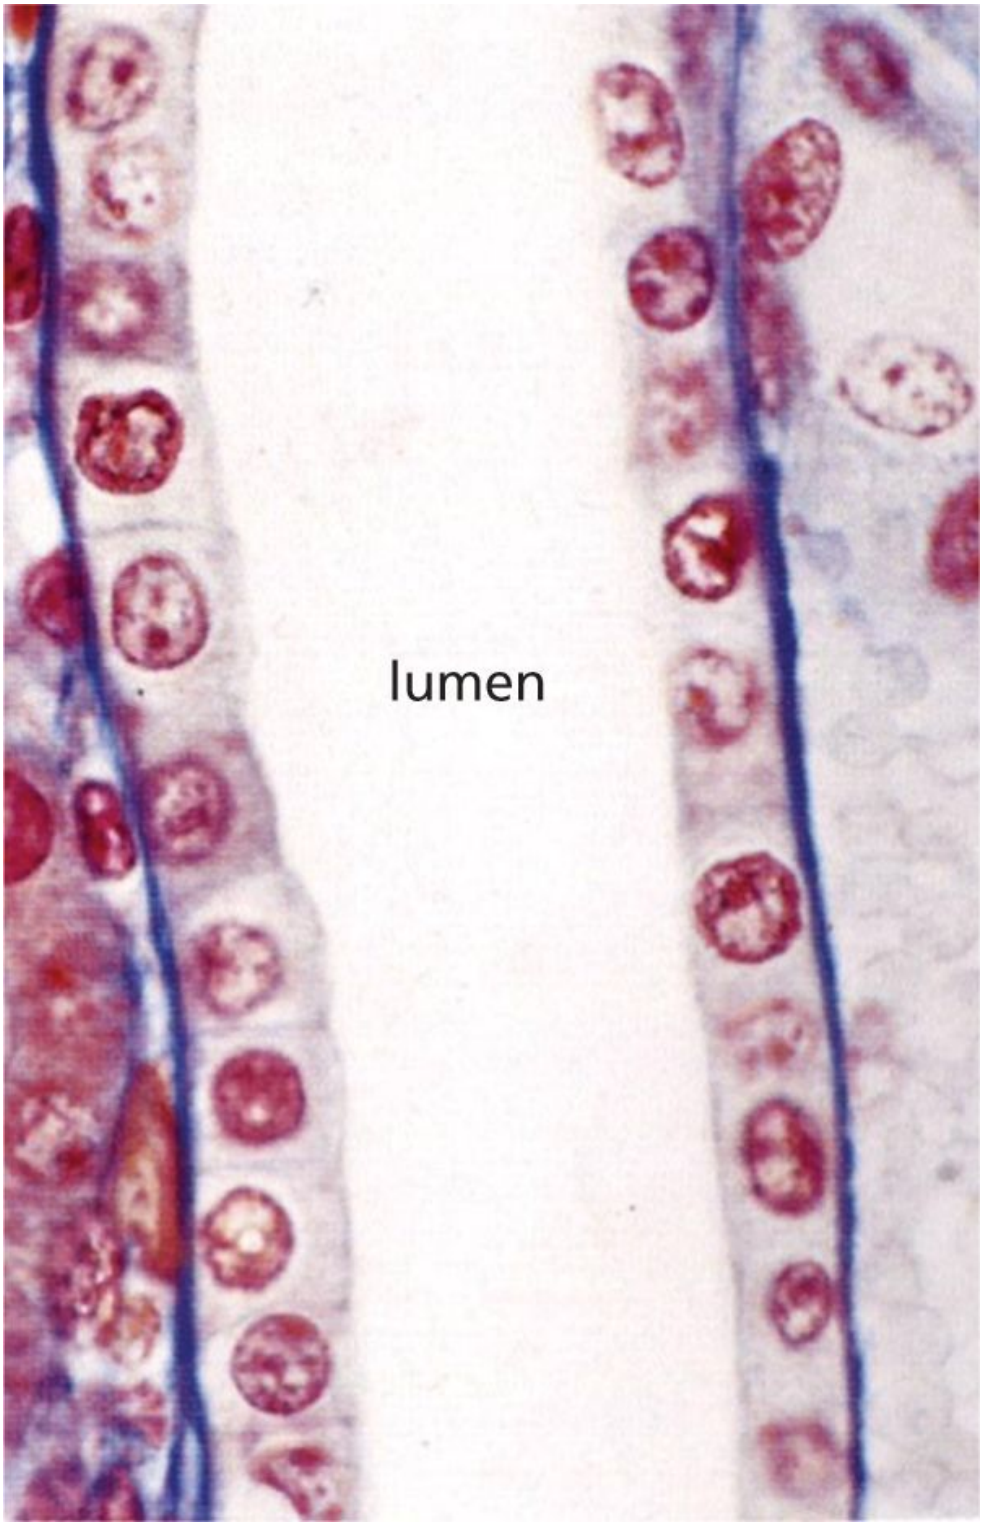
A brightly colored image of three columnar structures, part of a longer row. Each looks like a tall, thin sea sponge, blue-green in color but with a dark core and a bright red layer forming the outer skin of the core. Densely packed green tendril-like villi extend out from the core. These structures are attached at the base to a continuous horizontal structure.

(B)

Figure 2.3 Basement membranes (A) This scanning electron micrograph of a chick corneal epithelium illustrates the basic plan of epithelial tissues, in which epithelial cells are tethered to one side of the basement membrane, sometimes termed the “basal lamina.” Seen here as a continuous sheet, it is formed as a meshwork of extracellular matrix proteins. A network of collagen fibers anchors the underside of the basement membrane to the extracellular matrix (ECM) of the stroma. (B) While basement membranes cannot be detected using conventional staining techniques, use of immunofluorescence with an antibody against a basement membrane protein—in this case laminin 5 (*red*)—allows its visualization. Epithelial cells coating the villi of mouse small intestine have been stained with an antibody against E-cadherin (*green*), while all cell nuclei are stained *blue*. Here the convoluted basement membrane separates the outer villus layer of epithelial cells, termed enterocytes, from the mesenchymal cells forming the core of each villus (*not stained*). [A, courtesy of Robert Trelstad. B, from Z.X. Mahoney et al., *J. Cell Sci.* 121:2493–2502, 2008 (cover image). With permission from the authors.]

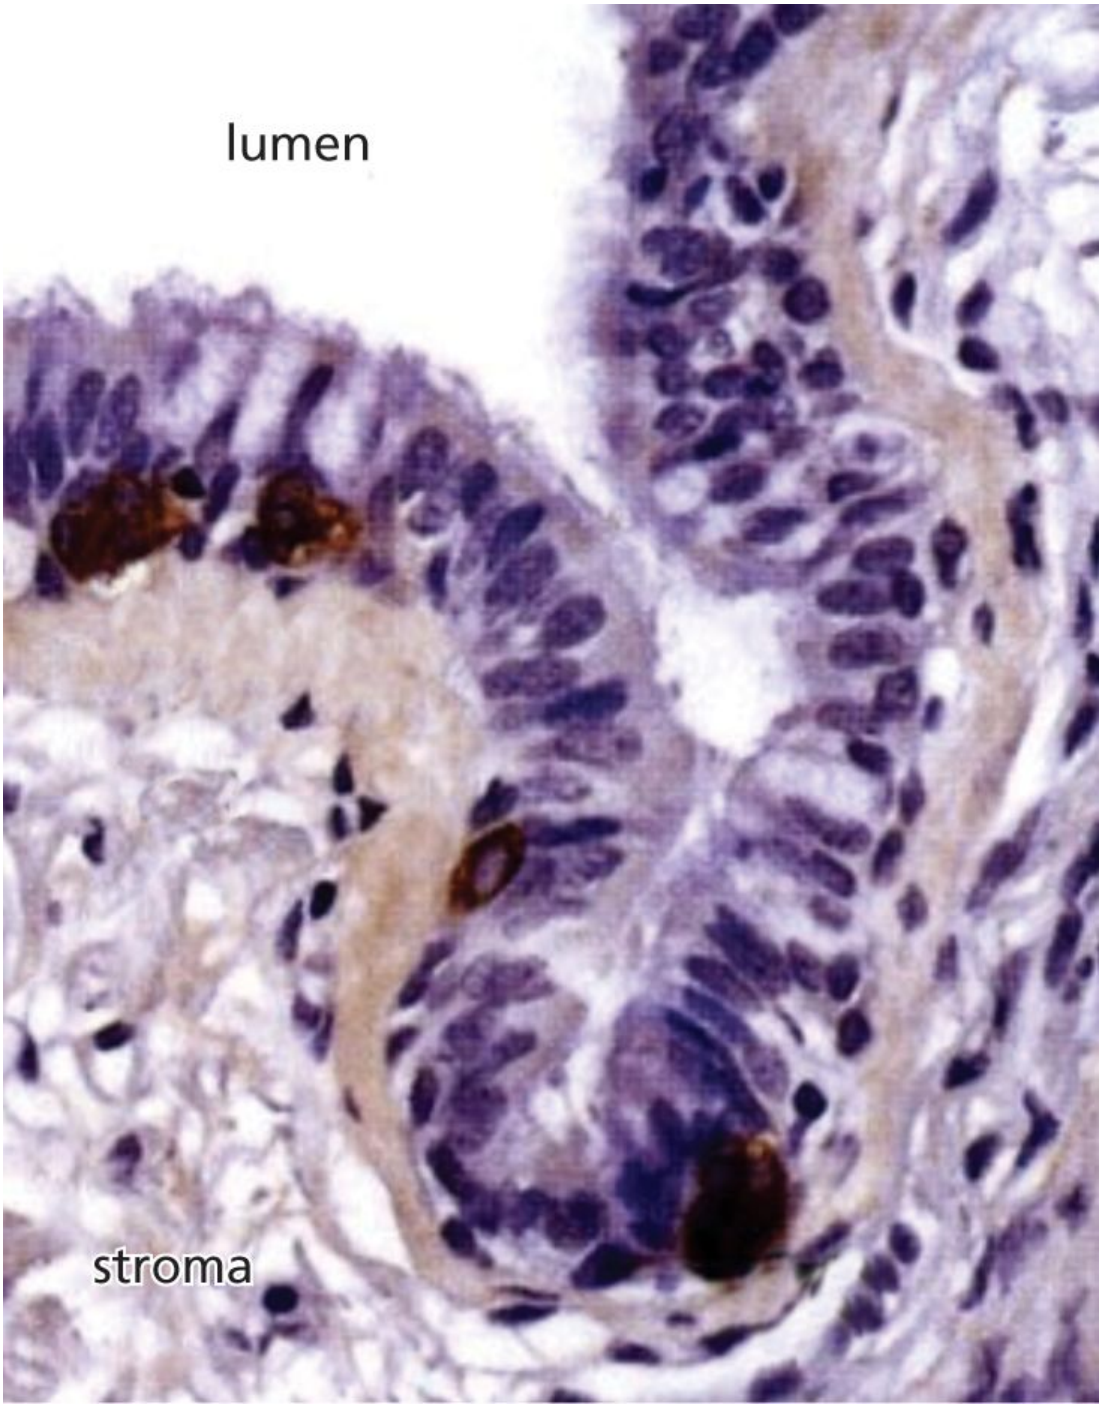
The basement membrane is a specialized type of extracellular matrix (ECM) and is assembled from proteins secreted largely by the epithelial cells. Another type of basement membrane separates endothelial cells, which form the inner linings of capillaries and larger vessels, from an outer layer of specialized smooth muscle cells. In all cases, these basement membranes serve as a structural scaffolding of the tissue. In addition, as we will learn later, cells attach a variety of biologically active signaling molecules to both the ECM and basement membrane; such molecules, including the growth factors to be described in Chapter 5, are then liberated later to stimulate epithelial cell proliferation.

Epithelia are of special interest here, because they spawn the most common human cancers—the carcinomas. These tumors are responsible for more than 80% of the cancer-related deaths in the Western world. Included among the carcinomas are tumors arising from the epithelial cell layers of the gastrointestinal tract—which includes mouth, esophagus, stomach, and small and large intestines—as well as the skin, mammary gland, pancreas, lung, liver, ovary, uterus, prostate, gallbladder, and urinary bladder. Examples of normal epithelial tissues are presented in **Figure 2.4**.



A columnar cavity, labeled lumen, surrounded by a sheath of tissue one cell thick. Each cell in the sheath appears generally square and has a red-stained nucleus.

(A)

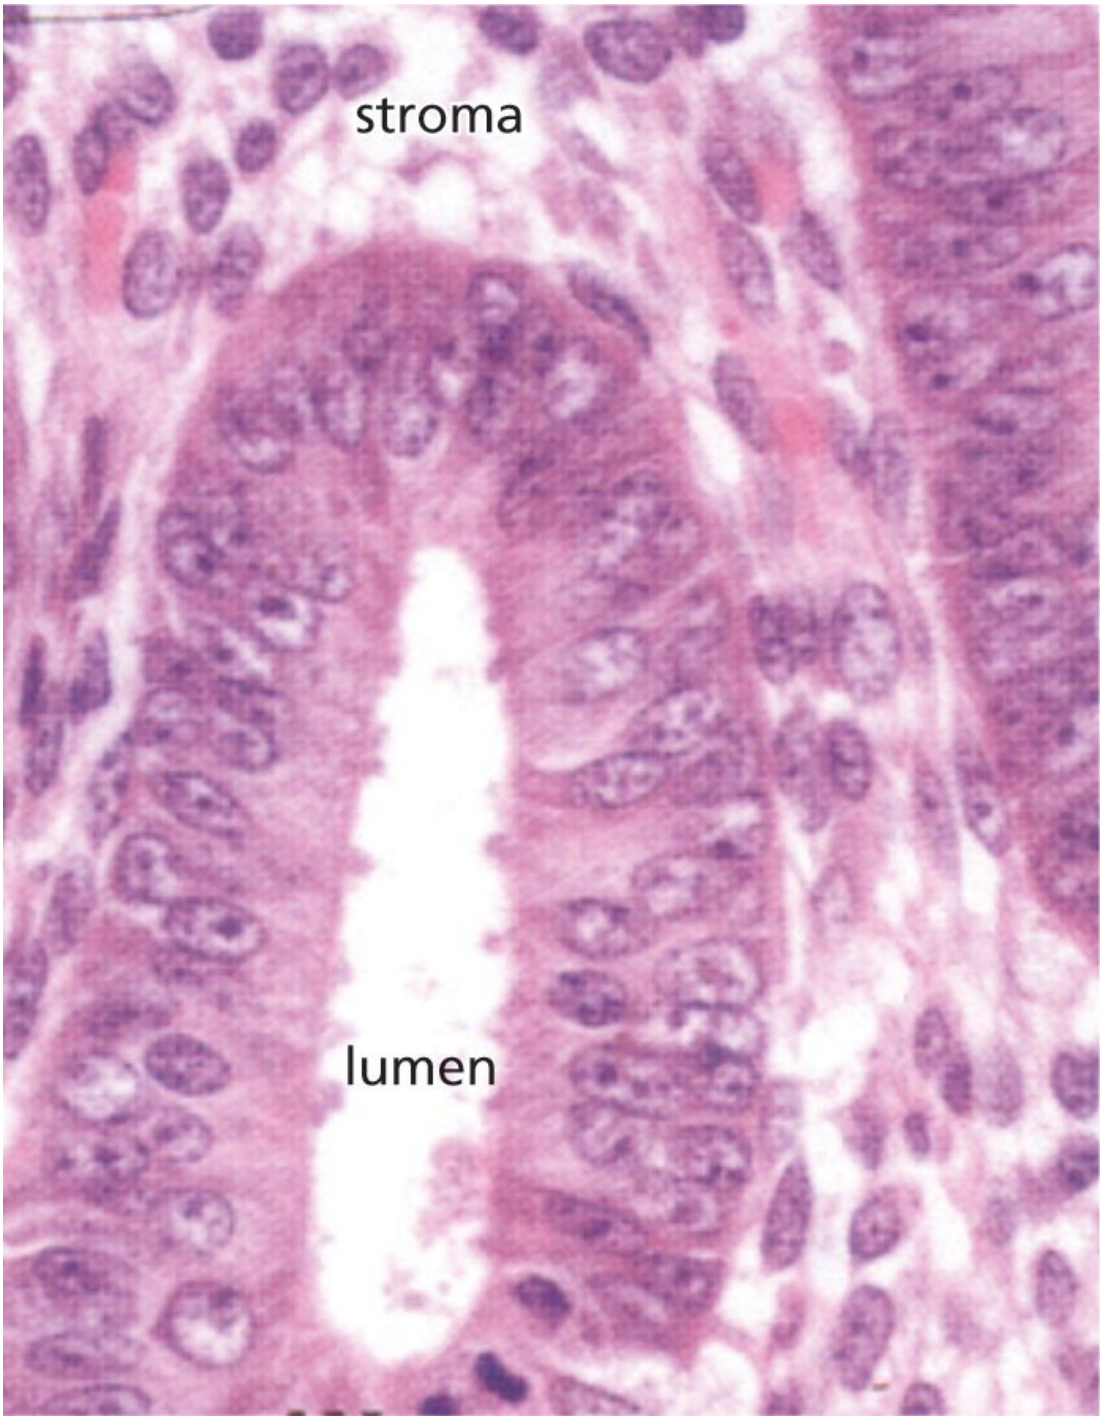


An irregular cavity, labeled lumen, surrounded by a layer of tissue consisting of densely packed cells. Each cell in this layer is stained purple with a dark purple nucleus. The surrounding lighter tissue is labeled stroma.

(B)

An extreme close-up of a pancake-like stack of cells stained pink, each with one dark pink nucleus. These cells separate more irregular tissue on the left from a cavity labeled lumen on the right.

(C)



An elongated oval cavity labeled lumen, surrounded by a ring of dark pink cells, surrounded by lighter tissue.

(D)

Figure 2.4 Architecture of epithelial tissues A common organizational plan describes most of the epithelial tissues in the body: The mature, differentiated epithelial cells are at the exposed surface of an epithelium. In many tissues, underlying these epithelia are less differentiated epithelial cells, not seen in this figure. Beneath the epithelial cell layer lies a basement membrane (see Figure 2.3), which is usually difficult to visualize in the light microscope. Shown here are epithelia of (A) a collecting tubule of the kidney, (B) a bronchiole of the lung with its thickened basement membrane, (C) the columnar epithelium of the gallbladder, and (D) the endometrium of the uterus. In each case, the epithelial cells protect the underlying tissue from the contents of the lumen (cavity) that they are lining. Panel C illustrates another property that is characteristic of the epithelial cells forming an epithelium: the state of apico-basal polarity, in which individual epithelial cells are organized to present their apical surface toward the lumen (*right*) and their basal surface toward the underlying basement membrane. (The side-by-side lateral interactions between adjacent epithelial cells are often included together with the basal surface to constitute the actions of the basolateral domain.) This polarization involves the asymmetric localization of the nuclei, which are more basally located, along with hundreds of cell surface (and associated cytoskeletal) proteins (*not shown*) that are specifically localized either to the apical, basal, or lateral surface of these cells. Moreover, the lateral surfaces of the epithelial cells establish several distinct types of junctions with their adjacent epithelial neighbors that bind together the epithelial cell sheet. (A, B, and D, from B. Young et al., Wheater's Functional Histology, 5th ed. Edinburgh: Churchill Livingstone, 2006. With permission from Elsevier. C, Jose Luis Calvo/Shutterstock.)

This group of tissues encompasses cell types that arise from all three of the primitive cell layers in the early vertebrate embryo. Thus, the epithelia of the lungs, liver, gallbladder, pancreas, esophagus, stomach, and intestines all derive from the inner cell layer, the endoderm. Skin arises from the outer embryonic cell layer, termed the ectoderm, while the ovaries originate embryologically from the middle layer, the mesoderm (**Supplementary Sidebar 2.2**). Therefore, in the case of carcinomas, histopathological classification is not informed by the early developmental history of the tissue of origin.

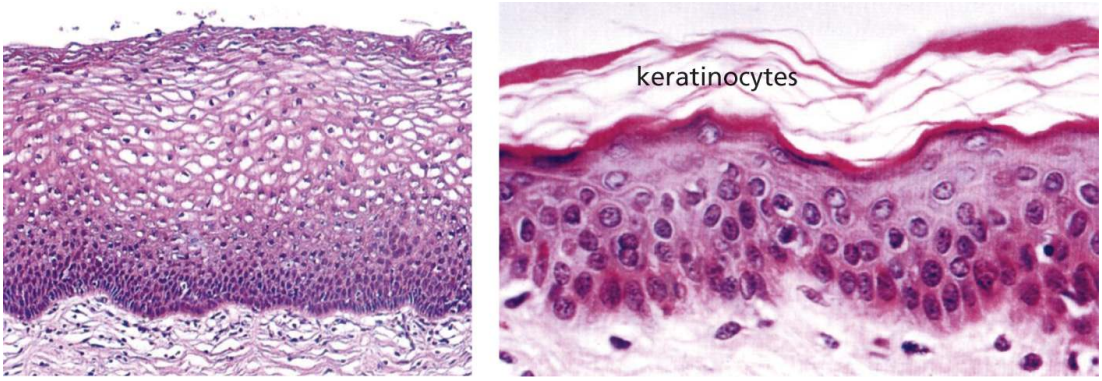
The epithelial and stromal cells of these various tissues collaborate in forming and maintaining the epithelial sheets. When viewed from the perspective of evolution, it now seems that the embryologic mechanisms for organizing and structuring epithelial tissues were invented early in metazoan evolution, likely more than 600 million years ago, and that these structural principles have been applied time and again during metazoan evolution to construct tissues and organs having a wide array of physiologic functions.

Most carcinomas fall into two major categories that reflect the two major biological functions associated with epithelia (**Table 2.1**). Some epithelial sheets serve largely to seal the cavity or channel that they line and to protect the underlying cell populations (**Figure 2.5**). Tumors that arise from epithelial cells forming these protective cell layers are termed squamous cell carcinomas. For example, the epithelial cells lining the skin (keratinocytes) and most of the oral cavity spawn tumors of this type.

Table 2.1 Carcinomas

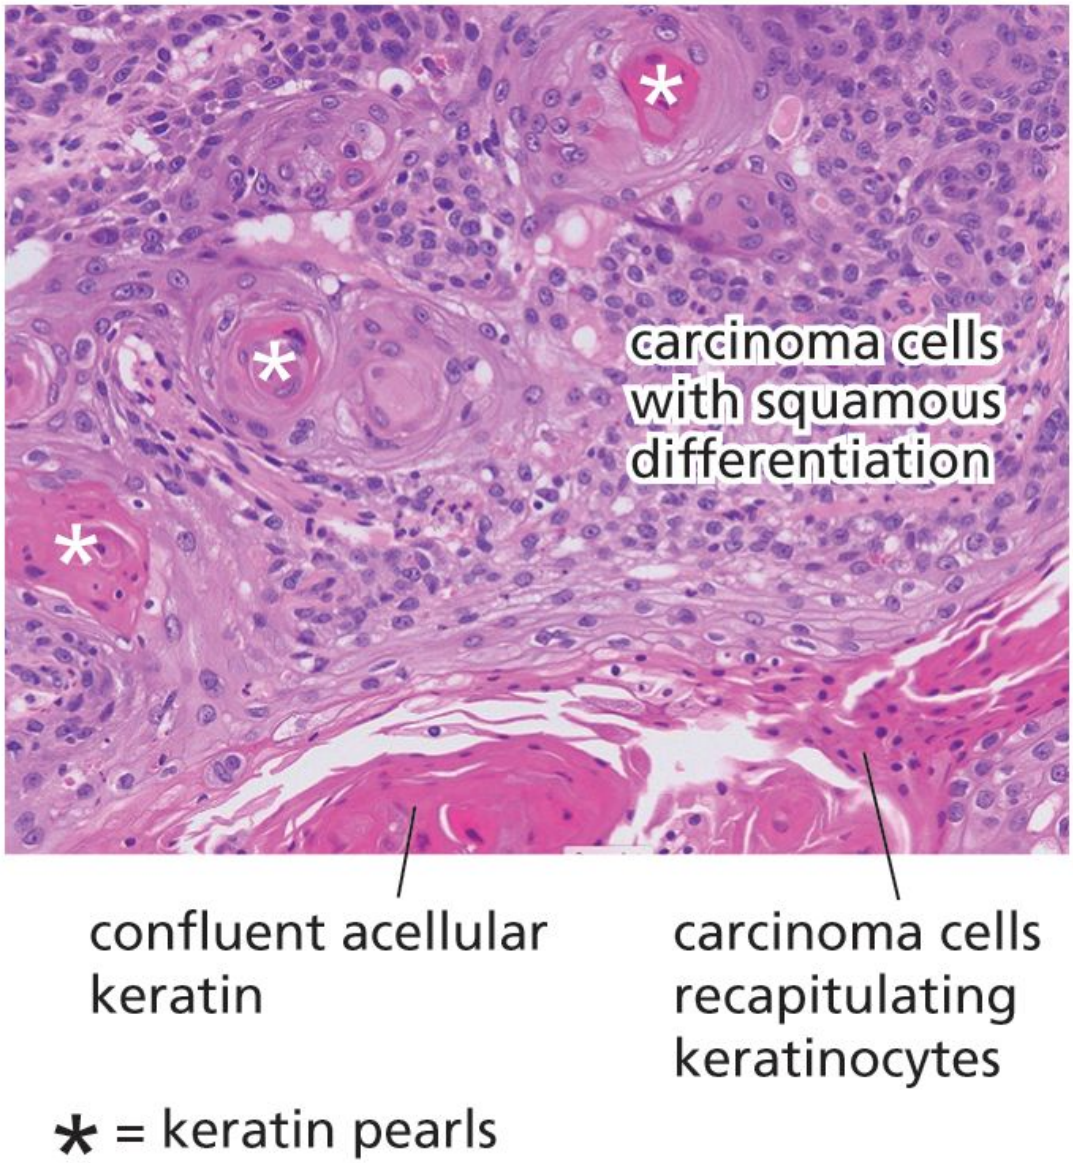
Tissue sites of more common types of adenocarcinoma
lung colon breast pancreas stomach esophagus prostate endometrium ovary
Tissue sites of more common types of squamous cell carcinoma
skin nasal cavity oropharynx larynx lung

Tissue sites of more common types of adenocarcinoma
esophagus cervix
Other types of carcinoma
small-cell lung carcinoma large-cell lung carcinoma hepatocellular carcinoma renal cell carcinoma transitional-cell carcinoma (of urinary bladder)



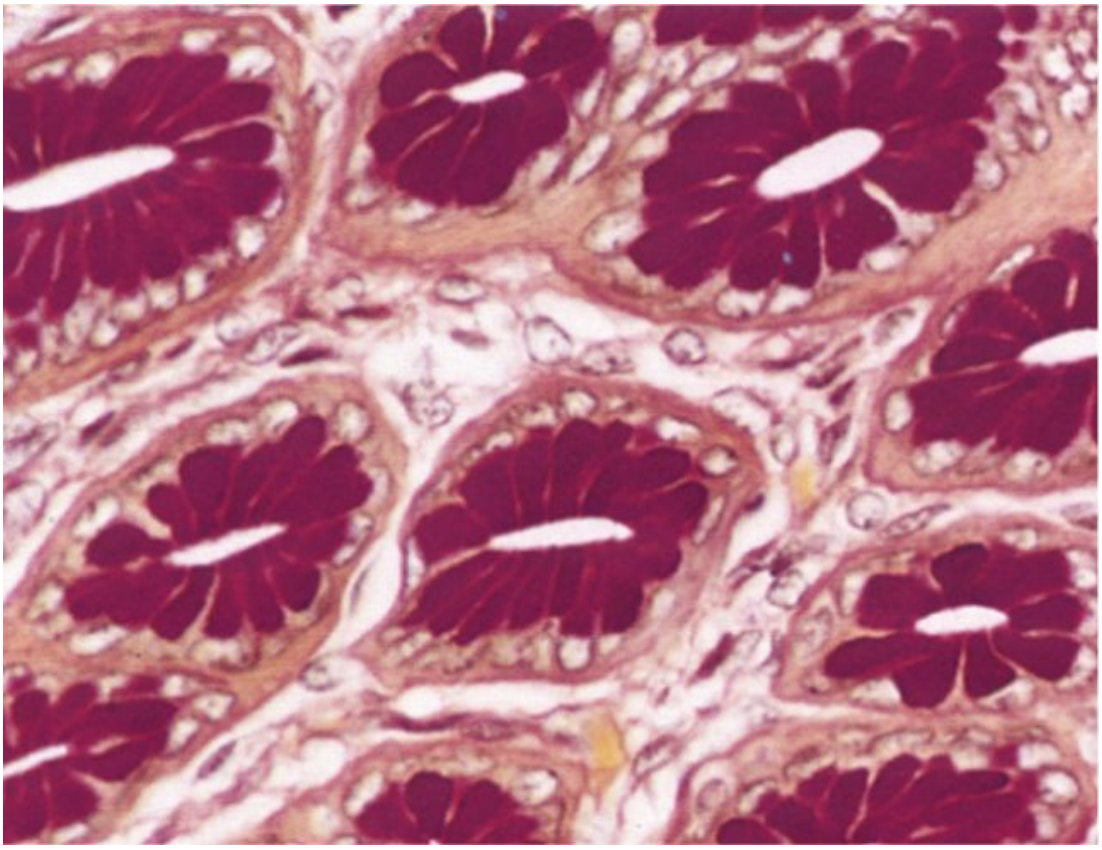
Two samples of normal squamous cell tissue layers. In the first sample, the layer is many cells thick. Toward the bottom of the layer, the cells are densely packed and somewhat elongated vertically. Toward the top, the cells are more loosely packed and somewhat elongated horizontally. In the second sample, the layer is only a few cells thick, but again the cells are more loosely packed at the top and less vertically elongated. There is also a layer of horizontally elongated cells on top, labeled keratinocytes. These cells have no nuclei.

(A)



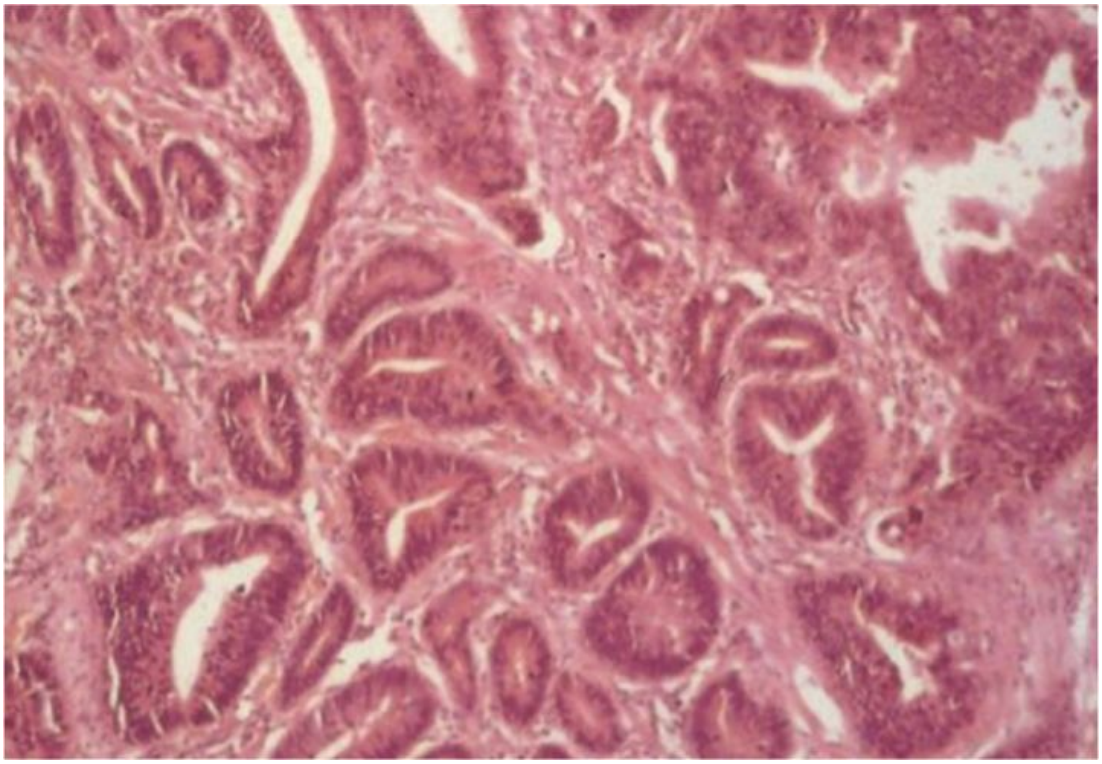
Cancerous squamous cells. The cells have no overall orientation pattern, and there are three round keratin pearls that appear as pink nodules within the purple-stained normal cells. Near the bottom of the image, there is a large pink, lumpy tissue labeled confluent acellular keratin, and within it there are carcinoma cells recapitulating keratinocytes.

(B)



A sample of normal stomach lining tissue. Seven or eight lumina appear as white ovals, surrounded by deep red cells to give the appearance of a blood-red daisy with a white center. The appearance is fairly regular from one lumen to the next.

(C)



A sample of cancerous stomach tissue. Many lumina appear as irregular or greatly elongated white shapes, surrounded by dark cells. The lumina vary greatly in size and shape from one lumen to the next.

(D)

Figure 2.5 Epithelia and derived carcinomas Epithelia can be classified into subtypes depending on their normal shape and function and on the carcinomas arising from them. Two major subtypes and their respective derived carcinomas—squamous cell carcinomas and adenocarcinomas—are seen here. Squamous cell carcinomas derive from normal squamous epithelial cells whereas adenocarcinomas derive from epithelial cells with secretory function. (A) Normal squamous cells are often flattened and function to protect the epithelium and underlying tissue from the contents of the lumen or, in the case of skin, from the outside world. The squamous epithelia of the cervix of the uterus (*left*) and the skin (*right*) are organized quite similarly, with mature flattened cells at the surface being continually shed (for example, the dead keratinocytes of the skin) and replaced by less differentiated cells that move upward and proceed to differentiate. (B) Keratin pearl formation is a characteristic feature among a malignant tumor cell population that shows squamous differentiation. Confluent areas of accumulation of acellular keratin (*white asterisk*) and tumor cells recapitulating the appearance of normal keratinocytes are common in addition to large numbers of carcinoma cells exhibiting a morphology characteristic of squamous cell

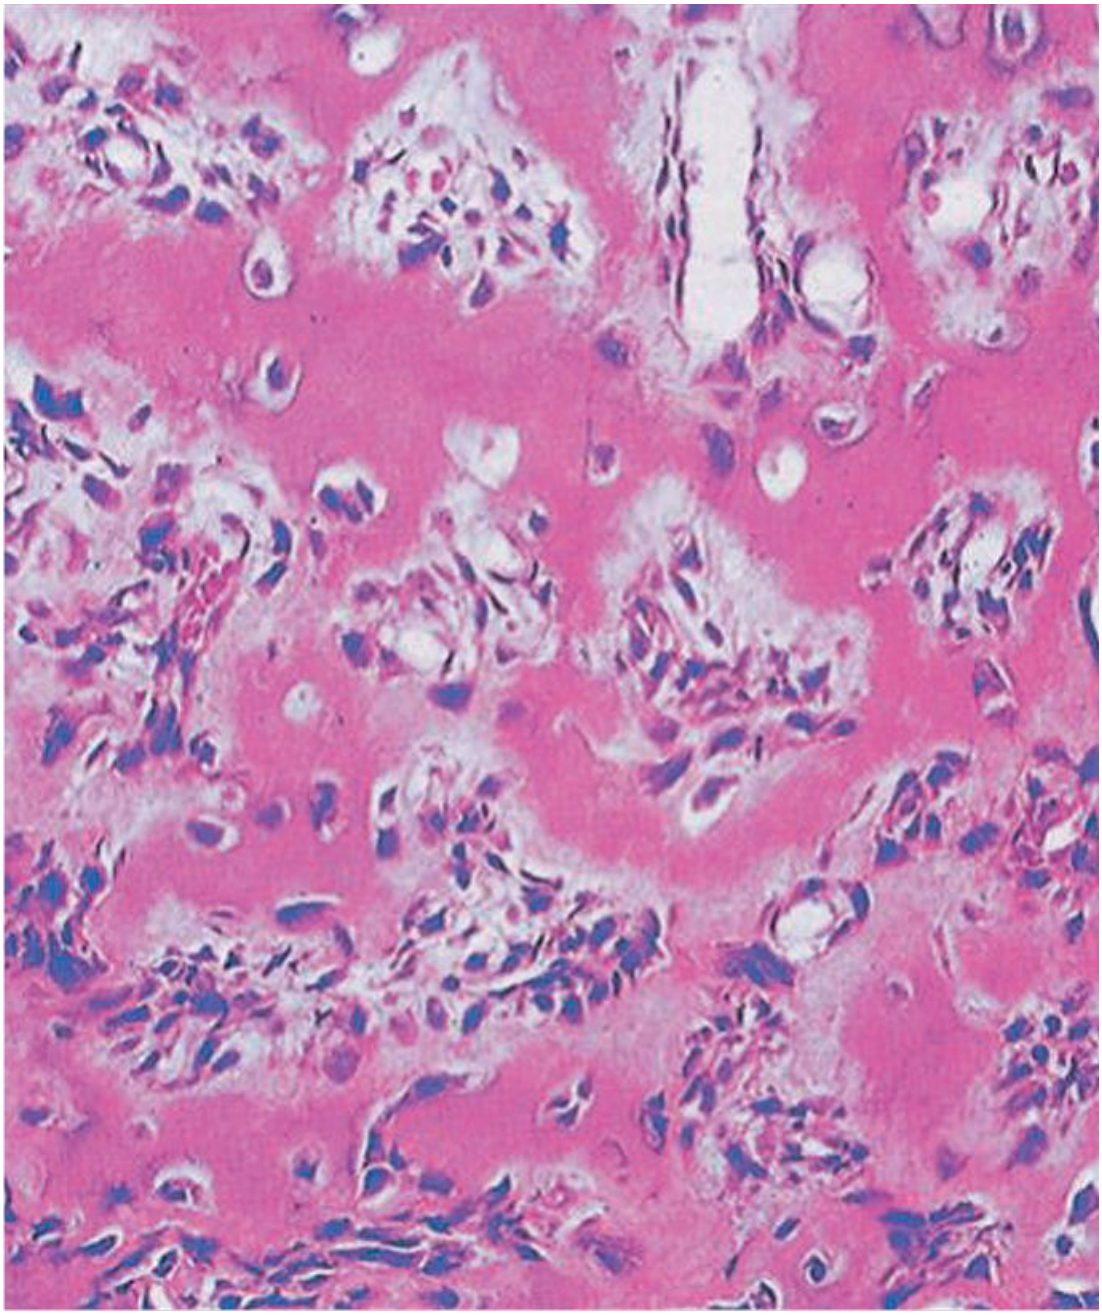
carcinomas. (C) In some tissues, the glandular cells within epithelia secrete mucopolysaccharides to protect the epithelium; in other tissues, they secrete proteins that function within the lumina (cavities) of ducts or are distributed to distant sites in the body. Pits in the stomach wall are lined by mucus-secreting cells (*dark red*). (D) This adenocarcinoma of the stomach shows multiple ductal elements, which are clear indications of its derivation from secretory epithelia such as those in panel C. (A and C, from B. Young et al., Wheater's Functional Histology, 5th ed. Edinburgh: Churchill Livingstone, 2006. With permission from Elsevier. B, Dr. Vickle Young Jo. D, from A.T. Skarin, Atlas of Diagnostic Oncology, 3rd ed. Philadelphia: Elsevier Science Ltd., 2003. With permission from Elsevier.)

Many epithelia also contain specialized cells that secrete substances into the ducts or cavities that they line. This class of epithelial cells generates adenocarcinomas. Often these secreted products are used to protect the epithelial cell layers from the contents of the cavities (lumina) that they surround (see Figure 2.5). Thus, some epithelial cells lining the lung and stomach secrete mucus layers that protect them, respectively, from the air (and airborne particles) and from the corrosive effects of high concentrations of acid. The epithelia in some organs, such as the lung, uterus, and cervix, have the capacity to give rise to pure adenocarcinomas or pure squamous cell carcinomas; quite frequently, however, tumors in these organs are found in which both types of carcinoma cells coexist.

The remainder of malignant tumors arise from nonepithelial tissues throughout the body. The first major class of nonepithelial cancers derive from the various connective tissues, all of which share a common origin in the mesoderm of the embryo (**Table 2.2**). These tumors, the sarcomas, constitute only about 1% of the tumors encountered in the oncology clinic. Sarcomas derive from a variety of mesenchymal cell types. Included among these are fibroblasts and related connective tissue cell types that secrete collagen, the major structural component of the extracellular matrix of tendons and skin; adipocytes, which store fat in their cytoplasm; osteoblasts, which assemble calcium phosphate crystals within matrices of collagen to form bone; and myocytes, which assemble to form muscle (**Figure 2.6**). Hemangiomas, which are relatively common in children, arise from precursors of the endothelial cells. The stromal layers of epithelial tissues include a variety of these mesenchymal cell types, notably fibroblasts and adipocytes.

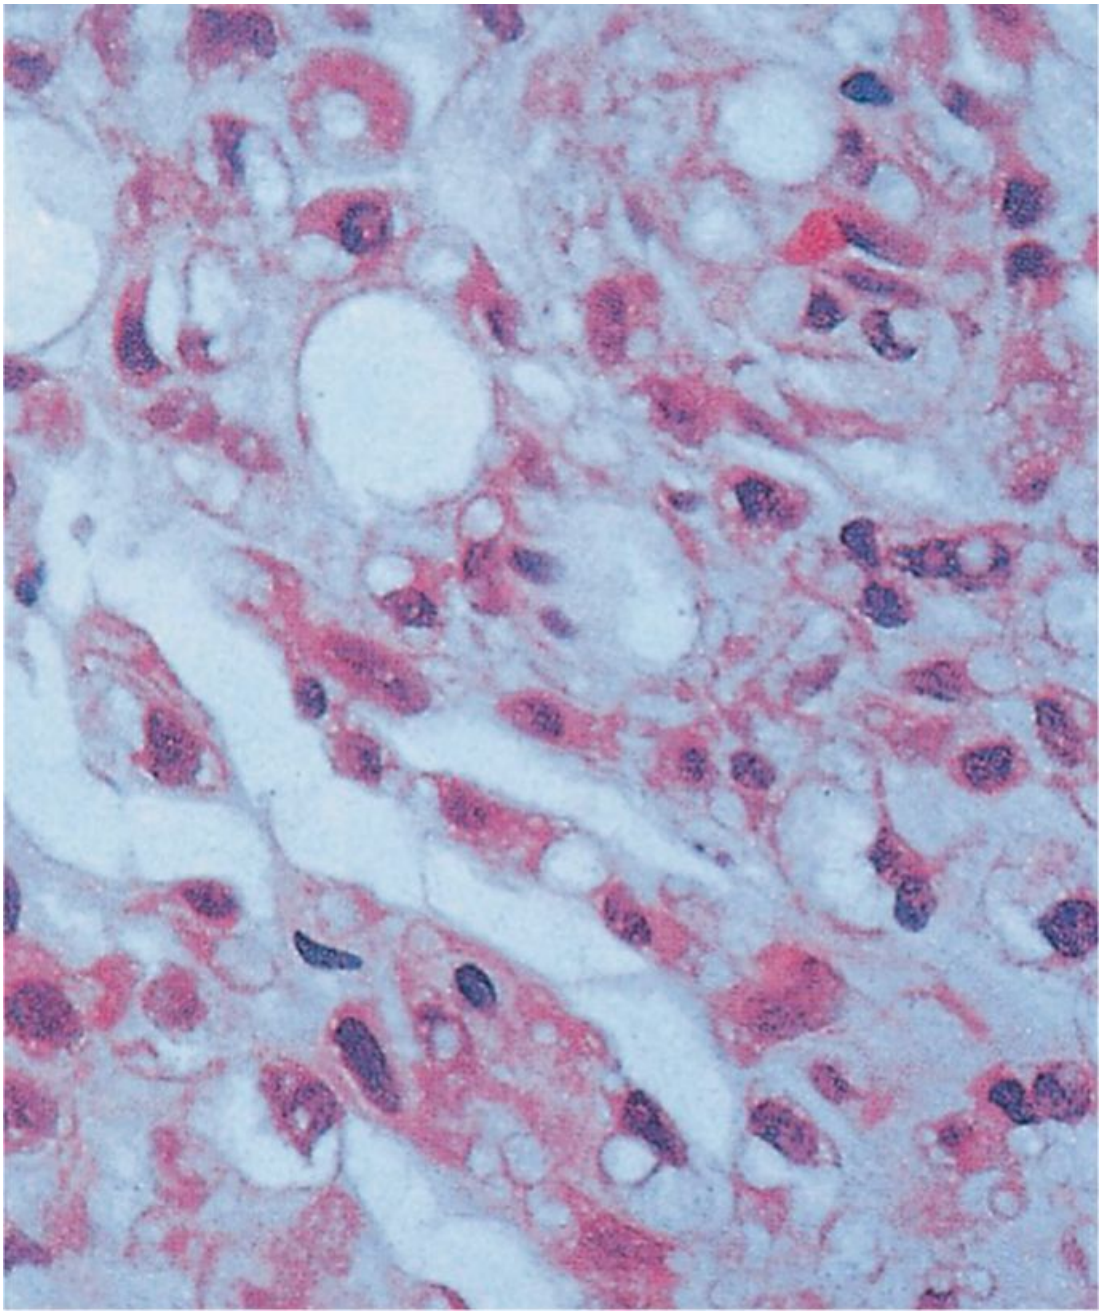
Table 2.2 Various types of more common sarcomas

Type of tumor	**Presumed cell lineage of founding cell**
Osteosarcoma	osteoblast (bone-forming cell)
Liposarcoma	adipocyte (fat cell)
Leiomyosarcoma	smooth muscle cell (e.g., in gut)
Rhabdomyosarcoma	striated/skeletal muscle cell
Malignant fibrous histiocytoma	adipocyte/muscle cell
Fibrosarcoma	fibroblast (connective tissue cell)
Angiosarcoma	endothelial cells (lining of blood vessels)
Chondrosarcoma	chondrocyte (cartilage-forming cell)



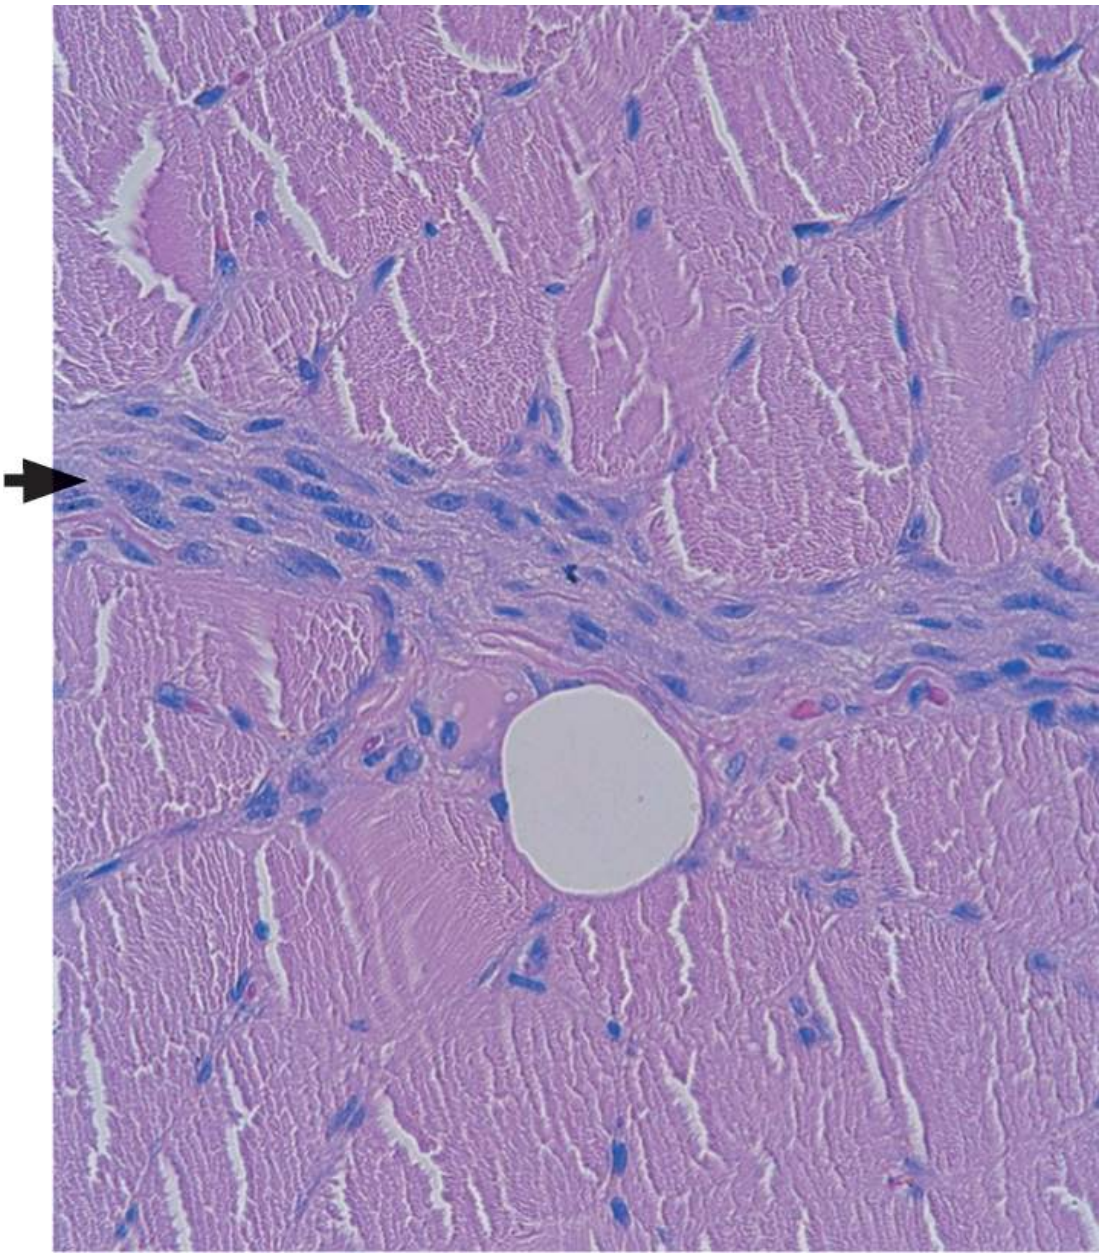
Cancer cells in bone. Irregular clumps of dark purple nuclei surrounded by pale halos appear within a pink matrix in which no nuclei are visible.

(A)



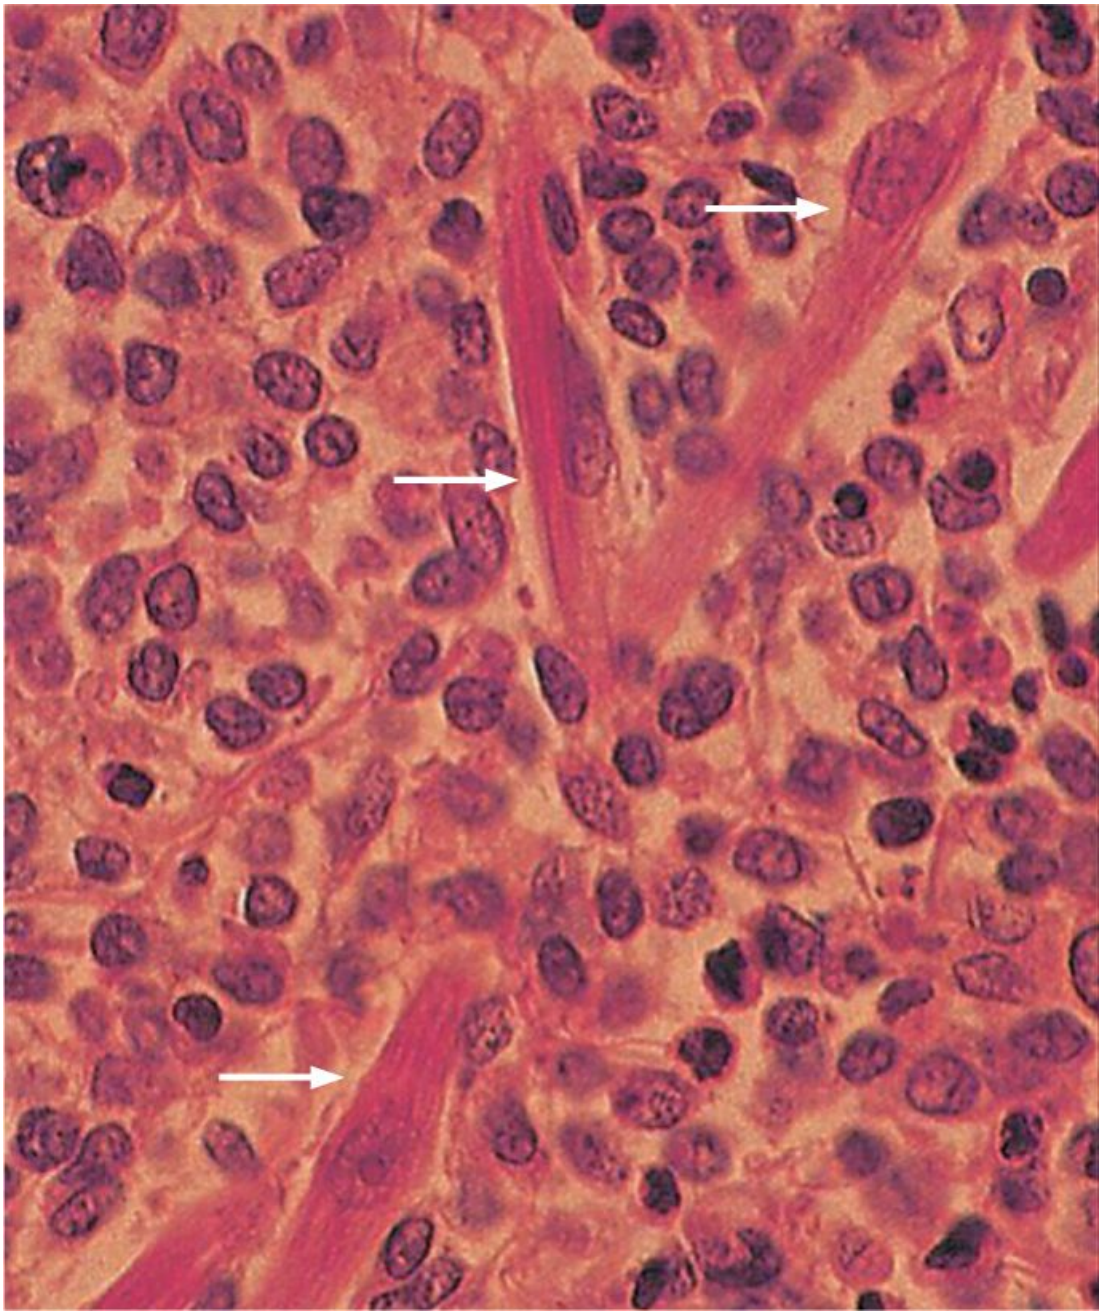
Cancerous fatty tissue. White globules appear within tissue formed of irregularly arranged cells.

(B)



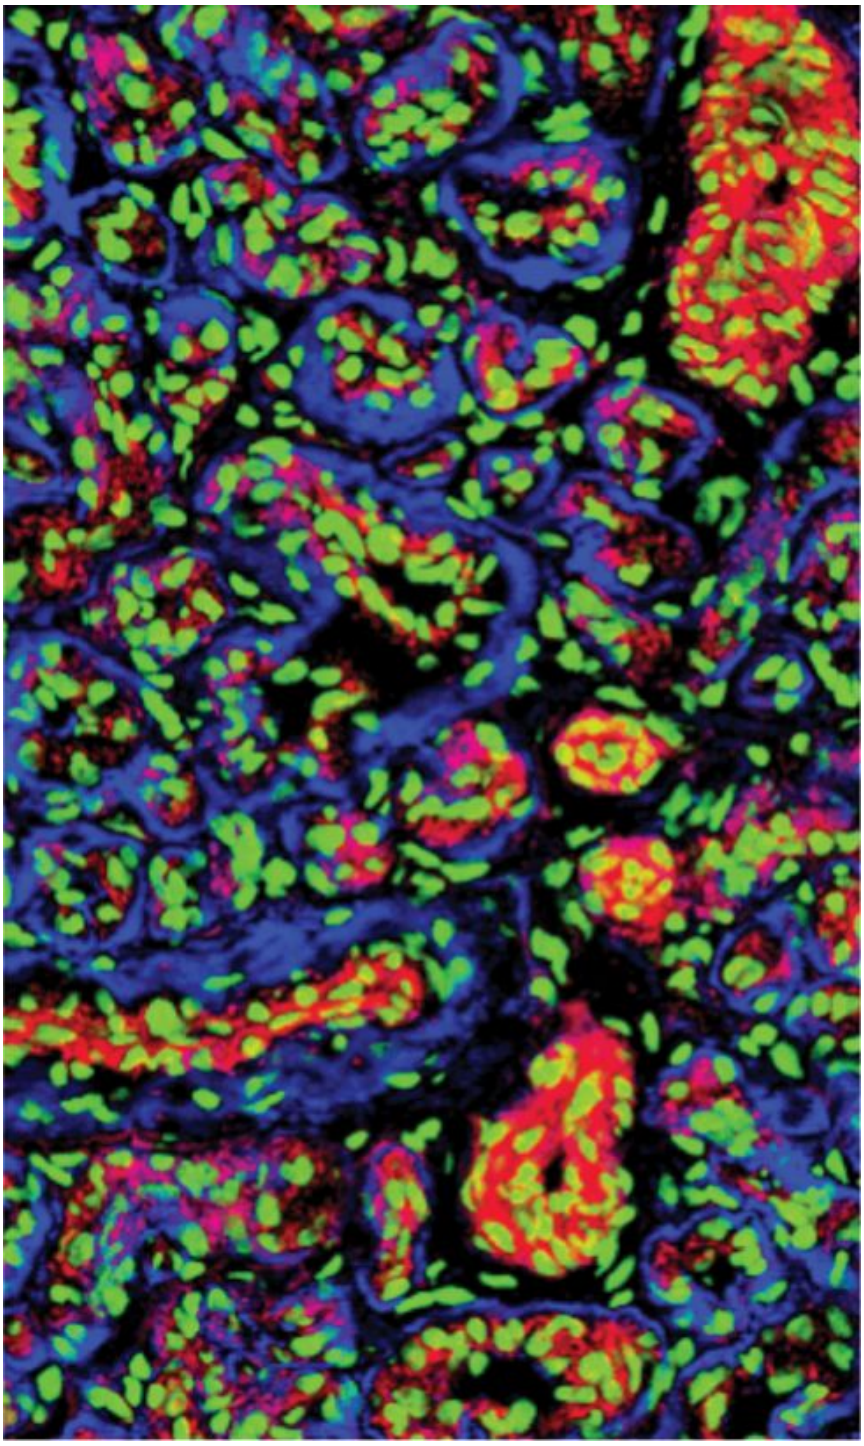
Cancerous smooth muscle tissue. The cancerous cells appear a dark band with many nuclei, running through lighter colored tissue. Smaller dark bands branch in different directions from the main one. The appearance is someone like veins of ore running through rock.

(C)



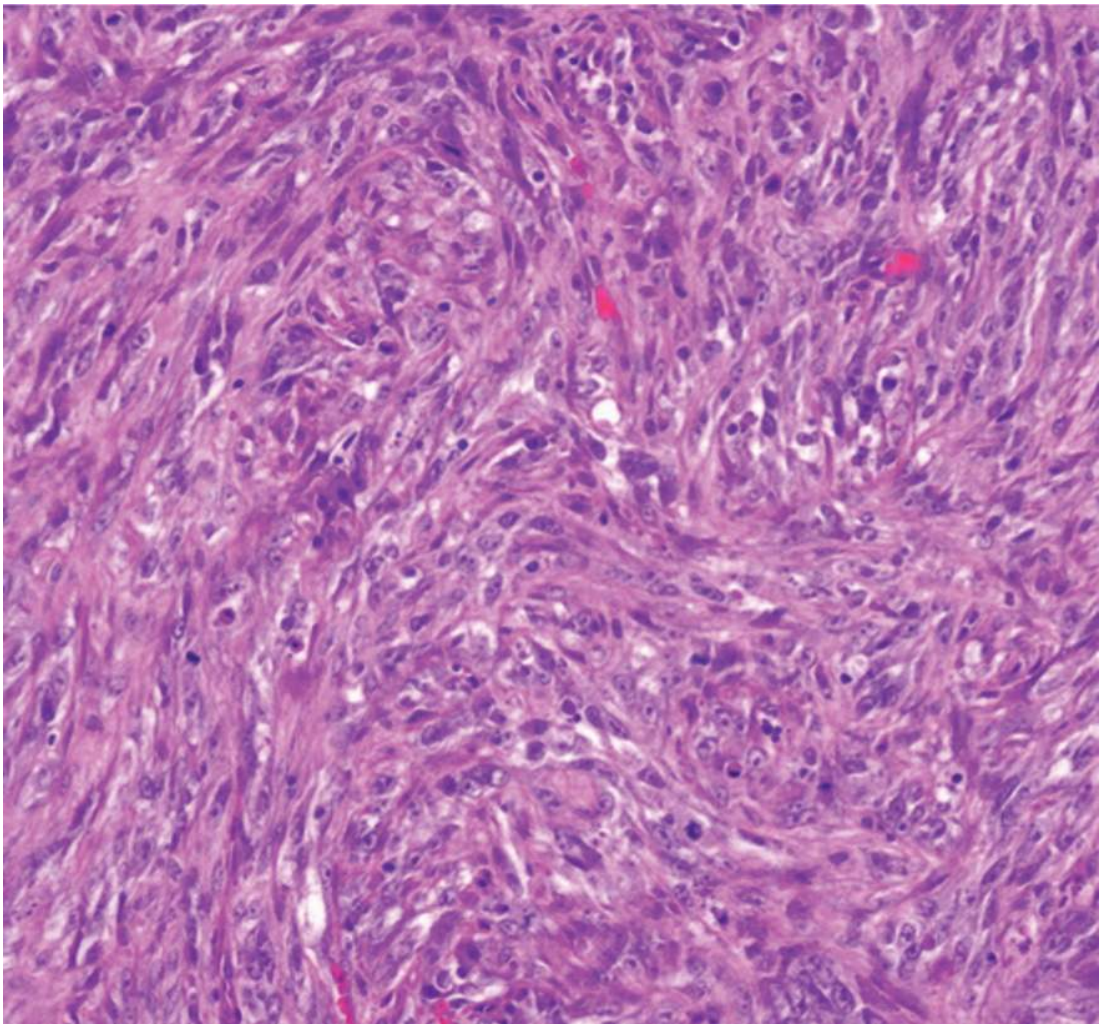
Cancerous skeletal muscle tissue. Many dark brown-red nuclei crowd around a few elongated bright red structures, which are normal cells.

(D)



Cancerous endothelial cells, in an image with a black background. Many small green flecks appear within larger shapes, most of which are dark blue but a few of which are bright red.

(E)



A spindle cell sarcoma sample. Many cells are arranged in irregularly. The general appearance is like that of the grain in a wood burl.

(F)

Figure 2.6 Mesenchymal tumors (A) Seen in this osteosarcoma are malignant bone-forming cells—osteoblasts (*dark purple nuclei*)—amid the mineralized bone (*pink*) they have assembled in the surrounding extracellular matrix. (B) A liposarcoma arises from cells closely related to adipocytes, which store lipid globules in various tissues. The presence of these globules throughout this tumor gives it a foamy appearance. (C) This leiomyosarcoma (*arrow, dark purple nuclei*), which arises in cells that form smooth muscle, is dispatching individual tumor cells to grow among adjacent normal muscle fibers (*light purple*). (D) Rhabdomyosarcomas arise from the cells forming striated skeletal muscles; the cancer cells (*dark red nuclei*) are seen here amid several normal muscle cells (*arrows*). (E) Hemangiomas—common benign tumors in infants that regress

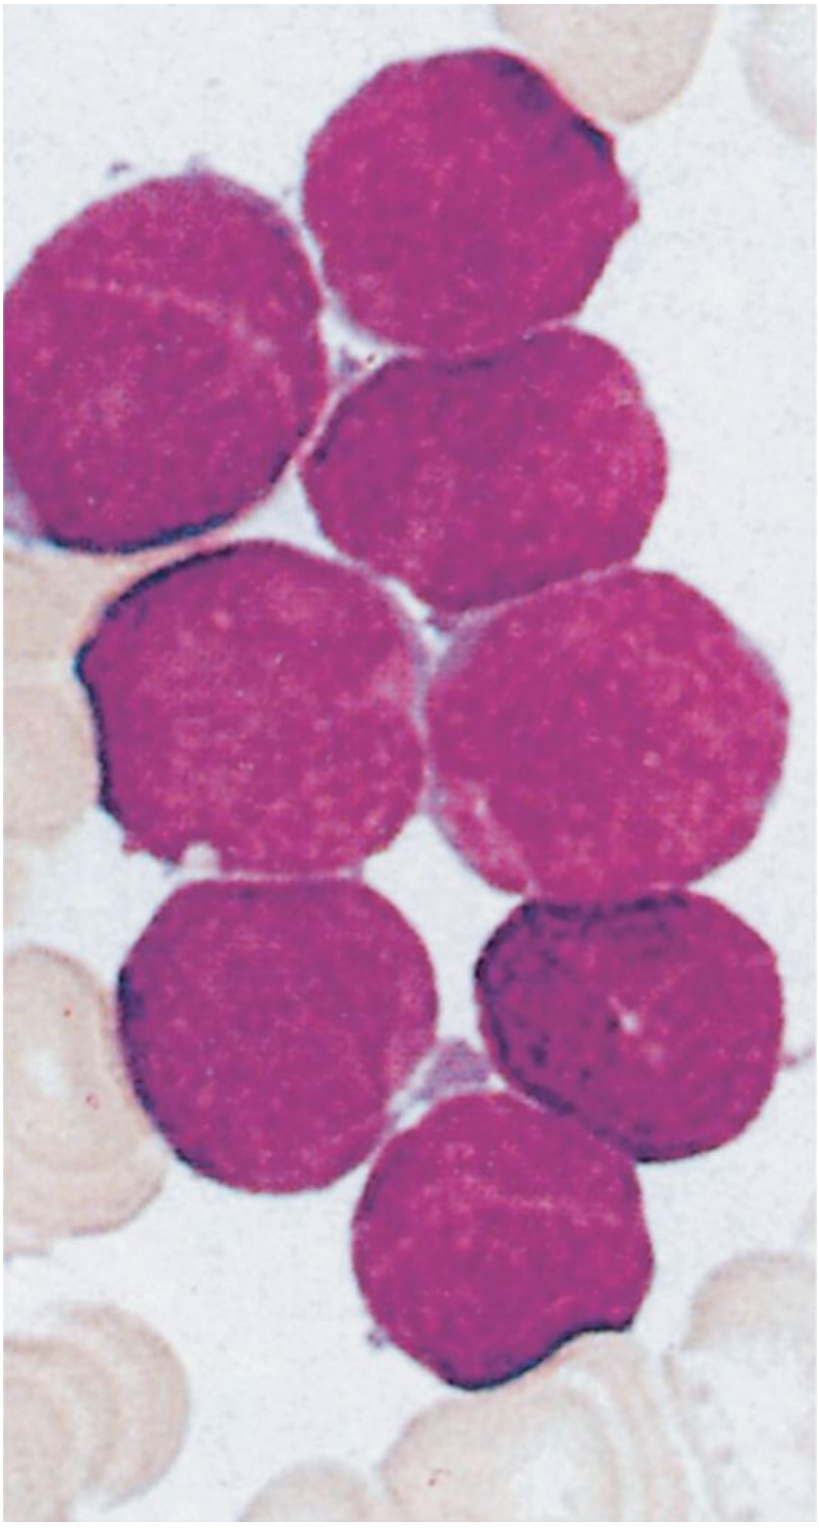
spontaneously—derive from the endothelial cells that form the lining of the lumina of small and large blood vessels. The densely packed capillaries in this particular tumor are formed from endothelial cells with cell nuclei stained *green* and cytoplasms stained *red*. Like epithelial cells, endothelial cells form basement membranes to which they attach, seen here in *blue*. (F) A dedifferentiated, high-grade spindle cell sarcoma. The dedifferentiated component may show an osteosarcoma, a fibrosarcoma, a malignant fibrous histiocytoma, or rarer subtypes including angiosarcoma and rhabdomyosarcoma, and therefore may mimic the common mesenchymal precursor of these various mesenchymal cell types. (A–C, from A.T. Skarin, Atlas of Diagnostic Oncology, 3rd ed. Philadelphia: Elsevier Science Ltd., 2003. With permission from Elsevier. D, from H. Okazaki and B.W. Scheithauer, Atlas of Neuropathology. New York: Gower Medical Publishing, 1988. With permission of Mayo Foundation for Medical Education and Research. E, from M.R Ritter et al., *Proc. Natl. Acad. Sci. USA* 99:7455–7460, 2002. With permission of National Academy of Sciences, U.S.A. F, Courtesy of Dharam M. Ramnani.)

The second group of nonepithelial cancers arise from the various cell types that constitute the blood-forming (hematopoietic) tissues, including the cells of the immune system (**Table 2.3** and **Figure 2.7**); these cells also derive from the embryonic mesoderm. Among them are cells destined to form erythrocytes (red blood cells), antibody-secreting (plasma) cells, and T and B lymphocytes. The term leukemia (literally “white blood”) refers to malignant derivatives of several of these hematopoietic cell lineages that move freely through the circulation and, unlike the red blood cells, are nonpigmented. Lymphomas include tumors of the lymphoid lineages (B and T lymphocytes) that aggregate to form solid tumor masses, most frequently found in lymph nodes, rather than the dispersed, single-cell populations of tumor cells seen in leukemias. This class of tumors is responsible for ∼7% of cancer-associated mortality in the United States.

Table 2.3 Various types of more common hematopoietic malignancies

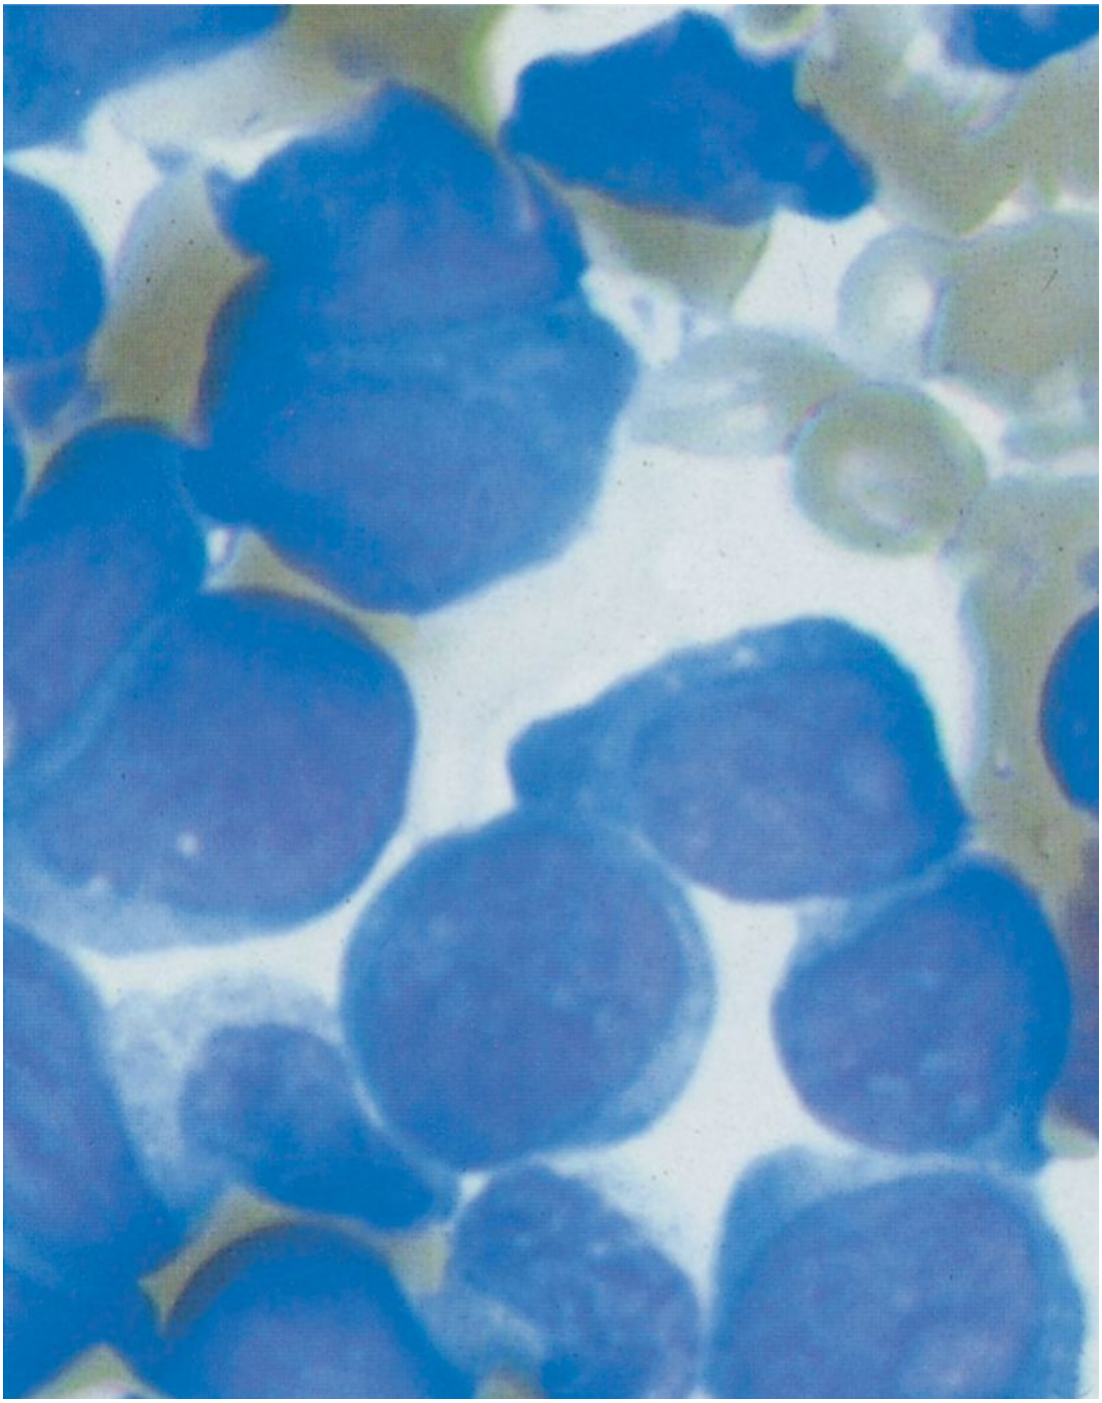
Acute lymphocytic leukemia (ALL)
Acute myelogenous leukemia (AML)
Chronic myelogenous leukemia (CML)

Chronic lymphocytic leukemia (CLL)
Multiple myeloma (MM)
Non-Hodgkin’s lymphoma[a] (NHL)
Hodgkin’s lymphoma (HL)



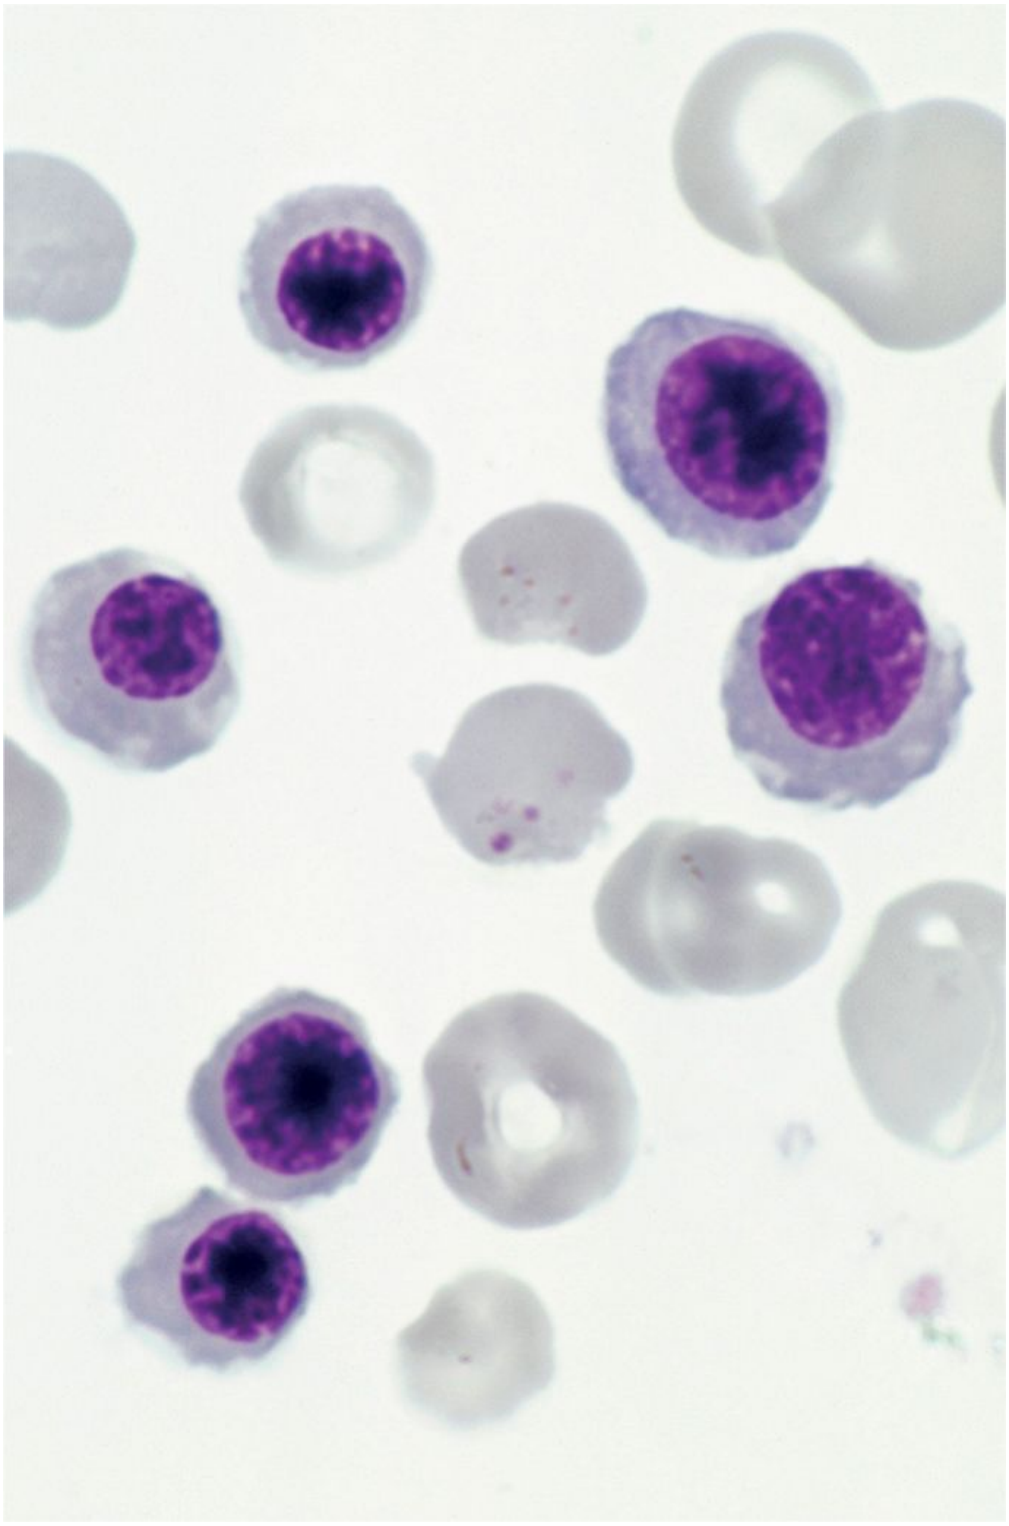
Eight round lymphocytic leukemia cells are stained wine-red and look like a small cluster of grapes, surrounded by pale gray normal cells.

(A)



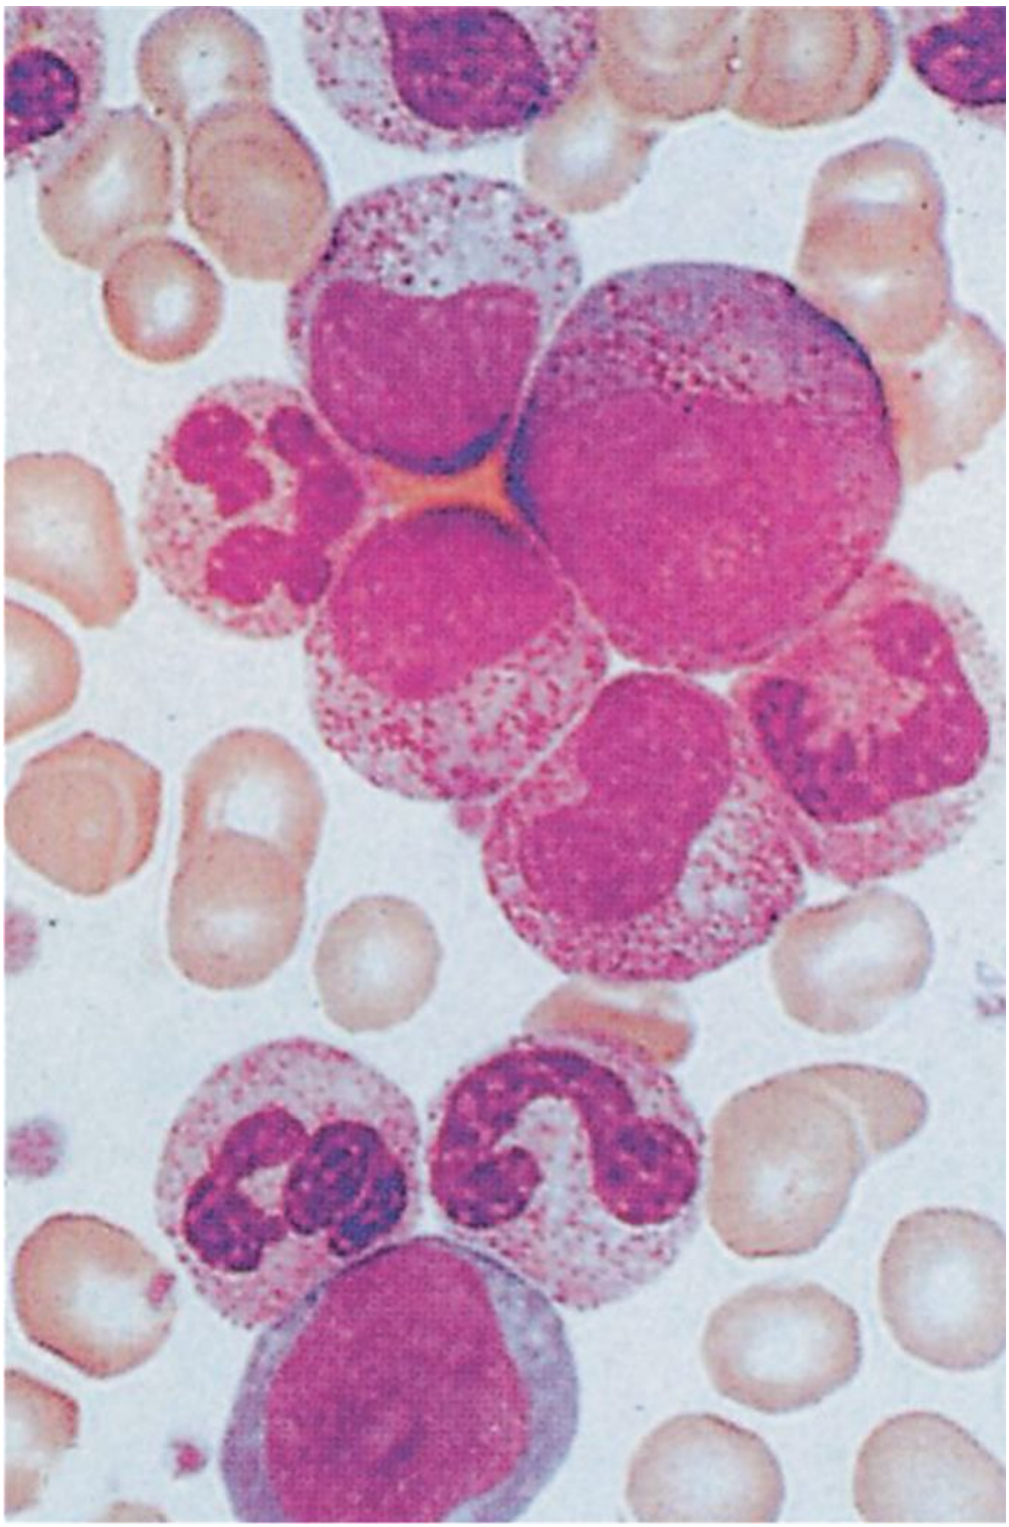
Acute myelogenous leukemia cells are stained sapphire blue. They contrast strongly with pale gray normal cells.

(B)



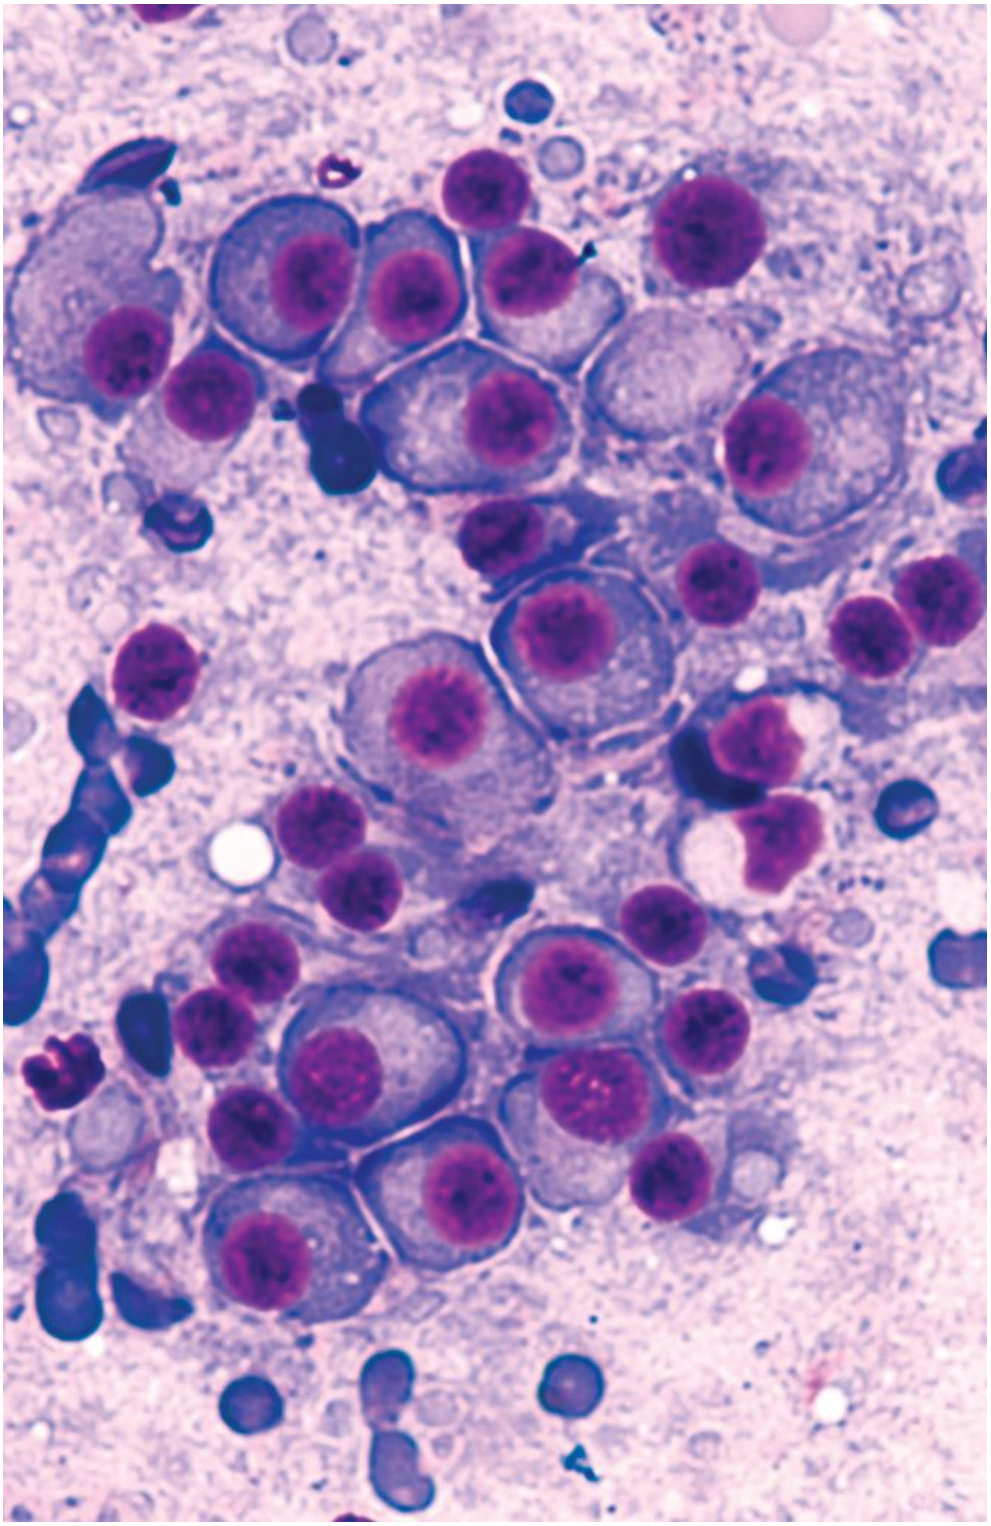
Erythroleukemia cells. Seventeen cells appear as irregular but generally round pale gray shapes. Six of them contain large, round structures that appear in purple.

(C)



Chronic myelogenous leukemia cells. Many cells appear as generally round pale gray shapes. Most are small and contain no visible nuclei, but some are

enlarged and contain visible nuclei stained red. Some of the nuclei appears as large red globes. Others appear as dark, wormlike structures or as clusters of small clumps.
(D)



Multiple myeloma cells. The cells appear against a pale pink background. Their bodies are stained dark blue. The nuclei are visible as purple globes within.

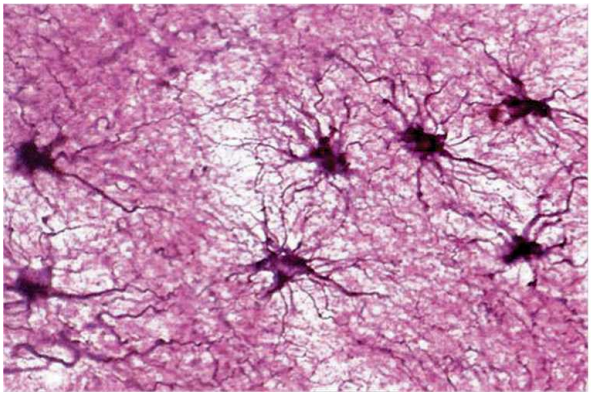
(E)

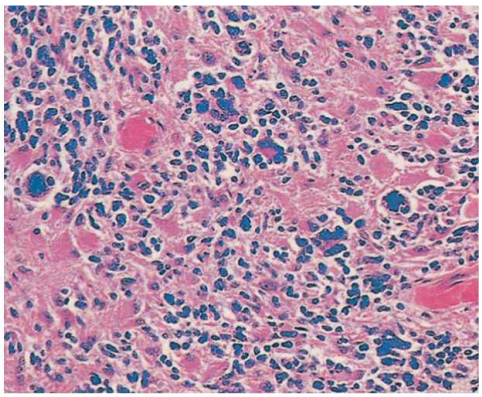
Figure 2.7 Hematologic malignancies (A) Acute lymphocytic leukemias (ALLs) arise from both the B-cell (80%) and T-cell (20%) lineages of lymphocytes. The cells forming this particular tumor (*red-purple*) exhibited the antigenic markers indicating origin from pre-B cells. (B) As in many hematopoietic malignancies, these acute myelogenous leukemia (AML) cells (*blue*) have only a small rim of cytoplasm around their large nuclei. They derive from precursor cells of the lineage that forms various types of granulocytes as well as monocytes, the latter developing, in turn, into macrophages, dendritic cells, osteoclasts, and other tissue-specific phagocytic cells. (C) The large erythroblasts in this erythroleukemia (*dark purple*) closely resemble the precursors of differentiated red blood cells—erythrocytes. (D) In chronic myelogenous leukemia (CML), a variety of leukemic cells of the myeloid (marrow) lineage are apparent (*red nuclei*), suggesting the differentiation of myeloid leukemia stem cells into several distinct cell types. (E) Multiple myeloma (MM) is a malignancy of the plasma cells of the B-cell lineage, which secrete antibody molecules, explaining their relatively large cytoplasms in which proteins destined for secretion are processed and matured. Seen here are plasma cells of MM at various stages of differentiation (*purple nuclei*). In some of these micrographs, numerous lightly staining erythrocytes are seen in the background. (A, B, and D, from A.T. Skarin, Atlas of Diagnostic Oncology, 3rd ed. Philadelphia: Elsevier Science Ltd., 2003. With permission from Elsevier. C, Richard J. Green / Science Source. E, David A. Litman / Shutterstock.)

The third and last major grouping of nonepithelial tumors arises from cells that form various components of the central and peripheral nervous systems (**Table 2.4**). These are often termed neuroectodermal tumors to reflect their origins in the outer cell layer of the early embryo. Included in this category are gliomas, glioblastomas, neuroblastomas, schwannomas, and medulloblastomas (**Figure 2.8**). While comprising only 1.3% of all diagnosed cancers, these are responsible for about 2.5% of cancer-related deaths. Of note, the developmental origin of much of the central nervous system (CNS) from a primitive neuroepithelial cell layer seems to explain some of the striking similarities between CNS tumors and the carcinomas listed earlier.

Table 2.4 Various types of neuroectodermal malignancies

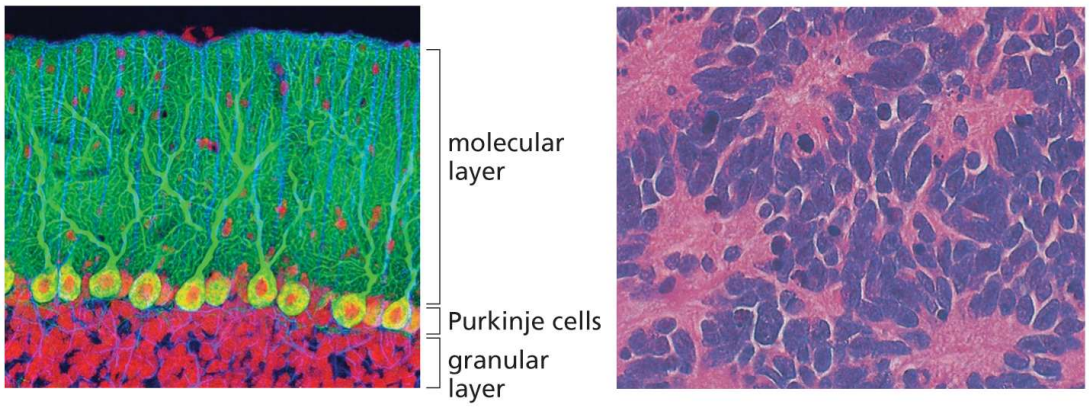
Name of tumor	**Lineage of founding cell**
Glioblastoma multiforme	highly progressed astrocytoma
Astrocytoma	astrocyte (type of glial cell)[a]
Meningioma	arachnoidal cells of meninges[b]
Schwannoma	Schwann cell around axons[c]
Retinoblastoma	cone cell in retina[d]
Neuroblastoma[e]	cells of peripheral nervous system
Ependymoma	glial cells lining ventricles of brain[f]
Oligodendroglioma	oligodendrocyte covering axons[g]
Medulloblastoma	granular cells of cerebellum[h]





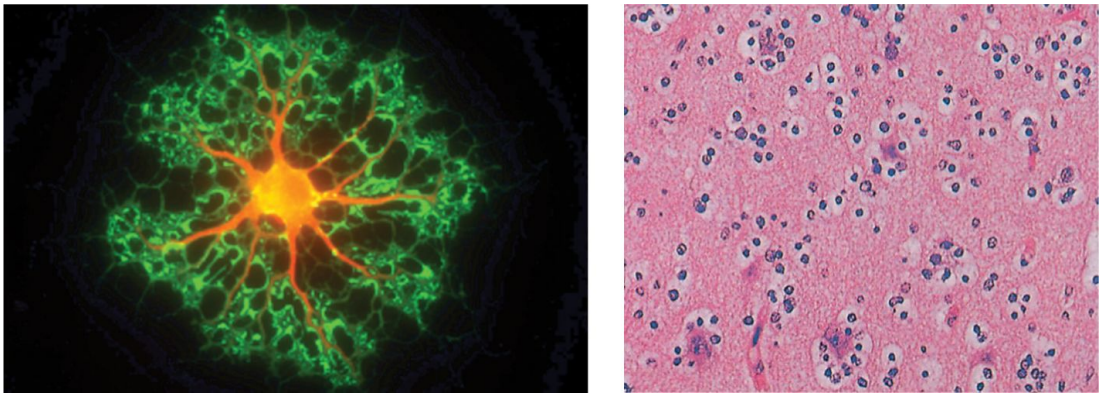
On the left are normal astrocytes, appearing as dark, spidery structures within lighter colored brain tissue. On the right is a sample of cancerous brain tissue. The tissue is irregular and crowded with dark nuclei. A few isolated regions are free of these nuclei.

(A)



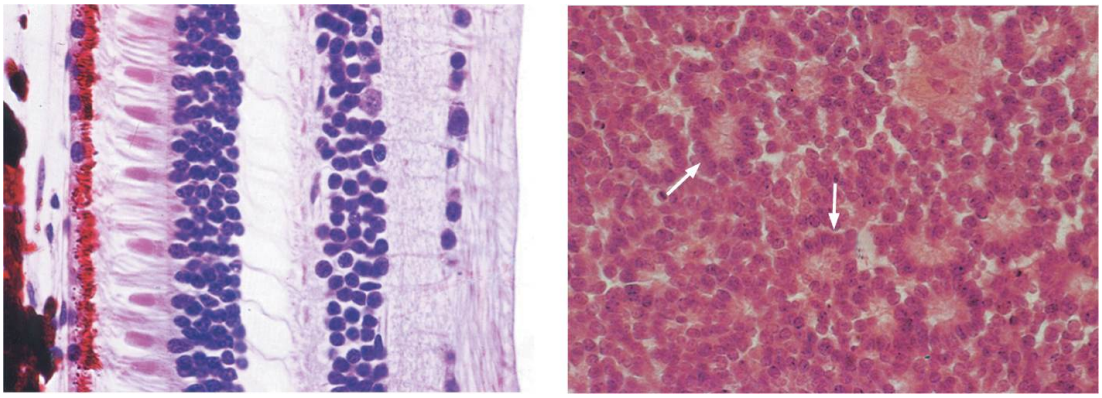
On the left is a cross section of cerebellum cells. At the bottom is the granular layer, with cells that look like a layer of gravel but in bright red. On top of them is a single layer of Purkinje cells, round cells with yellow centers; they look like a long row of fried eggs. Up from these sprouts a thick, spongy blue-green layer that looks like vegetation. This is the molecular layer. On the right are medulloblastomas. Many purple nuclei appear crowded together, but some isolated regions are pink, creating the appearance of a field of flowers with purple petals and pink centers.

(B)



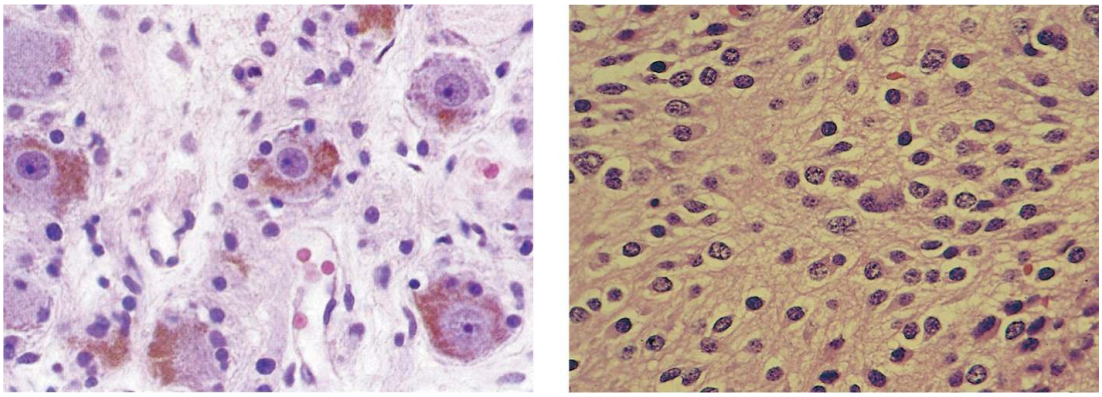
On the right is a tissue sample from an oligodendroglioma. Many cell nuclei appear dark blue within pale halos against a pink background. On the left is a

single normal oligodendrocyte. It looks like a spherical green broccoli floret but with a glowing golden center.
(C)



On the left is a cross section of a normal retina, showing cleanly defined, even layers of cells. On the right is a sample of cancerous retinal tissue, with cells clustered into rosette-like clumps with reddish peripheries and orangish centers.

(D)



On the left are normal nerve cells. Sympathetic ganglia appear dark and round within paler surrounding tissue. On the right is a sample of neuroblastoma tissue, with spidery filaments weaving around and among many tumor cells.

(E)

Figure 2.8 Neuroectodermal tumors (A) Astrocytes—nonneuronal, supporting cells of the brain (*dark purple, left panel*)—are the presumed precursors of astrocytomas and glioblastomas (*right panel*). Glioblastoma multiforme takes its name from the multiple distinct neuroectodermal cell types that constitute the

tumor. The tumor cells are seen to have nuclei of various sizes (*purple*). (B) Cells of the granular layer of the cerebellum (*left panel*) reside below Purkinje cells and cells of the molecular layer in the cortex of the cerebellum. The precursors of granular cells yield medulloblastomas (*right panel*), the cells of which are notable for their ability to differentiate into neurons, glial cells, and pigmented neuroepithelial cells (*purple nuclei, pink cytoplasms*). About one-third of these tumors show the rosettes of cells seen here. (C) Shown is an oligodendroglioma (*right*), which derives from oligodendrocytes, nonneuronal cells of ectodermal origin that support and insulate axons in the central nervous system. Each of the neoplastic cell nuclei here has a halo around it, which is characteristic of this tumor. The cultured normal oligodendrocyte shown here (*left*) exhibits a number of branching (dendritic) arms—each of which associates with one or several axons and proceeds to form an insulating myelin sheath around a segment of each of these axons. The cell body has been immunostained (*yellow/orange*) for the O4 oligodendrocyte marker, while the tips of the dendritic arms (*green*) have been stained for CNPase, an enzyme associated with myelination of axons. (D) Rods, cones, and other neuronal cell types (*left panel*) constitute important components of the normal retina. Retinoblastomas (*right panel*) arise from cells with attributes of the cone precursors present in the normal developing retina. Retinoblastomas often show the characteristic rosettes, indicated here with arrows. (E) Cells of the sympathetic ganglia of the peripheral nervous system (*larger cells, left panel*) give rise to neuroblastomas (*right panel*), which are usually seen in children. The individual tumor cells here are surrounded by dense fibrillary webs, which are derived from neurites—cytoplasmic processes used by neurons to communicate with one another. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier.)

OceanofPDF.com

Glossary

basement membrane
: The specialized extracellular matrix that forms a sheet separating epithelial from stromal cells or endothelial cells from pericytes. *Also termed* **basal lamina**.

basal lamina
: The specialized extracellular matrix that forms a sheet separating epithelial from stromal cells or endothelial cells from pericytes. *Also termed* **basement membrane**.

stroma
: (pl., **stromata**; adj., **stromal**) (1) The mesenchymal components of normal epithelial and hematopoietic tissues, which may include fibroblasts, adipocytes, endothelial cells, and various immunocytes as well as associated extracellular matrix. (2) A spectrum of similar cell types that constitute the stromal cells within a tumor and are recruited into the tumor from host tissues and lack the somatic mutations born by the tumor cells. *See also* **reactive stroma**.

extracellular matrix
: Meshwork of secreted proteins, largely glycoproteins and proteoglycans, that surrounds most cells within tissues and creates a structural scaffold in the intercellular space.

growth factor
: Secreted protein that is able to stimulate the growth and/or proliferation of a cell by binding to a specific cell-surface receptor displayed by that cell.

carcinoma
: (adj., - **omatous**) A cancer arising from epithelial cells.

endoderm
: Innermost layer of cells in an early embryo, which in chordates serves as precursor of the gastrointestinal tract and associated tissues, including the lungs, liver, and pancreas.

ectoderm
: Outermost layer of cells in an early chordate embryo that gives rise to the skin and nervous system.

mesoderm

Middle layer of cells in an early chordate embryo lying between the ectoderm and endoderm, which is the precursor of mesenchymal tissues, including connective tissues and the hematopoietic system. *See also* mesenchymal.

squamous cell carcinoma

Tumor arising from squamous cells. *See also* **adenocarcinoma**.

keratinocyte

Epithelial cell type found in a variety of epithelial tissues, notably the skin. These cells are named after the cytokeratins that they express, which form key components of the cytoskeleton of these cells. *See also* **cytokeratin.**

adenocarcinoma

Tumor derived from secretory epithelial cells. *See also* **squamous cell carcinoma**.

sarcoma

Tumor derived from mesenchymal cells, usually those constituting various connective tissue cell types, including fibroblasts, osteoblasts, endothelial cell precursors, and chondrocytes.

mesenchymal

(1) Referring to tissue composed of cells of mesodermal origin, including fibroblasts, smooth muscle cells, endothelial cells, and adipocytes. (2) Referring to an individual cell type belonging to this class of cells. (3) Referring to a phenotypic state associated with mesenchymal markers and created by the epithelial–mesenchymal transition cell-biological program. *See* **epithelial–mesenchymal transition**.

fibroblast

Mesenchymal cell type that is common in connective tissues and in the stromal compartment of epithelial tissues and is characterized by its secretion of collagen.

adipocytes

Specialized cells of the mesenchymal lineage, closely related to fibroblasts, that create fat and store it in large globules in the cytoplasm; the dominant cell type in fatty tissues.

osteoblast

Mesenchymal cell type related to fibroblasts that constructs mineralized bone through the deposition of a collagenous matrix and

apatite crystals.

myocytes
: The individual contractile cells that assemble to form functional muscles. *See also* **myoblasts**.

hemangioma
: Benign tumor of endothelial cell origin often seen in infants.

erythrocyte
: Red blood cell.

plasma
: The fluid component of blood that is left behind when its cellular components are removed, usually by centrifugation.

lymphocytes
: Class of leukocytes that mediate humoral or cellular immunity, encompassing B cells, T cells, and NK cells and derivatives thereof.

leukemia
: Malignancy of any of a variety of hematopoietic cell types, including the lineages leading to lymphocytes and granulocytes, in which the tumor cells are nonpigmented and dispersed throughout the circulation. *Compare* **lymphoma**.

lymphoma
: Solid tumor of lymphoid cells. *Compare* **leukemia**.

lymphoid
: (1) Referring to the lymphatic system and its associated organelles. (2) Referring to the lineage of hematopoietic cells that yields B and T lymphocytes as well as natural killer cells. *Compare* **myeloid**.

neuroectodermal
: Referring to the components of the nervous system, which derive from the embryonic ectoderm.

glioma
: A group of central nervous system tumors that arise from glial cells and include ependymomas, astrocytomas, and oligodendrogliomas. *See also* **glioblastoma**.

glioblastoma
: A malignant high-grade glioma that often originates from a low-grade astrocytoma. *Also termed* glioblastoma multiforme. *See also* **glioma**.

neuroblastoma

Tumor of primitive neuronal precursor cells of the peripheral nervous system and adrenal medulla.

schwannoma

Tumor of the Schwann cells.

medulloblastoma

Tumor of the primitive precursors of neurons in the cerebellum.

epithelium

(pl., **epithelia**) A layer of cells that forms the lining of a cavity or duct and the specialized epithelium that forms the skin.

endothelial cells

(1) Mesenchymal cells that form the walls of capillaries or lymph ducts by assuming shapes that allow the assembly of tubelike structures. (2) Mesenchymal cells lining the luminal walls of larger blood vessels or lymph ducts.

lumen

(pl., **lumina**; adj., **luminal**) (1) The bore of a hollow, tubelike structure, such as the gut, a bronchiole in the lung, a blood vessel, or a duct in a secretory organ. (2) The enclosed cavity within a spherical structure, such as a membranous vesicle.

endothelial cells

(1) Mesenchymal cells that form the walls of capillaries or lymph ducts by assuming shapes that allow the assembly of tubelike structures. (2) Mesenchymal cells lining the luminal walls of larger blood vessels or lymph ducts.

hematopoiesis

See **hematopoiesis**: Process that results in the formation of all of the cells in the blood, including its red and white cells, the latter including various cells of the immune system.

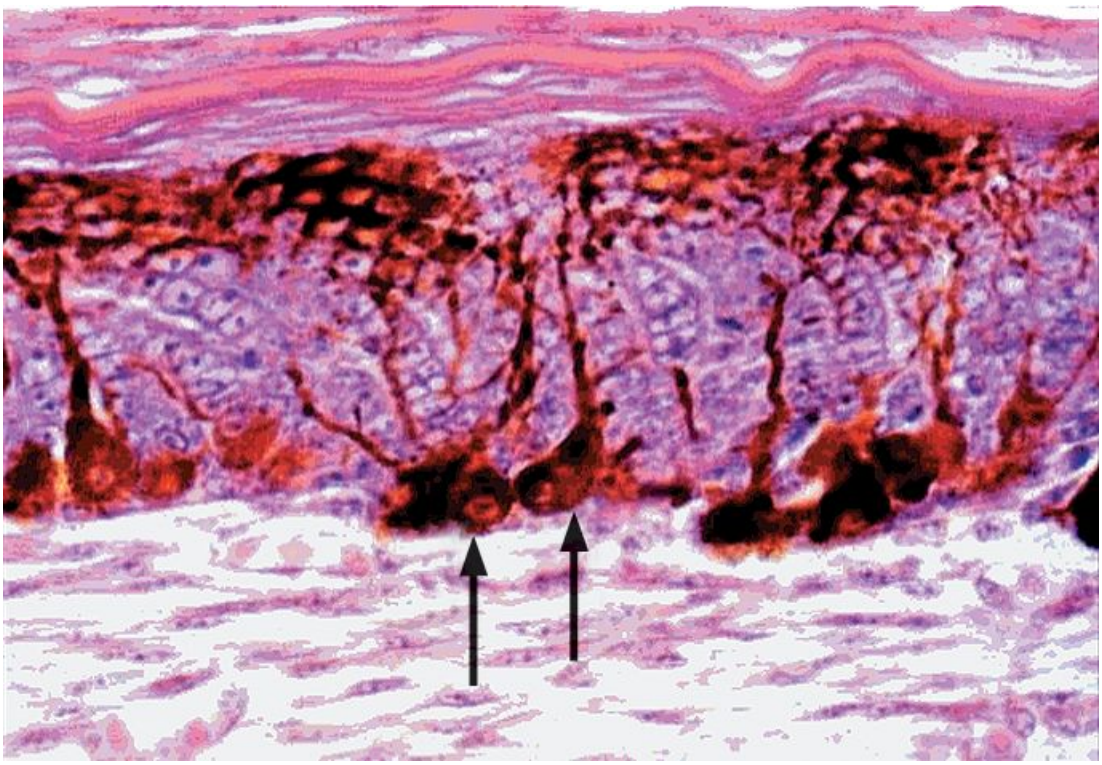
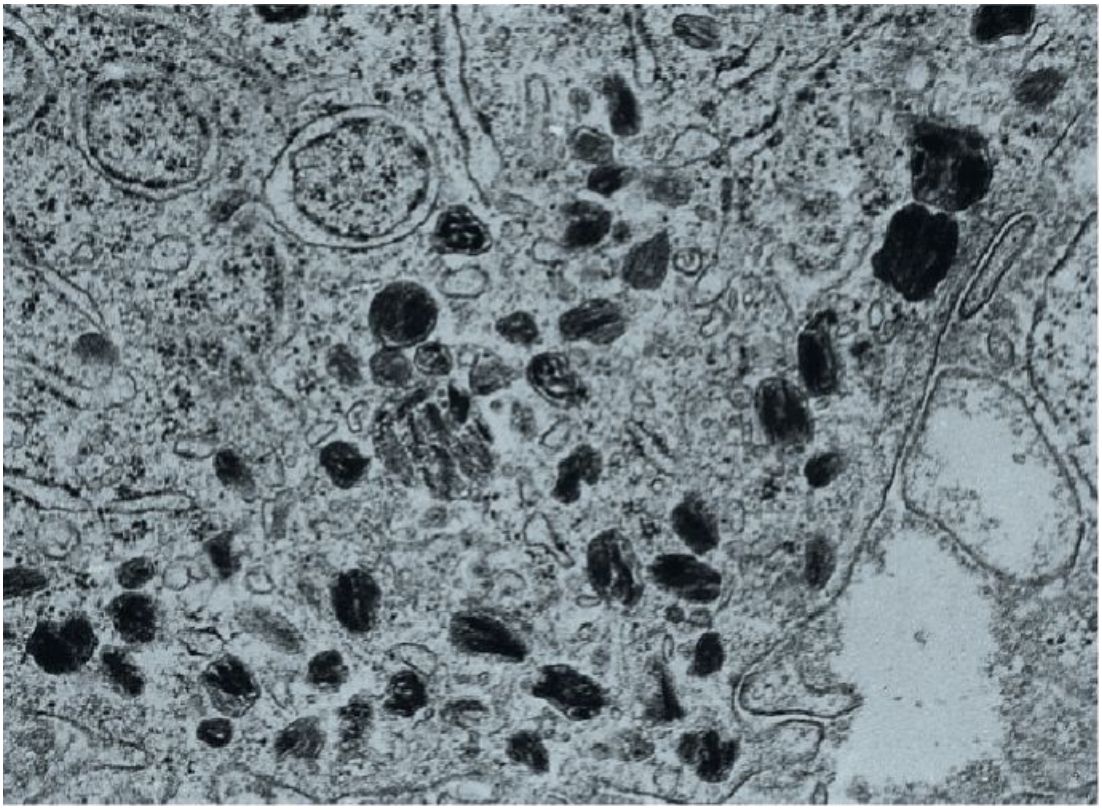
2.3 Some types of tumors do not fit into the major classifications

Not all tumors fall neatly into one of these four major groups. For example, melanomas derive from melanocytes, the pigmented cells of the skin and the retina. The melanocytes, in turn, arise from a primitive embryonic structure termed the neural crest. While having an embryonic origin close to that of the neuroectodermal cells, the precursors of melanocytes end up during development as wanderers that settle in the skin and the eye and provide pigment to these tissues, but establish no direct connections with the nervous system (**Figure 2.9**). Moreover, melanoma cells share many features in common with certain types of carcinoma cells.



Part A shows a cross-section of normal skin. The epithelium layer consists of live keratinocytes. Below the epithelium is stroma tissue, and above the epithelium is layer of dead, flattened keratinocytes. Melanocytes, visible as dark nodues, lie at the boundary between the epithelium and the stroma tissue and extend branches up into the epithelium.

(A)



Part B shows an electron micrograph of dark pigment granules within lighter colored tissue. They look like many small lakes in a large forest.

(B)

Part C is a color photograph of cutaneous melanoma on a person. The cancerous tissue appears as a large collection of black bumps that look like bubbles of tar rising to the surface of the skin.

(C)

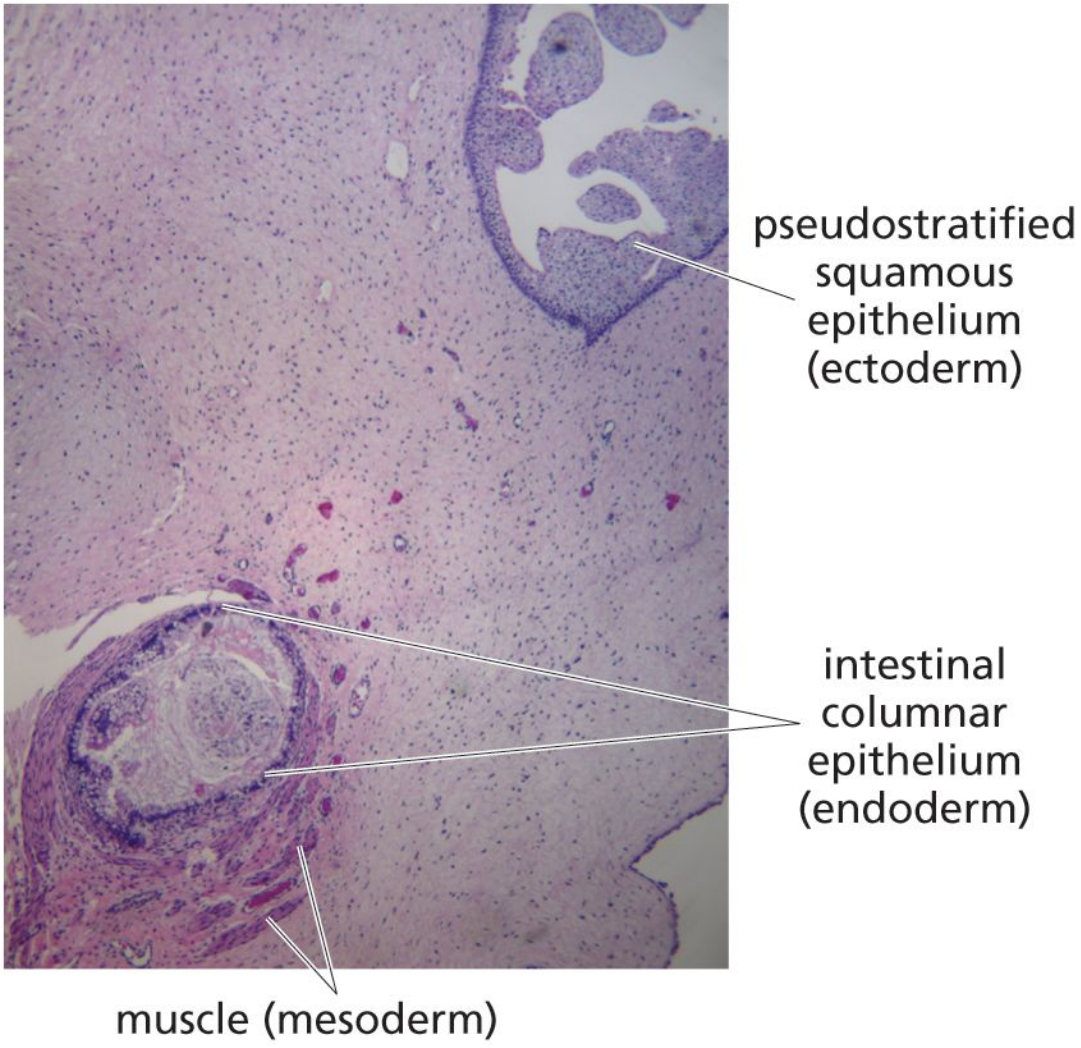
Figure 2.9 Melanocytes and melanomas (A) Melanocytes (*arrows*), which form melanin pigment granules, are normally scattered among the basal keratinocytes of the skin. They extend long, thin cytoplasmic processes through which they deposit these granules in the cytoplasm of keratinocytes, which form the bulk of the epithelium (see Figure 2.5A). Layers of dead keratinocytes at the surface of the skin (*above*) and stroma cells (*below*) are also apparent. (B) The pigment granules, visualized here by transmission electron microscopy, have made melanomas favored objects of research because the metastases that they form are easily visualized. Once melanomas have begun to invade vertically from the superficial layers of the skin into the underlying stroma, they have a high tendency to metastasize to distant tissues. (C) This case of cutaneous melanoma dramatizes the metastatic nature of the disease and the readily observed, pigmented metastases. (A, from W.J. Bacha Jr. et al., Color Atlas of Veterinary Histology, 2nd ed. Ames, IA: Wiley–Blackwell, 2012. With permission from John Wiley & Sons. B and C, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier.)

Small-cell lung carcinomas (SCLCs) contain cells having many attributes of neurosecretory cells, such as those of neural crest origin in the adrenal glands that sit above the kidneys. Such cells, often in response to neuronal signaling, secrete biologically active peptides. It appears that these tumors originate in endodermal stem cell populations of the lung that have shed some of their epithelial characteristics and acquired others that are characteristic of a neuroectodermal lineage.

This switching of tissue lineage and resulting acquisition of an entirely new set of differentiated characteristics is often termed transdifferentiation. The term implies that the commitments that cells have made by individual cells during embryogenesis to enter into one or another tissue and cell lineage are not irreversible, and that under certain conditions, descendant cells can move from one differentiation lineage to another. Such a change in phenotype may affect both normal and cancer cells. For example, at the borders of many carcinomas, epithelial cancer cells often change shape and gene expression programs and take on certain attributes that are usually associated with cells of mesenchymal origin. This dramatic shift in cell phenotype, termed the epithelial–mesenchymal transition, or simply EMT, implies great phenotypic plasticity on the part of cells that normally seem to be fully committed to behaving like epithelial cells. As described later (Chapters 13 and 14), this transition may often accompany and enable the invasion by carcinoma cells into adjacent normal tissues. (This carcinoma-associated EMT exploits a cell-biological program operating in normal tissues during the healing of damaged epithelial cell sheets.) Cells activating an EMT program usually do so reversibly, in contrast to most types of transdifferentiation in which cells shift their tissue-specific phenotypes irreversibly. Importantly, these interconversions involve changes in gene expression programs rather than mutations in the genomes of carcinoma cells.

Of the atypical tumor types, teratomas are arguably the most bizarre of all, in part because they defy all attempts at classification. While only ~10,000 cases are diagnosed worldwide annually, teratomas deserve mention because they are unique and shed light on the biology of embryonic stem (ES) cells, which have become so important to biologists; ES cells enable genetic manipulation of the mouse germ line and are central to certain types of stem cell therapies currently under development. Teratomas seem to arise from germ cell (egg and sperm) diploid precursors (see Section 1.3) that have failed to migrate to their proper destinations during embryonic development and persist at ectopic (inappropriate) sites in the developing fetus. They retain the pluripotency of early embryonic cells—the ability to generate most and possibly all of the differentiated cell types present in the fully developed fetus. The cells in different sectors of common “mature” teratomas—which are largely benign, localized growths—differentiate to create tissues that are very similar at the histopathological level to those found in a variety of adult tissues (**Figure 2.10**).

Typically, representatives of the three cell layers of the embryo—endoderm, mesoderm, and ectoderm (see **Supplementary Sidebar 2.2**)—coexist within a single tumor and often develop into recognizable tissue structures, such as those of teeth, hair, and bones. Occasionally these tumors progress to become highly malignant and thus life-threatening.



A tissue sample from a teratoma. Within a large, mostly undifferentiated expanse of pale pink tissue there appear two rounded regions with internal structure. The upper right one contains an irregular mix of empty space and darker tissue labeled pseudostratified squamous epithelium (ectoderm). The lower left rounded region contains a dark, granular ring around a pale core. The granular ring is labeled intestinal columnar epithelium (endoderm). Loosely encircling the dark, granular ring are segments of reddish tissue labeled muscle (mesoderm).

Figure 2.10 Teratomas This teratoma was created by implanting human embryonic stem (ES) cells into a mouse, yielding a tumor that is a phenocopy of the spontaneous teratomas found in children; such “mature” teratomas contain fully differentiated cells and are localized, noninvasive tumors. (Courtesy of Sumita Gokhale.)

Of special interest is the fact that careful karyotypic and molecular analyses of benign, mature teratomas have suggested that the associated tumor cells are genetically wild type. This suggests that such teratoma cells are unique, being the only type of tumorigenic cell whose genomes are truly wild type, in contrast to the cells of essentially all other tumor types described in this book, which almost always carry identifiable genetic aberrations, often in large number.

The occasional rule-breaking exceptions, such as those represented by teratomas and the products of the EMT, do not detract from one major biological principle that seems to govern the vast majority of cancers: while cancer cells deviate substantially in behavior from their normal cellular precursors, they almost always retain many of the distinctive attributes of the normal cell types from which they descend. These vestigial, differentiation-associated traits provide critical clues about the origins of most tumors; they enable pathologists to examine tumor biopsies under the microscope and assign a tissue-of-origin and tumor classification, even without prior knowledge of the anatomical sites from which these biopsies were prepared.

In a small minority of cases (2–5%), the tumor biopsies given to pathologists for analysis have shed virtually all of the characteristic tissue-specific, differentiated traits of the corresponding normal precursor tissues. The cells in such tumors are said to have dedifferentiated, and the tumors as a whole are anaplastic, in that it is no longer possible to use histopathological criteria to identify the tissues from which they have arisen (**Supplementary Sidebar 2.3**). A tumor of this type, by definition detected at a site of metastatic dissemination, is often classified as a cancer of unknown primary (CUP), reflecting the difficulty of identifying the original site of primary tumor formation in the patient. In recent years, however, analysis of molecular markers, such as the methylation patterns of DNA and gene expression patterns, has enabled the identification of the tissues-of-origin of almost 90% of CUPs that could not be classified using only histopathological criteria. It is unclear what forces have driven the shedding of tissue-specific differentiation markers; their elimination may reflect the potentially highly mutable genomes of CUPs (as discussed in Chapter 12), or immunological attacks may have weeded out cancer cell subpopulations within growing tumors that express differentiation-specific proteins (as described in Chapter 15).

OceanofPDF.com

Glossary

melanoma
: Tumor arising from the melanocytes present as the pigmented cells of the skin, iris, and retinal pigmented epithelium.

neural crest
: Dorsal region of the early chordate embryo that contains cells serving as precursors of various specialized tissue and cell types, including certain cells of the peripheral nervous system, bones of the face, melanocytes, and several types of neurosecretory cells.

small-cell lung carcinoma
: Lung cancer of specialized pulmonary cells having neurosecretory properties.

neurosecretory
: Referring to a cell type that will secrete a substance, such as a hormone, in response to neuronal signals.

adrenal
: Referring to the hormone-producing secretory glands that sit above the kidneys.

transdifferentiation
: Transition by a cell from one differentiation lineage into the phenotypic state characteristic of cells from another, distinct differentiation lineage.

epithelial–mesenchymal transition
: Cell-biological program enabling acquisition by epithelial cells of some of the phenotypes of mesenchymal cells such as fibroblasts. *Compare* **mesenchymal–epithelial transition**.

teratoma
: Benign tumor formed by embryonic stem cells in which a wide variety of differentiated cell types are formed.

germ cell
: An egg (ovum) or sperm (spermatocyte) or its immediate precursor within the ovary or testis, respectively.

ectopic
: (1) Referring to the expression of a gene or protein in a location or physiological situation where it normally would not be expressed. (2)

Referring to the presence of cells or tissues in an anatomical site where they would not naturally be found in the body. *See also* **orthotopic**.

anaplastic

(Referring to a tumor) having a tissue and cellular architecture lacking the differentiated characteristics of an identifiable tissue-of-origin or tumor type.

cancer of unknown primary

A tumor, often a metastasis, whose histopathological appearance does not permit a determination of its tissue-of-origin within a patient. *See also* **primary tumor**.

pluripotent

Referring to the ability of a stem cell to generate progeny that can participate in the formation of all of the tissues of an embryo except the extraembryonic membranes. *See also* **multipotent**, **totipotent**.

embryonic stem cell

A cell that derives from the inner cell mass of an early embryo and exhibits pluripotent powers, being able to spawn derivatives that can differentiate into all the cell types of an embryo except the placenta. *See also* **pluripotent**.

dedifferentiation

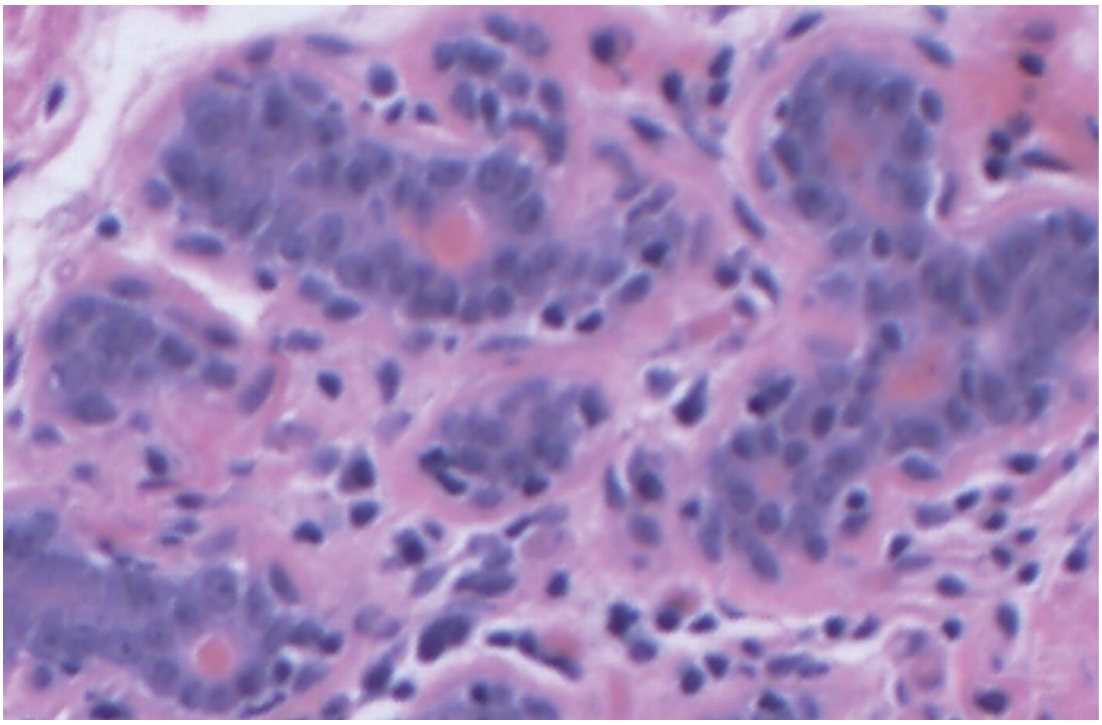
Reversion of a more differentiated cell to the phenotype of a less differentiated cell, such as its stem cell precursor.

OceanofPDF.com

2.4 Cancers seem to develop progressively

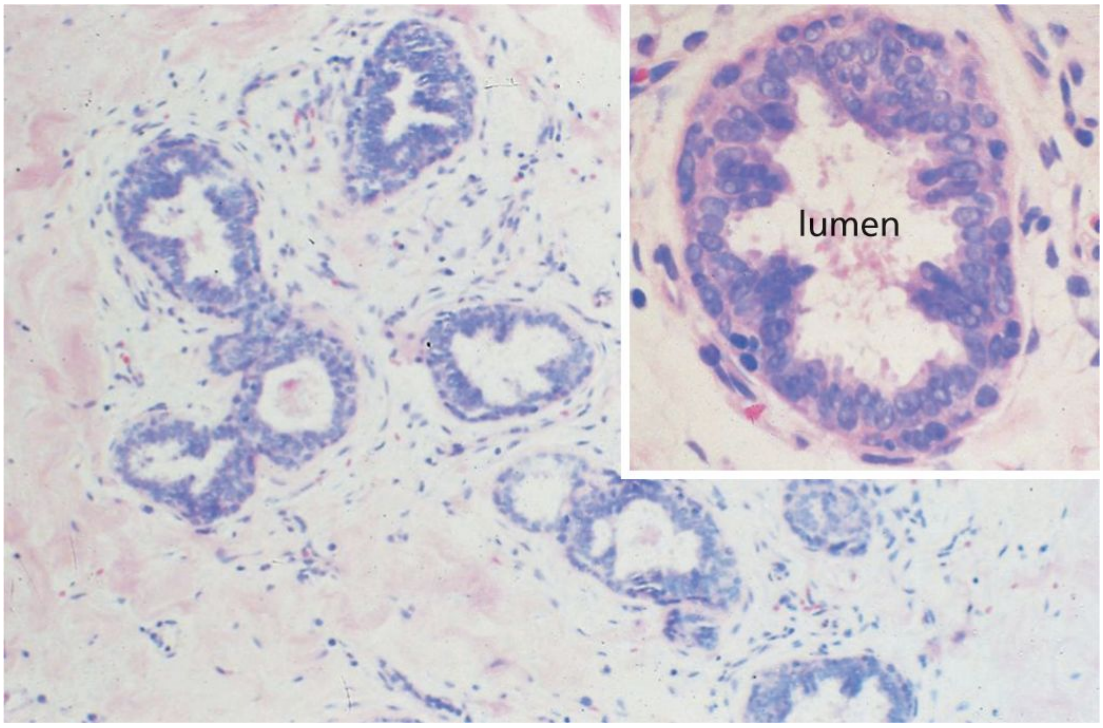
Between the two extremes of fully normal and highly malignant tissue architectures lies a broad spectrum of tissues of intermediate histopathological appearance. The different gradations of abnormality may well reflect cell populations that are evolving progressively toward greater degrees of aggressive and invasive behavior. Thus, each type of abnormal growth detected within a tissue may represent a distinct step along this evolutionary pathway. If so, these architectures suggest, but hardly prove, that the development of tumors is a complex, multi-step process, a subject that is discussed in great detail in Chapter 11.

Some growths contain cells that deviate only minimally from those of normal tissues but may nevertheless be abnormal in that they contain excessive *numbers* of cells. Such growths are termed hyperplastic (**Figure 2.11**). In spite of their apparently deregulated proliferation, the cells forming hyperplastic growths have retained the ability to assemble into tissues that appear reasonably normal.



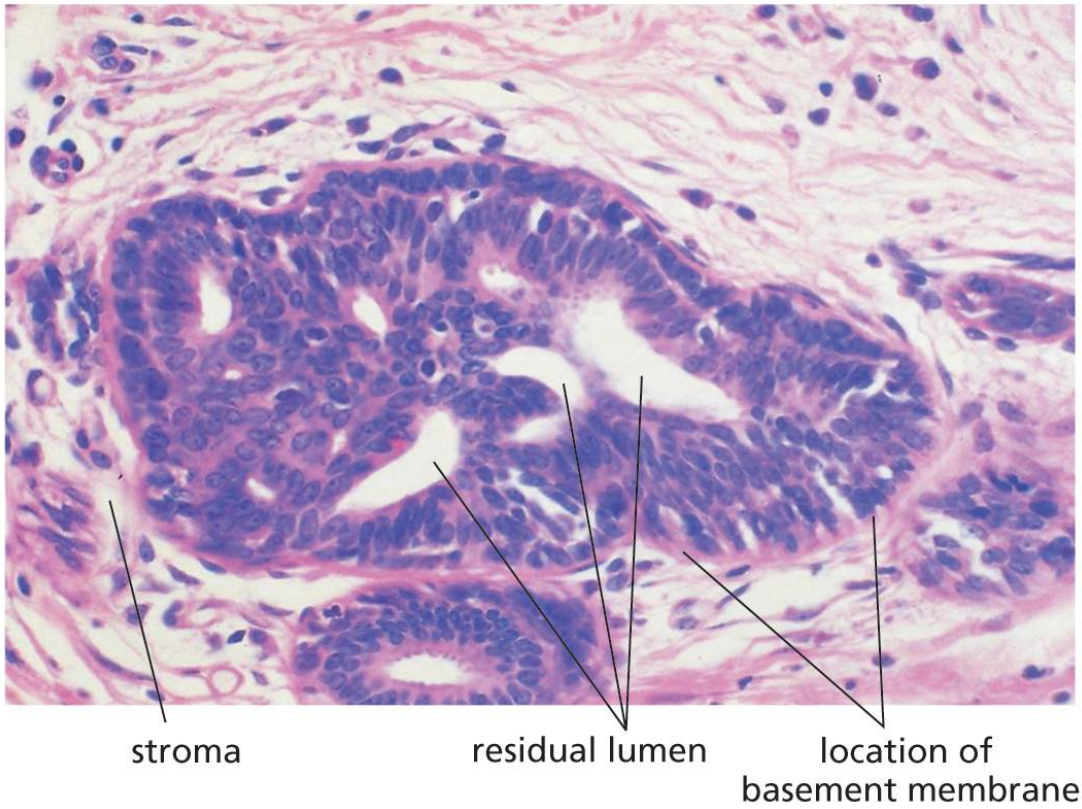
Part A shows normal mammary gland tissue. It is only mildly differentiated into dark, densely packed clusters of epithelial cells within lighter tissue.

(A)



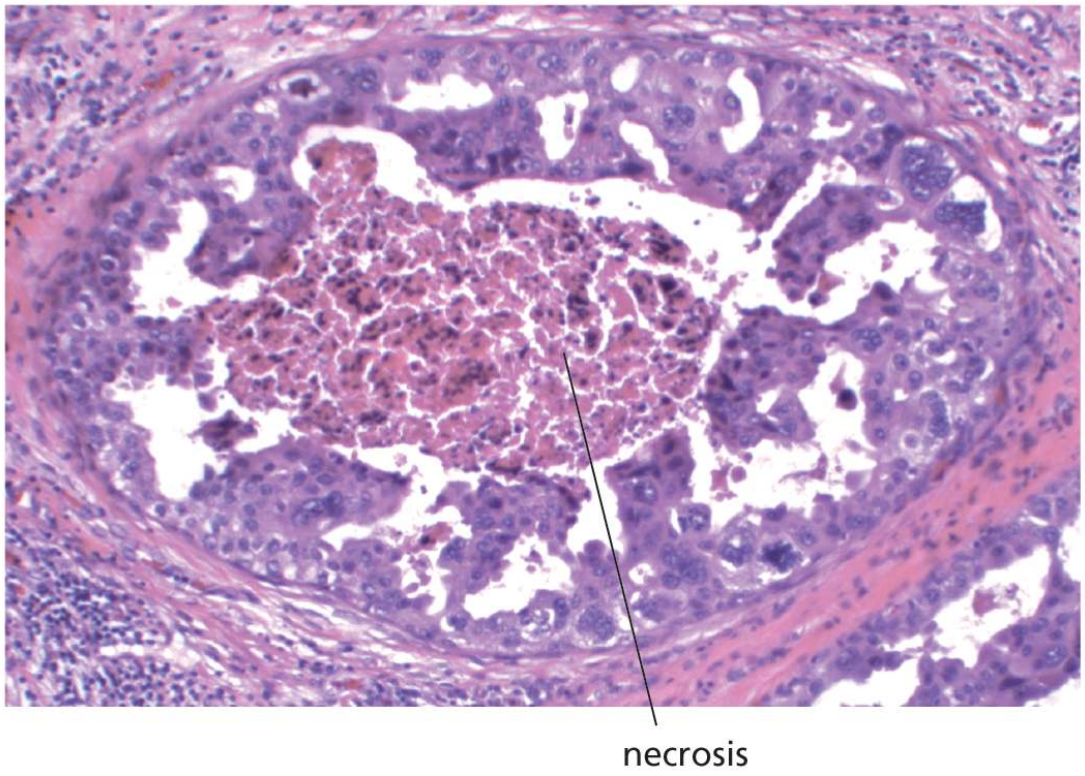
Part B shows mildly hyperplastic mammary gland tissue. It is fairly sharply differentiated into thick, dark epithelial rings each separating a lumen on the inside from much lighter tissue on the outside. An inset shows a dark ring sending spiky projections inward, into the lumen.

(B)



Part C shows severely hyperplastic mammary gland tissue. Epithelial rings have thickened to almost close the inner lumen shut. A few remaining white regions are labeled residual lumen. The tissue outside the rings is labeled stroma. The outer layer of the mass of epithelial tissue is a thin pink layer labeled location of basement membrane.

(C)

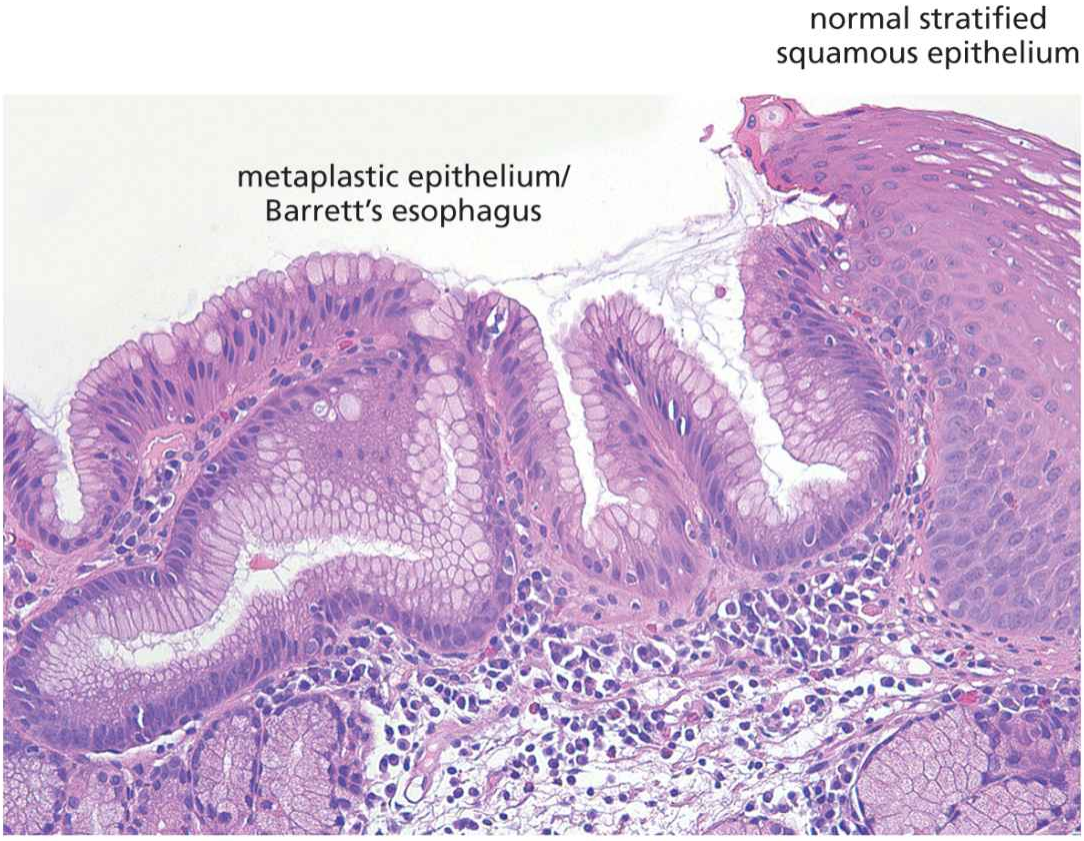


Part D shows an epithelial mass in which the lumen has completely disappeared but irregular open spaces have reappeared due to die-off of the epithelial tissue in the center of the mass. The dead center is labeled necrosis.

(D)

Figure 2.11 Progression of normal mammary tissue to ductal carcinoma *in situ* The morphology of the normal ductal epithelium of the mammary gland, termed a normal terminal ductal lobular unit (A), can be compared with mildly hyperplastic milk ducts (B), shown at low magnification and high magnification (*inset*), in which mammary epithelial cells have begun to form piles that protrude into the lumina. (C) A more advanced hyperplastic mammary duct shows epithelial cells that are crowded together and almost completely fill the lumen. (D) In this ductal carcinoma *in situ* (DCIS) the pre-neoplastic cells have proliferated to generate a mass that fills the lumen of a duct and has then suffered necrosis, ostensibly because they lacked access to an adequate blood supply. However, the involved cells have not penetrated the basement membrane (*not visible*) and invaded the surrounding stroma. (A and D, Courtesy of Deborah Dillon. B and C, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier.)

An equally minimal deviation from normal is seen in metaplasia, where one type of normal cell layer within a tissue is displaced by cells of another type that are not normally encountered there. These invaders, although present in the wrong location, often appear completely normal under the microscope. Metaplasia is most frequent in epithelial transition zones where one type of epithelium meets another. Transition zones like these are found at the junction of the cervix with the uterus and the junction of the esophagus and the stomach. In both locations, a squamous epithelium normally undergoes an abrupt transition into a mucus-secreting epithelium. For example, an early indication of premalignant change in the esophagus is the metaplastic condition termed Barrett's esophagus, in which the normally present squamous epithelium is replaced by secretory epithelial cells of a type usually found within the stomach (**Figure 2.12**). Even though these gastric cells have a quite normal appearance, this metaplasia is considered an early step in the development of esophageal adenocarcinomas. Indeed, patients suffering from Barrett's esophagus have a thirtyfold increased risk of eventually developing these highly malignant tumors.



Esophageal epithelial tissue undergoing metaplastic conversion. On the right is normal stratified squamous epithelium, with a layer of flattened cells on the surface. On the left is metaplastic epithelium or Barrett's esophagus. This epithelium is more characteristic of stomach lining. The surface cells are columnar

and the epithelium is multiply folded. The image shows a gradual transition between the two types of epithelium.

Figure 2.12 Metaplastic conversion of epithelia In certain precancerous conditions, the normally present epithelium is replaced by an epithelium from a nearby tissue—the process of metaplasia. For example, in Barrett's esophagus (sometimes termed Barrett's esophagitis), the squamous cells that normally line the wall of the esophagus (residual squamous mucosa) are replaced by secretory cells that migrate from the lining of the stomach (metaplastic Barrett's epithelium). This particular metaplasia, which is provoked by chronic acid reflux from the stomach, can progress to an esophageal carcinoma, which occurs in ~0.5% of Barrett's esophagus patients per year. As seen here, the *left three-quarters* of this image shows the invading columnar epithelium, which is typical of the gastric mucosa, while the *right quarter* shows the remaining squamous epithelium that is typical of the normal esophagus. (From New England Journal of Medicine, Stuart J. Spechler, M.D., Rhonda F. Souza, M.D., Barrett's Esophagus, 371, 836-45. Copyright © 2014 Massachusetts Medical Society. A slightly more abnormal tissue is said to be dysplastic. Cells within a dysplasia are usually abnormal cytologically, that is, the appearance of individual cells is no longer normal. The cytological changes include variability in nuclear size and shape, increased nuclear staining by dyes, increased ratio of nuclear versus cytoplasmic size, increased mitotic activity, and lack of the cytoplasmic features associated with the normal differentiated cells of the tissue (**Figure 2.13**). In dysplastic growths, the relative proportions of the various cell types seen in the normal tissue are no longer observed. Together, these changes in individual cells and in cell numbers have major effects on the overall tissue architecture. Dysplasia is considered to be a transitional state between completely benign growths and those that are premalignant.

Normal and dysplastic cervical epithelial tissue, side by side in the same sample. On the left, the normal tissue appears as an orderly arrangement of pink cells with dark nuclei. On the right, the dysplastic tissue appears more chaotic and the nuclei are visibly more densely packed together. White arrows point to many small, round inclusions within the dysplastic tissue. The basement membrane separating the epithelium from the underlying stroma runs irregularly left to right across the figure.

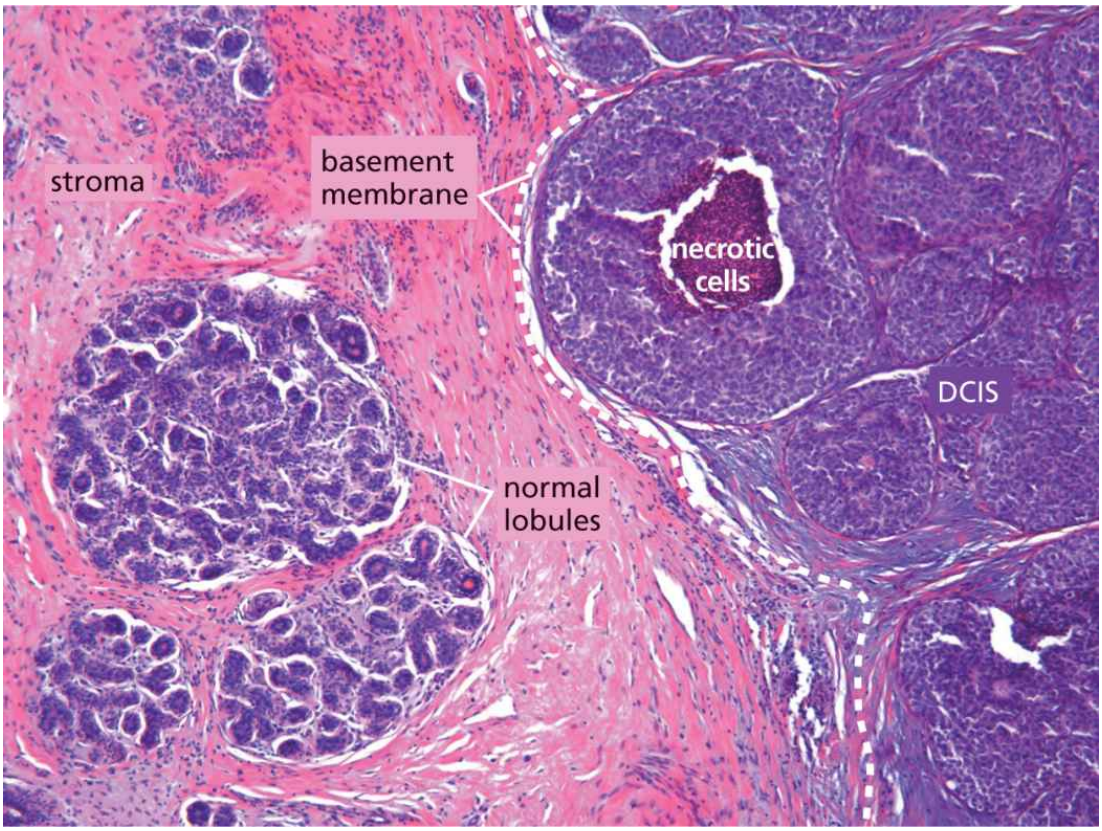
Figure 2.13 Formation of dysplastic epithelium In this intraepithelial squamous neoplasia of the cervix (*to right of white dotted line, large white arrow*), the epithelial cells have not broken through the basement membrane (*not visible, indicated by white dashed line*) and invaded the underlying stroma. The cells in this dysplasia continue to be densely packed all the way to the luminal surface (*above*), in contrast to the more diffuse distribution of cells in the normal epithelium (*left*), whose cytoplasms (*light pink*) increase in size as the cells differentiate. Numerous mitotic figures are also apparent in the dysplasia (*small white arrows*), indicating extensive cell proliferation. (Courtesy of T.A. Ince.)

Even more abnormal are the growths that are seen in epithelial tissues and termed variously adenomas, polyps, adenomatous polyps, papillomas, and, in skin, warts

(**Figure 2.14**). These are often large growths that can be readily detected with the naked eye. They contain all the cell types found in the normal epithelial tissue, but this assemblage of cells has launched a program of substantial expansion, creating a macroscopic mass. Under the microscope, the tissue within these adenomatous growths is seen to be dysplastic. These tumors usually grow to a certain size and then stop growing, and they respect the boundary created by the basement membrane, which continues to separate them from the underlying stroma. Since adenomatous growths do not penetrate the basement membrane and invade underlying tissues, they are considered to be benign.

A polyp protruding from the surface of a colon wall. It looks like a tree rising above a landscape of round shrubs.

(A)



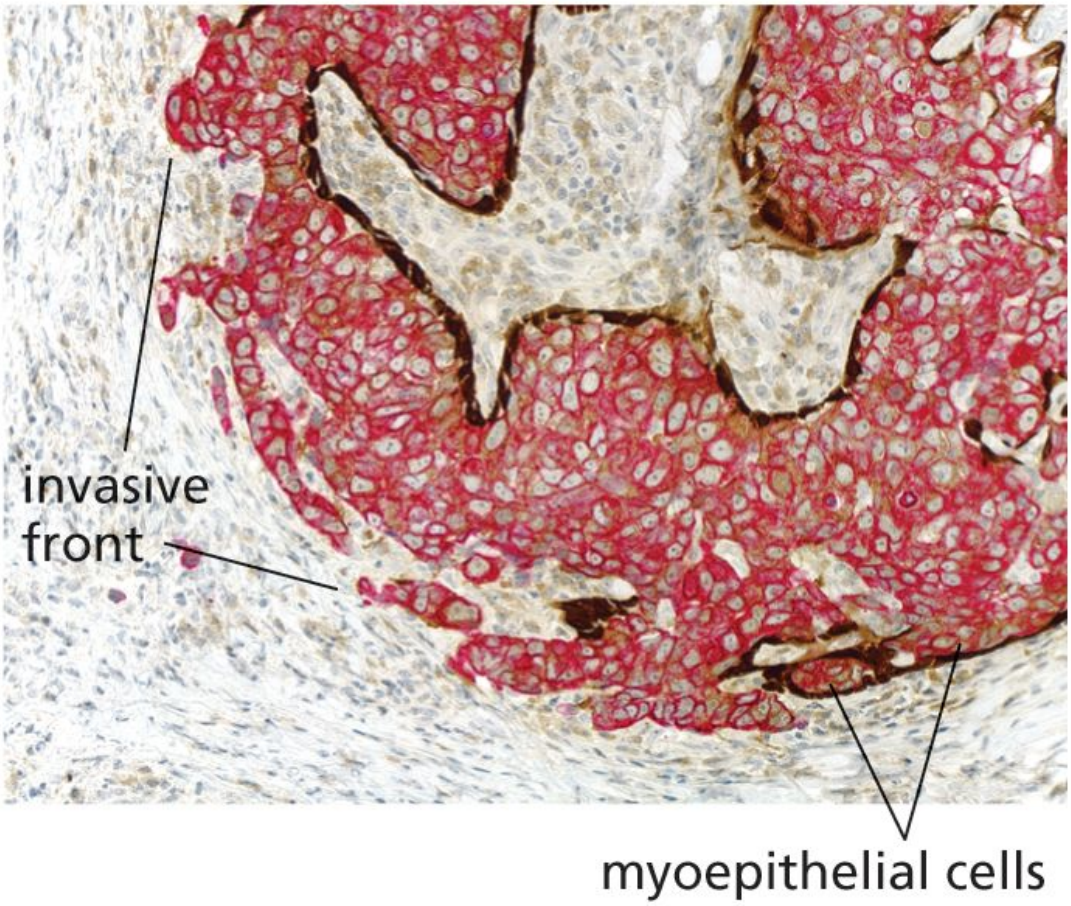
A micrograph of normal and cancerous breast tissue, side by side in the same sample. On the left is normal tissue, with milk-producing lobules that appear purple within the pink stroma surrounding them. Each lobule is a clump of small, round structures. On the right, separated from the normal tissue by basement membrane, is cancerous tissue labeled D C I S. It consists of large purple lumps packed together, with no visible stroma. In one of the lumps, the center has cracked away from its surroundings and appears redder than the other cells. This area is labeled necrotic cells.

(B)

Figure 2.14 Pre-invasive adenomas and carcinomas Adenomatous growths, termed polyps in certain organs, have a morphology that sets them clearly apart from normal and dysplastic epithelium. (A) In the colon, pre-invasive growths appear as either flat thickenings of the colonic wall (sessile polyps; *not shown*) or as the stalk-like growths (pedunculated polyps) shown here in a photograph. These growths, also termed “adenomas,” have not penetrated the basement membrane and invaded the underlying stroma. (B) The lobules of the normal human breast (*purple islands, left half of figure*), each containing numerous small alveoli in which milk is produced, are surrounded by extensive fibrous stroma (*pink*). The cells of an intraductal carcinoma, often called a ductal carcinoma *in situ* (DCIS;

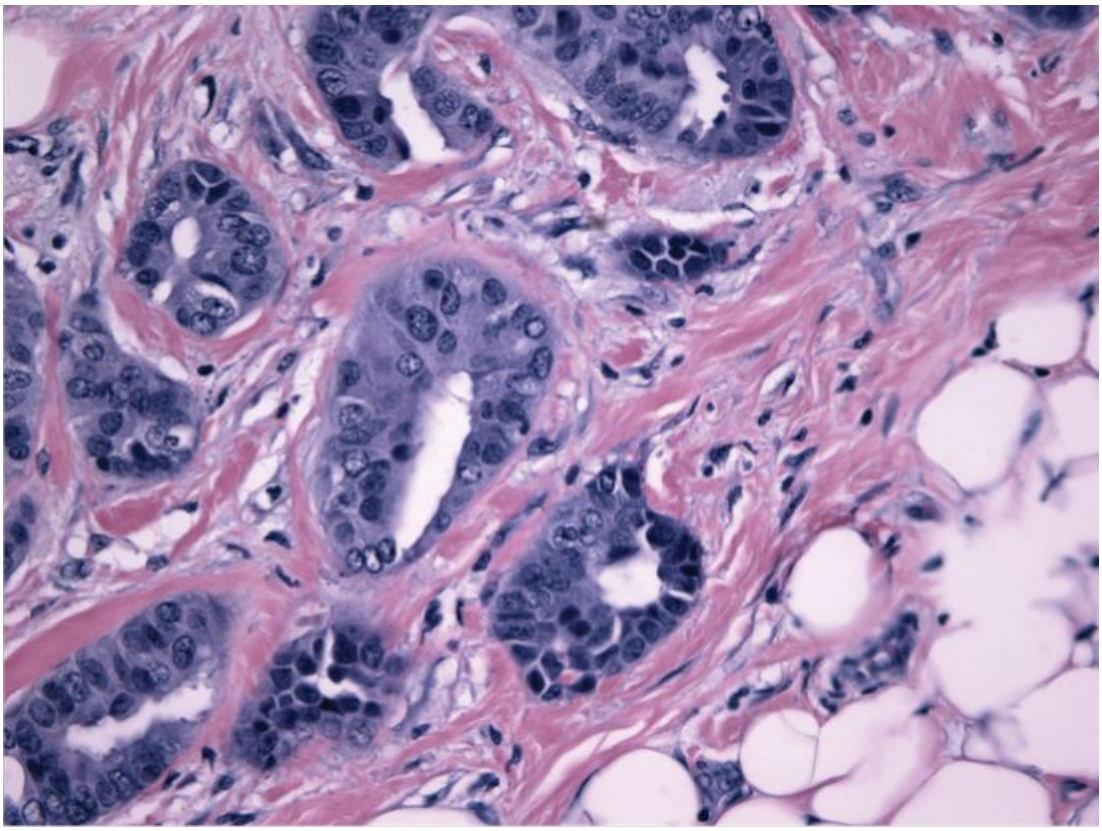
purple, to right of dashed line), fill and distend ducts but have not invaded through the basement membrane surrounding the ducts into the stroma. In the middle of one of these ducts is an island of necrotic carcinoma cells (*dark red*) that have died ostensibly because of inadequate access to the circulation. (A, courtesy of J. Northover and Cancer Research, UK. B, courtesy of T.A. Ince.)

A further degree of abnormality is represented by growths that do indeed invade underlying tissues. In the case of carcinomas, this incursion is signaled the moment carcinoma cells break through a basement membrane and invade into the adjacent stroma (**Figure 2.15**). Here, for the first time, we encounter malignant cells that have a substantial potential of threatening the life of the individual who carries them. Clinical oncologists and surgeons often reserve the word cancer for these and even more abnormal growths. However, in this book, as in much of contemporary cancer research, the word cancer is used more loosely to include all types of abnormal growths. (In the case of epithelial tissues, the term "carcinoma" is usually applied to growths that have acquired this degree of invasiveness.) This disparate collection of growths—both benign and malignant—are called collectively neoplasms, that is, new types of tissue. (Some reserve the term "neoplasm" for malignant tumors.) A summary of the overall pathological classification scheme of tumors is provided in **Figure 2.16**. A short discussion of some of the principles and techniques enabling these classifications can be found in **Supplementary Sidebar 2.4**.



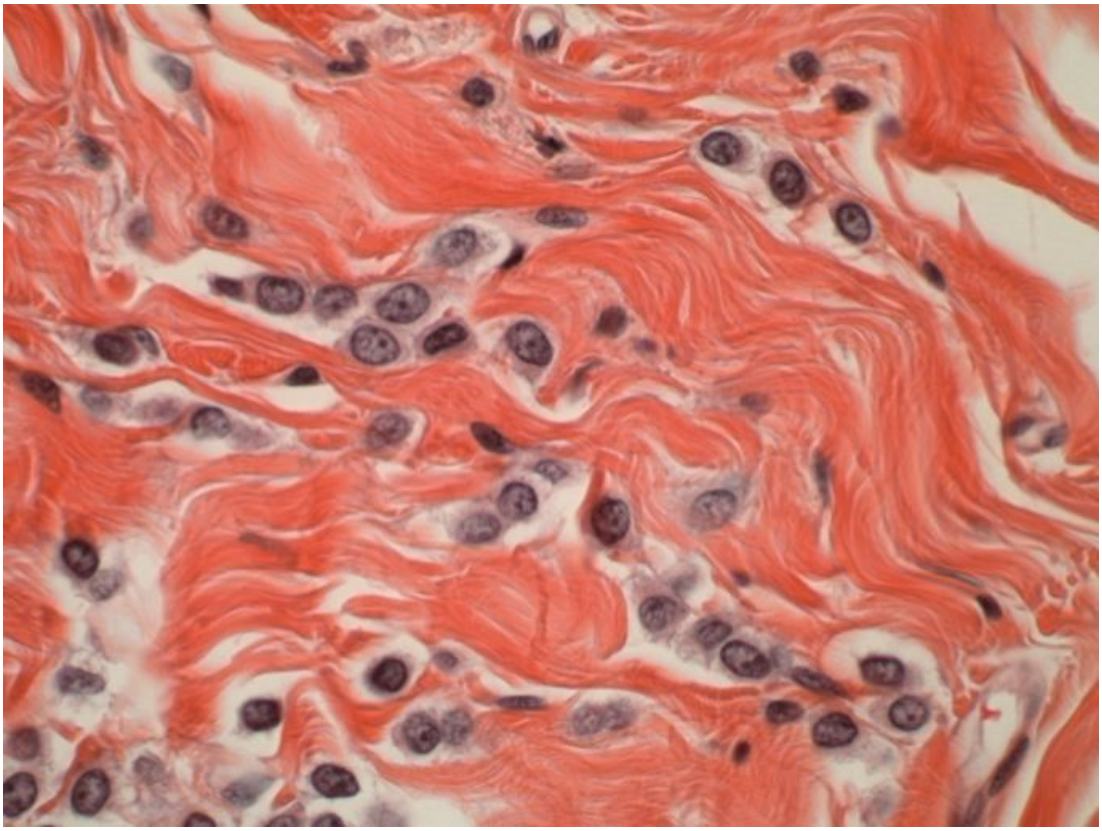
A region of dark red cancer cells appears beside two regions of pale gray stroma cells. In the upper middle and on the right, a thin border of dark brown myoepithelial cells separates the red and the gray. However, in an arc from the lower middle to the upper left, there is no such border, and the red cells are pushing irregularly into the gray area. This arc is the invasive front.

(A)



Rings of dark purple epithelial cancer cells, each ring enclosing a lumen, are interspersed amid dark pink stroma tissue.

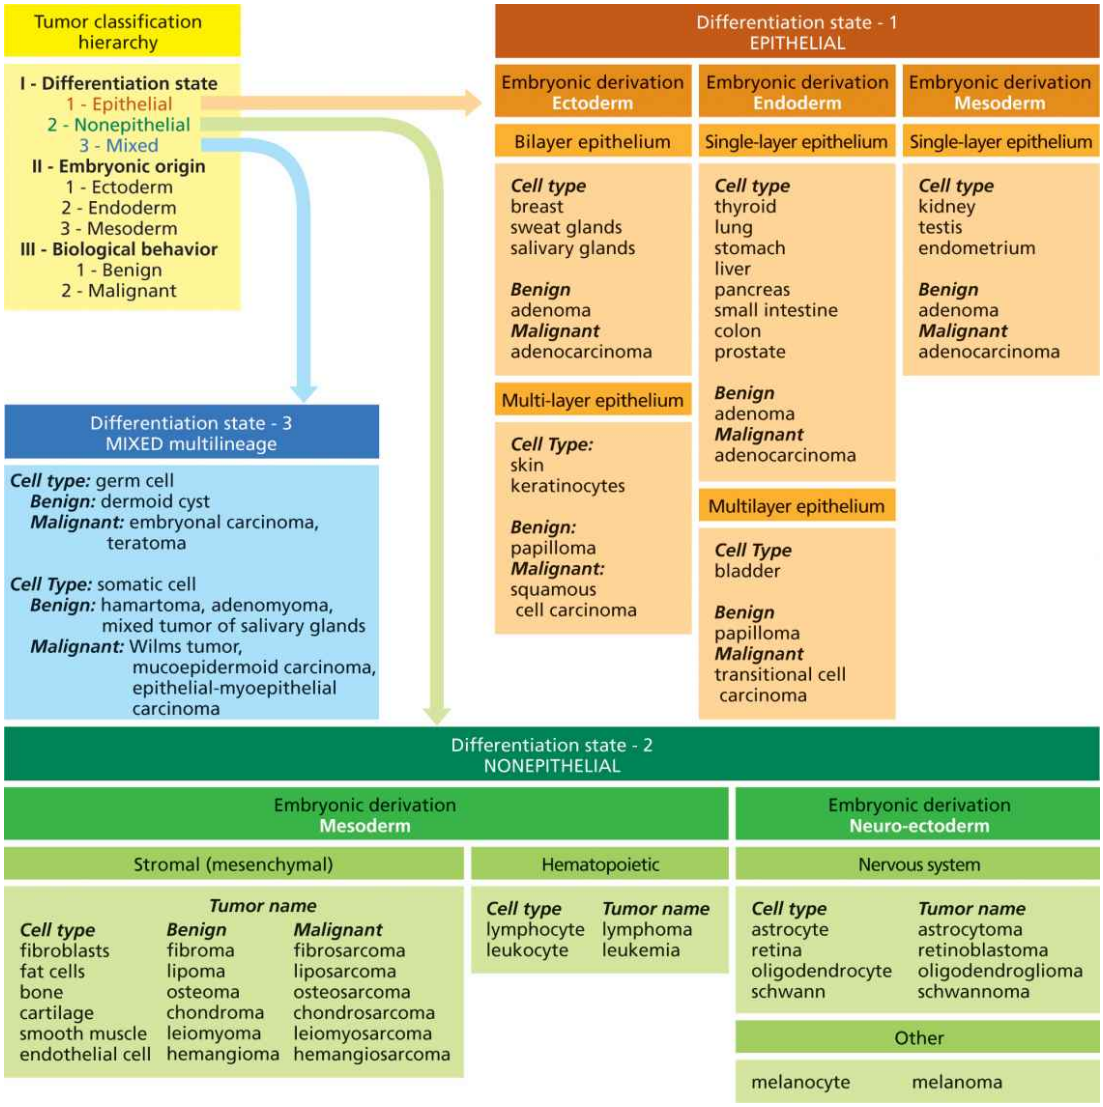
(B)



Striated stroma tissue appears as deep orange. Pale cancer cells with dark purple nuclei look like dark berries in a current of orange water.

(C)

Figure 2.15 Invasive carcinomas Tumors are considered malignant only after they have breached the basement membrane and invaded the surrounding stroma. (A) These breast cancer cells (*dark red*), which previously constituted a ductal carcinoma *in situ* (DCIS; see Figure 2.14B), have now broken through on a broad front the layer of myoepithelial cells (*dark brown, lower right*) and underlying attached basement membrane (*not visible*) into the stroma; this indicates that they have acquired a new trait: invasiveness. (B) After breaching the basement membrane, invasive cancer cells can appear in various configurations amid the stroma. In this invasive ductal carcinoma of the breast, islands of epithelial cancer cells (*dark purple*) are interspersed amid the stroma (*dark pink*). The ductal nature of this carcinoma is revealed by the numerous rudimentary ducts formed by the breast cancer cells. (C) In this invasive lobular carcinoma of the breast, individual carcinoma cells (*dark purple nuclei*) have ventured into the stroma (*red-orange*), often doing so in single-file formation. (A, from F. Koerner, Diagnostic Problems in Breast Pathology. Philadelphia: Saunders/Elsevier, 2008. With permission from Elsevier. B and C, courtesy of T.A. Ince.)



A classification scheme for tumors. Tumors are classified by Differentiation state, Embryonic origin, and Biological behavior.

Differentiation state 1 is epithelial. These cells may be derived from embryonic ectoderm, endoderm, or mesoderm.

Cells derived from embryonic ectoderm may be bilayer or multi-layer epithelium. The bilayer type includes cells in breast tissue, sweat glands, and salivary glands; benign growths are called adenomas, while malignant growths are called adenocarcinomas. The multi-layer type includes skin cells and keratinocytes; benign growths are called papillomas, while malignant growths are called squamous cell carcinomas.

Cells derived from embryonic endoderm may be single-layer or multi-layer epithelium. The single-layer type includes cells in the thyroid, lung, stomach, liver, pancreas, small intestine, colon, and prostate. Benign growths are called adenomas, while malignant growths are called adenocarcinomas. The multi-layer type includes cells in the bladder; benign growths are called papillomas, while malignant growths are called transitional cell carcinomas.

Cells derived from embryonic mesoderm are always single-layer epithelium. These include cells in the kidneys, testes, and endometrium. Benign growths are called adenomas, while cancerous growths are called adenocarcinomas.

Differentiation state 2 is nonepithelial. These cells may be derived from embryonic mesoderm or neuro-ectoderm.

Cells derived from embryonic mesoderm may be stromal (mesenchymal) or hematopoietic. There are six stromal types: fibroblasts, which form benign tumors called fibromas and malignant tumors called fibrosarcomas; fat cells, which form benign tumors called lipomas and malignant tumors called liposarcomas; bone cells, which form benign tumors called osteomas and malignant tumors called osteosarcomas; cartilage cells, which form benign tumors called chondromas and malignant tumors called chondrosarcomas; smooth muscle cells, which form benign tumors called leiomyomas and malignant tumors called leiomyosarcomas; and endothelial cells, which form benign tumors called hemangiomas and malignant tumors called hemangiosarcomas.

There are two hematopoietic types: lymphocytes, which form tumors called lymphomas; and leukocytes, which form tumors called leukemia.

Cells derived from embryonic neuro-ectoderm are most associated with the nervous system. There are four types of these: astrocytes, which form tumors called astrocytomas; retinal cells, which form tumors called retinoblastomas; oligodendrocytes, which form tumors called oligodendrogliomas; and schwann cells, which form tumors called schwannomas. The other cells derived from embryonic neuro-ectoderm are melanocytes, which form tumors called melanomas.

Differentiation state 3 is mixed or multilineage. These cells are of two types: germ cells, which form benign tumors called dermoid cysts and malignant tumors called embryonal carcinomas and teratomas; and somatic cells, which form benign tumors called hamartomas, adenomyomas, and mixed tumors of the salivary glands, and malignant tumors called Wilms tumors, mucoepidermoid carcinomas, and epithelial-myoepithelial carcinomas.

Figure 2.16 Classification scheme of tumors A clear understanding of the histopathological classification of tumors is essential for the study of cancer. However, the entire spectrum of tumors arising in various organs and tissues has been difficult to capture in a single classification scheme that is either purely morphologic or purely molecular. This has necessitated the use of histological features of tumor cells together with information about their respective tissues-of-origin, differentiation states, and biological behaviors; together these make it possible to develop a taxonomy of human tumors that has proven useful for the diagnosis and clinical management of most tumors. The scheme for classifying tumors presented here responds to three critical determinants of tumor biology: the embryonic tissue-of-origin and normal cell-of-origin of the tumor, the phenotype of the cell that has undergone transformation (e.g., epithelial vs. mesenchymal), and the extent of progression to a highly malignant state. This scheme allows classification of the great majority of, but not all, human tumors. (Courtesy of T.A. Ince.)

As mentioned earlier, cells in an initially formed primary tumor may seed new tumor colonies at distant sites in the body through the process of metastasis. This process is itself extraordinarily complex, and it depends upon the ability of cancer cells to invade adjacent tissues, to enter into blood and lymph vessels, to migrate through these vessels to distant anatomical sites, to leave the vessels and invade adjacent tissue, and to found new tumor cell colonies at the distant sites. These steps are the subject of detailed discussion in Chapter 14.

Because the various growths cataloged here represent increasing degrees of tissue abnormality, it would seem likely that they are distinct stopping points along the road of tumor progression, in which a normal tissue evolves progressively into one that is highly malignant. However, the precursor–product relationships of these various growths (that is, normal → hyperplastic → dysplastic → neoplastic → metastatic) are only suggested by the above descriptions but by no means proven.

We will postpone until Chapter 11 an in-depth discussion of multi-step tumor progression. Not discussed here are another set of changes that occur in cancer cells as they progress toward high-grade malignancy: their profound changes in metabolism, largely involving energy metabolism. The observed shifts in metabolic pathways appear to be critical for tumor growth, but for reasons that are not yet clear.

Glossary

metaplasia
: Replacement within a tissue of cells of one differentiation lineage by cells belonging to another lineage.

Barrett's esophagus
: Metaplasia in which squamous epithelium of the esophagus is replaced by secretory epithelial cells of a type normally found in the stomach. *See also* **metaplasia**.

adenoma
: (adj., - **omatous**) Any of a series of premalignant, noninvasive growths in various epithelial tissues, many of which have the potential to progress further to carcinomas. *See also* **polyp**.

polyp
: A tumor, usually presumed to be premalignant, protruding into the lumen of an organ, such as gut or bladder, often equated with an adenoma. *See also* **adenoma, polyposis**.

papilloma
: Benign, adenomatous proliferation of epithelial cells; term often used to describe benign lesions of the skin.

cancer
: (1) A clinical condition that is manifested by the presence of one or another type of neoplastic growth. (2) A malignant tumor.

neoplasm
: A tumor. *See also* **neoplasia**.

tumor progression
: (1) Process of multi-step evolution of a normal cell into a fully neoplastic, malignant tumor cell. (2) Evolution of a benign into a malignant cancer cell or growth. (3) Evolution of a premalignant cell from a promoter-dependent to a promoter-independent state.

hyperplasia
: (adj., - **plastic**) (1) Accumulation of excessive numbers of normal-appearing cells within an otherwise normal-appearing tissue. (2) An increase in the size of a tissue or organ, usually due to increased cell number rather than increased size of constituent cells.

dysplasia

(adj., - **plastic**) A premalignant tissue composed of abnormally appearing cells forming a tissue architecture that deviates from normal.

cytology

(adj., -**logical**) (1) Analysis of subcellular structure under the microscope. (2) The microscopic appearance of a cell.

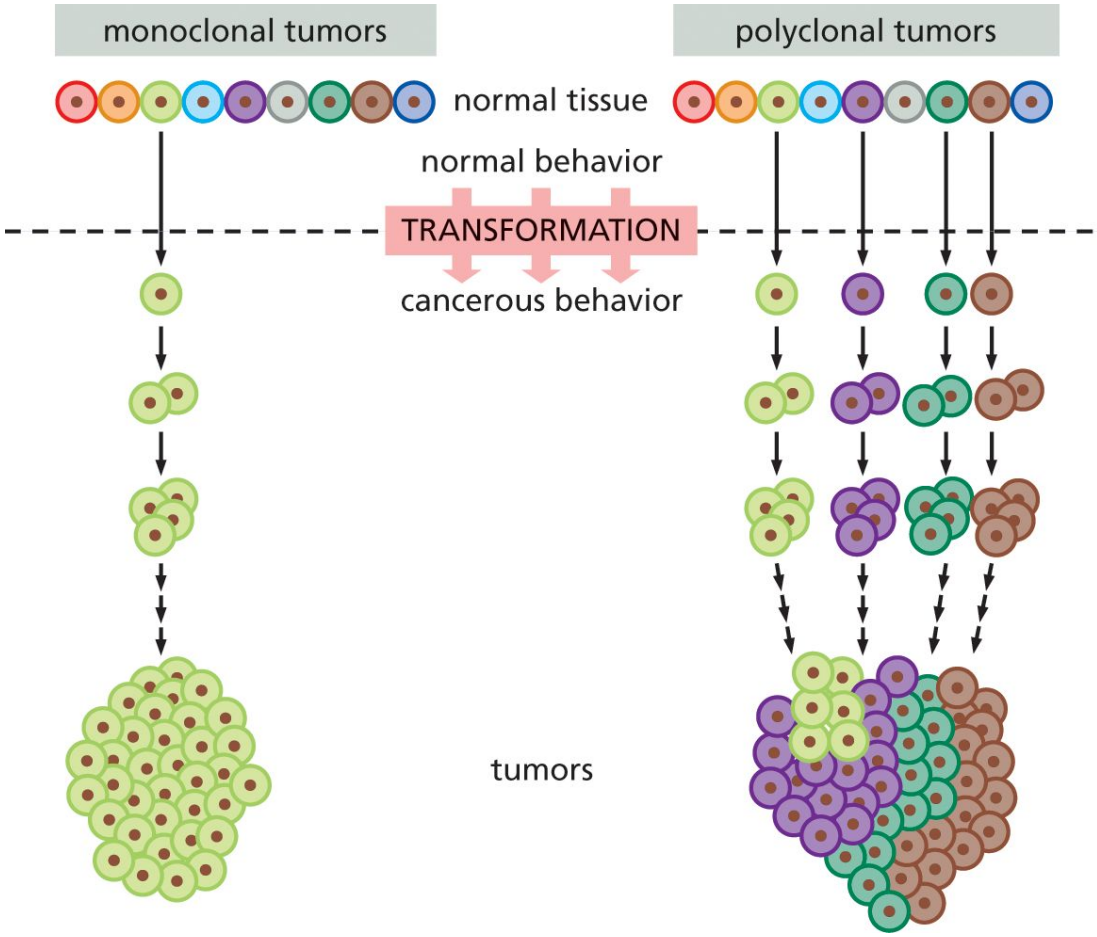
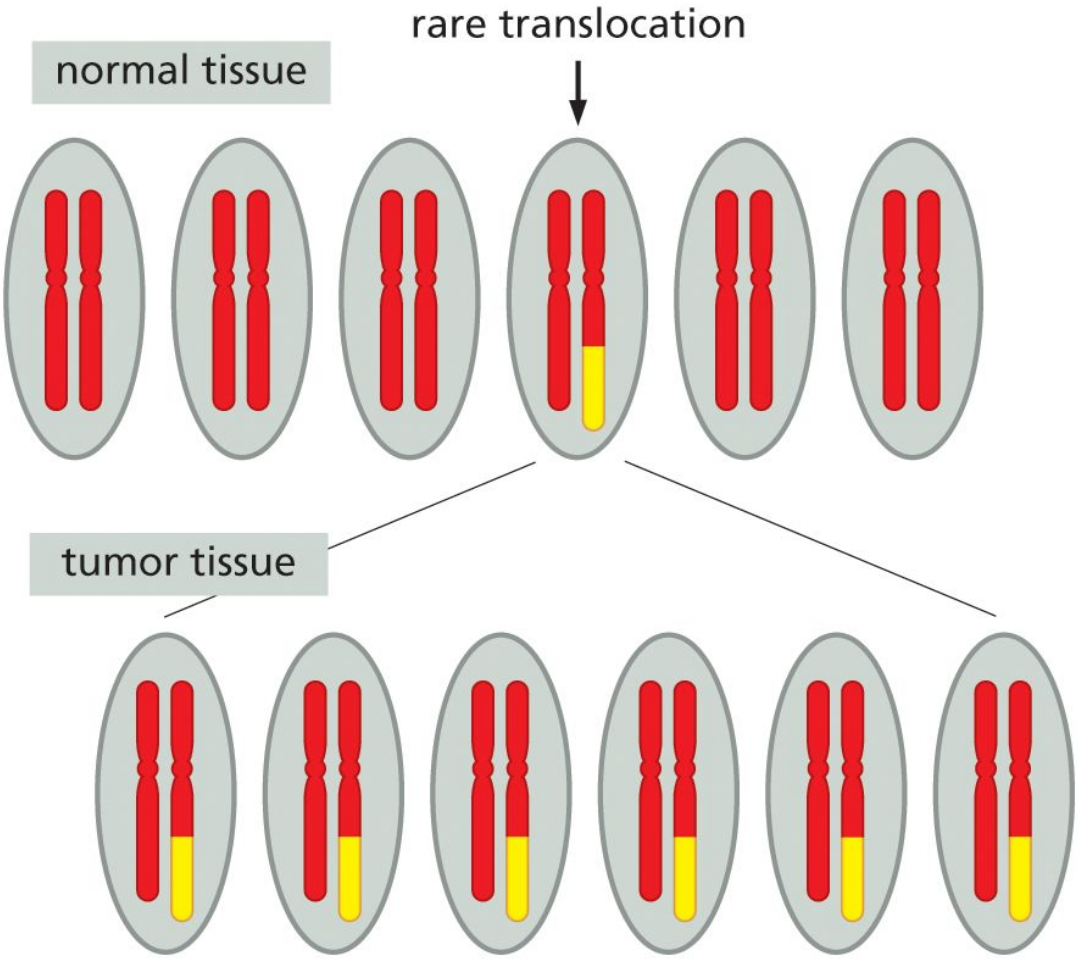
2.5 Tumors are monoclonal growths

Even if we accept the notion that tumors arise through the progressive alteration of normal cells, another question remains unanswered: How many normal cells are the ancestors of those cells that congregate to form a tumor (**Figure 2.17A**)? Do the tumor cells descend from a single ancestral cell that crossed over the boundary from normal to abnormal growth? Or did a large cohort of normal cells undergo this change, each becoming the ancestor of a distinct subpopulation of cells within a tumor mass?



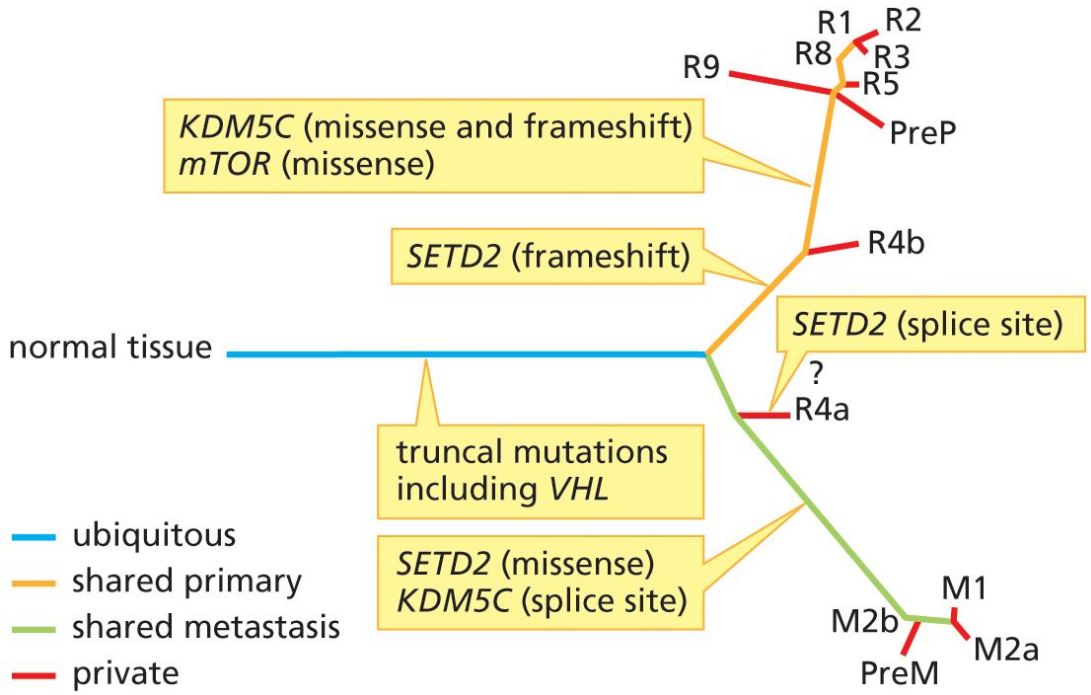
A monoclonal tumor after a single cell type within normal tissue undergoes transformation and multiplies expressing cancerous behavior. It also shows a polyclonal tumor forming after several different cell types within normal tissue undergo transformation, multiply, and the resulting tumors clump together.

(A)



A row of similar, normal tissue cells with a pair of chromosomes in each. One of them contains a rare translocation, an exchange of segments between two different nonhomologous chromosomes. When this cell multiplies, all cells in the resulting tumor tissue have the same translocation.

(B)



A genealogic tree that depicts the genetic relationships between the multiple subpopulations of cells coexisting within an advanced kidney carcinoma. The long blue trunk of the tree begins with normal tissue. Truncal mutations, including V H L, take place along this trunk. This trunk ends with a branching in two directions. In one direction lies an orange branch labeled S E T D 2 (frameshift) and, farther along, K D M 5 C (missense and frameshift) and m T O R (missense). Points along the orange branch, many associated with small red branches, are labeled R1, R2, R3, R5, R8, R9, Pre P, and R4b. In the other direction from branching off the trunk lies a green branch labeled S E T D 2 (missense), K D M 5 C (splice site). Points along the green branch, many associated with small red branches, are labeled M1, M2a, M2b, and Pre M. A small red branch labeled M4a has a question mark by it. This is labeled S E T D 2 (splice site).

(C)

Figure 2.17 Monoclonality versus polyclonality of tumors (A) In theory, tumors may be polyclonal or monoclonal in origin. In a polyclonal tumor (*right*), multiple cells cross over the border from normalcy to malignancy to become the ancestors of several genetically distinct subpopulations of cells within a tumor mass. In a monoclonal tumor (*left*), only a single cell is transformed from normal to cancerous behavior to become the ancestor of the cells in a tumor mass. (B) Illustrated is an unusual translocation (*arrow*) that involves exchange of segments between two different (nonhomologous) chromosomes—a *red* and a *yellow*

chromosome. (Only one of the two chromosomal products of the translocation is shown here.) The translocation creates a characteristic “signature” that distinguishes the affected cell from the surrounding population of karyotypically normal cells (*top row*). Since all of the cancer cells within a subsequently arising tumor carry the identical, rare translocation (*bottom row*), this indicates their descent from a common progenitor in which this translocation initially occurred. (C) As tumors progress, an initial monoclonal cell population descended from a founder cell becomes increasingly heterogeneous due to progressive accumulation of random genetic errors affecting labeled genes; only some of these mutations may create functionally important alleles that drive further tumor progression. Each mutation creates a new genetically distinct subpopulation, and thus each subpopulation is characterized by the unique combination of mutant alleles that it carries. The resulting formation of multiple genetically distinct cancer cell subpopulations, however, disguises the fact that all of these subpopulations of cells trace their origins to a common genetic founding population that already carried its own set of mutations (e.g., *VHL*); these commonly shared (ubiquitous) mutant alleles are often termed truncal mutations to reflect their presence in the trunk (*blue*) of the genealogic tree that depicts the genetic relationships between the multiple subpopulations of cells coexisting within an advanced kidney carcinoma under study. The length of the branches is calculated by the numbers of random genetic errors accumulated in intergenic DNA. R, specific sub-regions of the primary tumor; M, metastasis; PreP, primary tumor sample isolated before chemotherapy; PreM, metastasis isolated before chemotherapy; private, found uniquely in this sample. (R4a and R4b are the subclones detected in R4. A question mark indicates that the detected *SETD2* splice-site mutation probably resides in R4a, whereas R4b most likely shares the *SETD2* frameshift mutation also found in other primary-tumor regions.) The fact that three subpopulations independently acquired a mutation in the *SETD2* gene indicates that each acquired significant proliferative advantage from mutation of this particular gene beyond the advantage conferred by the existing truncal mutations. (C, from M. Gerlinger et al., *New Engl. J. Med.* 366:883–892, 2012. With permission from Massachusetts Medical Society.)

The most effective way of addressing this issue is to determine whether all the cells in a tumor share a common, highly unique genetic or biochemical marker. For example, a randomly occurring somatic mutation might mark a cell in a very unusual way. If this particular genetic marker were present in all cells within a tumor, this would indicate that they all descend from an initially mutated cell. Such a population of cells, all of which derive from a common ancestral cell, is said to be monoclonal. Alternatively, if the tumor mass were composed of a series of genetically distinct subpopulations of cells that give no indication of a common origin, it can considered to be polyclonal.

A number of experimental strategies have been pursued to demonstrate the monoclonality of the neoplastic cells within a tumor (**Supplementary Sidebar 2.5**). Perhaps the most vivid demonstrations of tumor monoclonality have come from cancer cells sporting a variety of chromosomal aberrations that can be visualized microscopically when chromosomes condense during metaphase of mitosis. Often, a very peculiar chromosomal abnormality—the clear result of a rare random genetic accident—is seen in all the cancer cells within a tumor mass (Figure 2.17B). This observation makes it obvious that all the malignant cells within this tumor descend from the single ancestral cell in which this unusual chromosomal restructuring originally occurred.

While such observations seem to provide compelling proof that tumor populations are monoclonal, tumorigenesis may actually be more complex. Let us imagine, as a counterexample, that 10 normal cells in a tissue simultaneously crossed over the border from being normal to being malignant (or at least premalignant) and that each of these cells, and its descendants in turn, proliferated uncontrollably. Each of these founding cells would spawn a large monoclonal population, and the tumor mass, as a whole, consisting of a mixture of these 10 cell populations, would be polyclonal.

It is highly likely that each of these 10 clonal populations varies subtly from the other 9 in a number of characteristics, among them the time required for their cells to double. Simple mathematics indicates that a cell population that exhibits a slightly shorter doubling time will, sooner or later, outgrow all the others, and that the descendants of these cells will dominate in the tumor mass, creating what will appear to be a monoclonal tumor. In fact, many tumors seem to develop over decades, which is plenty of time for one clonal subpopulation to dominate in the overall tumor cell population. Hence, the monoclonality of the cells in a large tumor mass hardly proves that this tumor was strictly monoclonal during the early stages of its development.

As we will discuss in great detail in Chapters 11 and 12, the population of cells within a tumor may begin as a relatively homogeneous collection of cells (thereby constituting a true monoclonal growth), but soon may become quite heterogeneous because of the continual acquisition of new mutant alleles by some of its cells, this being the consequence of the elevated genetic instability observed in most neoplastic cells (described in Chapter 12). The great majority of acquired variant alleles may have minimal if any effects on the phenotype of the evolving cancer cells belonging to a subpopulation of cancer cells, neither aiding nor hindering their proliferation and thus their representation among the larger populations of cancer cells within a tumor. However, each of these mutant alleles demarcates a genetically distinct subclone and the tumor, as a whole, becomes polyclonal. In fact, analyses of the genomes of the cells within such a tumor generates the analog of a genealogical tree, with repeated cycles of branching and outgrowth of genetically distinct subpopulations (Figure 2.17C). Indeed, the accumulated genetic intra-tumoral heterogeneity may mask the

true monoclonal origin of the cells within this tumor. However, as the tree of Figure 2.17C reveals, all the variant subpopulations within a tumor will still share in common a mutation or set of mutant alleles that can be ascribed to a common ancestral population at the trunk of the tree, leading to the increasingly used term of truncal mutations. As we will see in Chapters 16 and 17, this genetic diversification of tumor cells holds important implications for cancer therapy and the successful eradication of populations of cancer cells.

OceanofPDF.com

Glossary

monoclonal
: Describing a population of cells, all of which derive by direct descent from a single common ancestral cell. *See also* **oligoclonal**, **polyclonal**.

polyclonal
: Describing a population of cells that trace their origins to multiple founding ancestral cells. *See also* **monoclonal**, **oligoclonal**.

truncal
: Referring to a genetic alteration that is present in the genomes of all of the otherwise-heterogeneous neoplastic cells within a tumor and is indicative of their shared descent from a common ancestral cell; such mutations are associated with the trunk of a branched tree drawn to depict graphically the evolutionary history of these cells from their common ancestor.

2.6 Cancers occur with vastly different frequencies in different human populations

The nature of cancer suggests that it is a disease of chaos, a breakdown of existing biological order within the body. More specifically, the disorder seen in cancer appears to derive directly from malfunctioning of the controls that are normally responsible for determining when and where cells throughout the body will multiply. In fact, there is ample opportunity for the disorder of cancer to strike a human body. Most of the more than the $\sim 3 \times 10^{13}$ cells in the adult body continue to carry the genetic information that previously allowed them to come into existence and might, in the future, allow them to multiply once again. This explains why the risk of uncontrolled cell proliferation in countless sites throughout the body is substantial throughout the lives of mammals like ourselves.

To be more precise, the risk of cancer is far greater than the $\sim 3 \times 10^{13}$ cell population size would suggest, since this number only represents the average, steady-state population of cells in the body at any point in time during adulthood. The aggregate number of cells that are formed during an average human lifetime is about 10^{16}, a number that testifies to the enormous amount of cell turnover—involving cell death and replacement (almost 10^7 events per second)—that occurs continuously in many tissues in the adult body. As discussed in various ways in Chapters 10 and 12, each time a new cell is formed by the complex process of cell growth and division, there are many opportunities for things to go awry. Hence, the chance for disaster to strike, including the inadvertent formation of cancer cells, is great.

Since a normal biological process (incessant cell division) is likely to create a substantial risk of cancer, it would seem logical that human populations throughout the world would experience similar frequencies of cancer. However, when cancer incidence rates (that is, the rates with which the disease is diagnosed) are examined in various countries, we learn that the risks of many types of cancer seem to vary dramatically (**Table 2.5**), while other cancers (not indicated in this table) do indeed show comparable incidence rates across the

globe. So, our speculation that all cancers should strike different human populations at comparable rates is simply wrong. Some do and some don't. But we need to be cautious here, simply because incidence rates for certain cancers may be highly misleading—the consequence of diagnostic bias (**Sidebar 2.1**).

Table 2.5 Geographic variation in cancer incidence and death rates

Countries showing highest and lowest incidence of specific types of cancer[a]			
Cancer site	**Country of highest risk**	**Country of lowest risk**	**Relative risk H/L**[b]
Skin (melanoma)	Australia (Queensland)	Japan	155
Lip	Canada (Newfoundland)	Japan	151
Nasopharynx	Hong Kong	United Kingdom	100
Prostate	U.S. (African American)	China	70
Liver	China (Shanghai)	Canada (Nova Scotia)	49
Penis	Brazil	Israel (Ashkenazic)	42
Cervix (uterus)	Brazil	Israel (non-Jews)	28

Countries showing highest and lowest incidence of specific types of cancer[a]			
Cancer site	**Country of highest risk**	**Country of lowest risk**	**Relative risk H/L**[b]
Stomach	Japan	Kuwait	22
Lung	U.S. (Louisiana, African American)	India (Madras)	19
Pancreas	U.S. (Los Angeles, Korean American)	India	11
Ovary	New Zealand (Polynesian)	Kuwait	8
Geographic areas showing highest and lowest death rates from specific types of cancer[c]			
Cancer site	**Area of highest risk**	**Area of lowest risk**	**Relative risk H/L**[b]
Lung, male	Eastern Europe	West Africa	33
Esophagus	Southern Africa	West Africa	16
Colon, male	Australia, New Zealand	Middle Africa	15

Countries showing highest and lowest incidence of specific types of cancer[a]			
Cancer site	**Country of highest risk**	**Country of lowest risk**	**Relative risk H/L[b]**
Breast, female	Northern Europe	China	6

Sidebar 2.1 Cancer incidence and mortality rates can be highly misleading

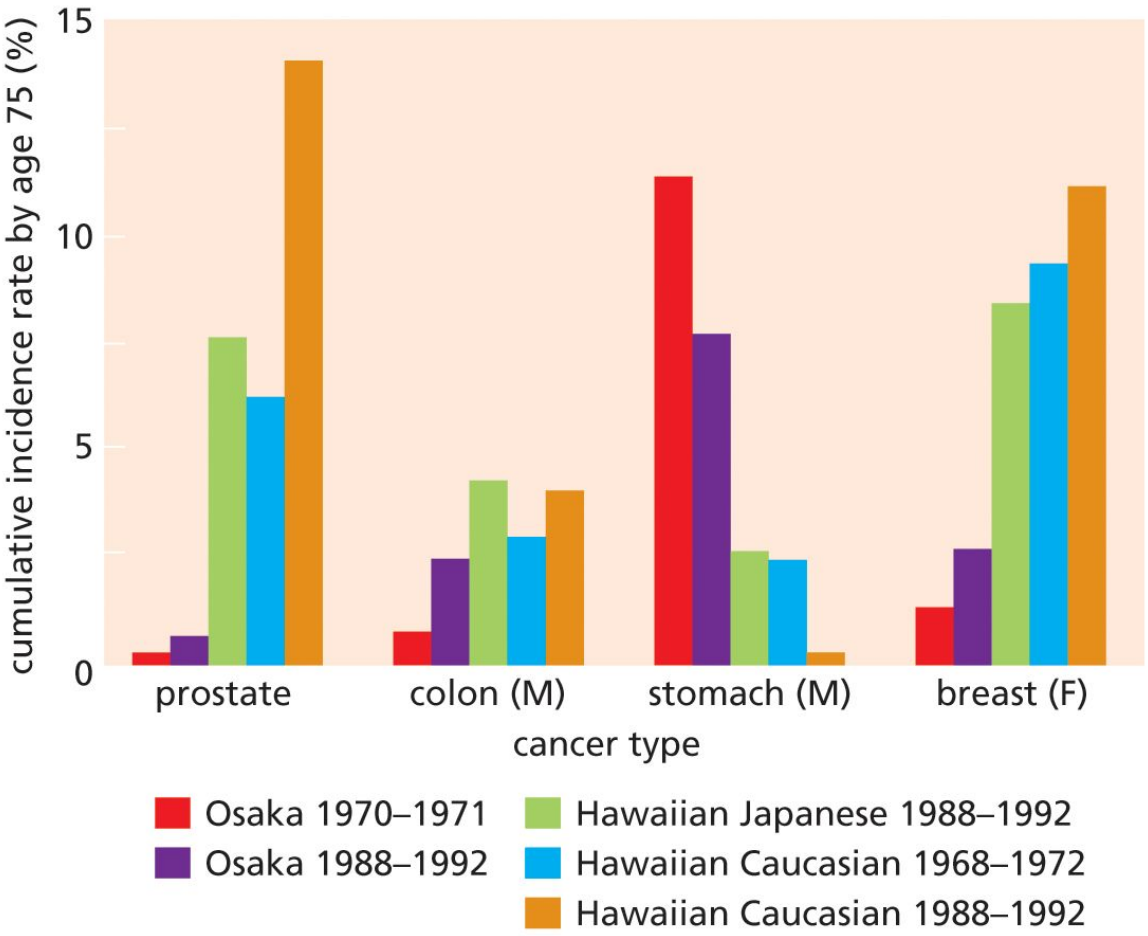
Cancer incidence rates, (reflecting the number of cases diagnosed) and mortality rates are usually presented in an age-adjusted form to compensate for the facts that (1) different cancers tend to arise at different times during the human lifetime and (2) different human populations have different age distributions. These numbers are then corrected for population sizes and often presented in rates per 100,000 of the general population. These corrections, on their own, cannot compensate for the difficulties in gauging the frequencies with which different tumors arise, since the resulting incidence rates are strongly influenced by diagnostic practices and conventions, reflecting the complex problem of diagnostic bias. Thus, as a prominent example, it is unclear how much of the sixfold difference in breast cancer incidence between China and the Western world derives from the relative occurrence of potentially life-threatening cancers in these two populations and how much derives from population-wide screening techniques, in this case by the highly sensitive technique of mammography, which reveals many small growths in the breast that would have remained indolent during the lifetime of the women bearing them and, because of their small size, remained undetected. (In the case of the United States, it is plausible that at least two-thirds of currently diagnosed “breast cancers” fall into this class.)

This explains why incidence rates often reflect the frequency with which population-wide, highly sensitive screening techniques are in force, indicating that for many types of cancer, the alternative metric—age-adjusted mortality rates—provides a more reliable index of the frequency with which life-threatening cancers strike in different populations (simply because deaths represent an unambiguous and easily measured outcome). Even here, we need to be cautious when attempting to assess the true rates at which cancers strike, since different

types of tumor are treated with more or less success in different countries. For example, cancer mortality rates in the United States have declined by almost 35% over the past generation, a reflection of successes in treating them; this decline on its own, would cause us to increase by about 35% our estimate of the rates with which true life-threatening breast cancers are formed each year in the United States. In addition, in many parts of the world, assessments about the causes of death, especially for diseases of internal organs, may not properly reflect the true disease state that led to death.

Table 2.5 indicates that, in spite of these reservations about cancer incidence and mortality rates, some cancers vary dramatically from country to country. Yet other tumor types, not listed in this table, seem to strike with comparable frequencies. Such tumors seem to be caused by random, essentially unavoidable accidents of nature. This seems to be especially true for a number of pediatric tumors that affect children with comparable frequencies across the globe.

Still, as Table 2.5 makes clear, other factors and processes appear to intervene in certain populations to increase dramatically the total number of cancer cases. Some of these differences are so dramatic as to essentially rule out important contributions from diagnostic bias and effectiveness of anti-cancer therapies. The two obvious factors contributing to these stark differences are heredity and environment. Which of these two alternatives is the dominant determinant of the country-to-country variability of cancer incidence and mortality rates? While many types of inherited disease-causing alleles are distributed unequally in the gene pools of different human populations, these inherited genetic factors do not seem to explain the dramatically different incidence and mortality rates of various cancers throughout the world. This point is demonstrated most dramatically by measuring cancer rates in migrant populations. For example, Japanese experience rates of stomach cancer that are 6 to 8 times higher than those of Americans. However, when Japanese settle in the United States, within a generation their offspring exhibit a stomach cancer rate that is comparable to that of the surrounding population (**Figure 2.18**). (Since the majority of those diagnosed with stomach cancer eventually die from the disease, the incidence rates track closely with mortality rates and therefore reflect how often life-threatening disease strikes.)



A bar chart comparing the cumulative incidence rates by age 75 of four different types of cancer in five different populations in Hawaii and Japan. The three Hawaiian populations are Hawaiian Japanese 1988 to 1992, Hawaiian Caucasian 1968 to 1972, and Hawaiian Caucasian 1988 to 1992. The two Japanese populations are Osaka 1970 to 1971 and Osaka 1988 to 1992. Both Japanese populations had extremely low rates of prostate cancer, and relatively rates of colon cancer in males and breast cancer in females, but higher rates of stomach cancer in males: about 12 percent for the early Osaka group and 8 percent for the later one. The three Hawaiian populations all had low to moderately low rates of colon and stomach cancer in males, but fairly high rates of prostate and breast cancer–especially the later Hawaiian Caucasian group, for which the incidence of prostate cancer was about 14 percent and the incidence of breast cancer was about 11 percent. Interestingly, however, this group had the lowest incidence of male stomach cancer of all five groups, less than 1 percent.

Figure 2.18 Country-to-country comparisons of cancer incidence Public health records reveal dramatic differences in the incidence of certain cancers in different countries. Here, the relative incidence rates of a group of cancers in Japan and in the American state of Hawaii are presented. Invariably, after Japanese have immigrated to Hawaii, within a generation their cancer rates approach those of the population that settled there before them. Cancer incidence numbers are strongly influenced by diagnostic bias (see Sidebar 2.1), especially in the cases of prostate and breast cancer. In contrast, the incidence rates of colon and stomach cancer are not strongly influenced by diagnostic bias and are thus more reflective of the frequency of developing life-threatening disease. This indicates that the differing cancer rates are not due to genetic differences between the Japanese and the American populations. M, male; F, female. (From J. Peto, *Nature* 411:390–395, 2001. With permission from Nature.)

As indicated in Table 2.5, the incidence (that is, the risk of developing diagnosed disease) of breast cancer in China was, at one point in time, about one-sixth as great as in the United States or Northern Europe (see Sidebar 2.1). Having excluded genetic contributions to this difference, we might conclude, perhaps simplistically, that as many as 85% of the breast cancers in the United States might in theory be avoidable if only American women were to experience an environment and lifestyle comparable to those of their Chinese counterparts; however, as we read above, these numbers need to be taken with great reservation, given the profound influence of diagnostic bias.

Even within the American population, there are vast differences in cancer mortality: the Seventh-day Adventists, whose religion discourages smoking, heavy drinking, and the consumption of animal protein, die from cancer at rates that are 40% lower for men and 24% lower for women than the general population. These numbers, which are robustly documented, reveal dramatically the key roles of environment within a human population, where “environment” encompasses both the surrounding physical environment and, more importantly in this case, lifestyle practices including prominently diet.

For those who wish to understand the etiologic (causative) mechanisms of cancer, these often-dramatic differences in incidence and mortality lead to an inescapable conclusion: the great majority of the commonly occurring cancers are caused by factors that can vary dramatically between one population and another, and between individuals within each of these populations. Most of these might be

traced to “lifestyle factors,” including smoking, diet and obesity, and physical activity, and to various types of infections; in addition, substantial variations in cancer risk may be attributable to differences in reproductive behavior and the resulting dramatic effects on the hormonal environment within the human female body. When comparing cancer risks across the globe, only a small proportion of the differences in cancer incidence and mortality can be ascribed to differences in genetic predisposition and, it would seem, environmental pollution.

Let us imagine, for the sake of argument, that avoidance of certain cancer-causing factors in diet and overall lifestyle, some discussed below, resulted in a 50% reduction in the risk of dying from cancer in the West, leaving the disease of cancer as the cause of only about 10% of overall mortality in this population. Under these conditions, given the approximately 10^{16} mitoses occurring in each human body during a normal life span, we calculate that only 1 in 10^{17} cell divisions—the total number in aggregate of cell divisions occurring in the bodies of 10 individuals during their lifetimes—would lead directly or indirectly to a clinically detectable cancer. Now, we become persuaded that in spite of the enormous intrinsic risk of developing cancer, the body must be able to mount highly effective defenses that usually succeed in holding off the disease for the 70 or 80 years that most of us spend on this planet. These built-in defenses are the subject of many discussions throughout this book.

Glossary

incidence
: Frequency with which a condition or a disease occurs or is diagnosed in a population.

diagnostic bias
: Tendency of an observation or conclusion to be influenced by the specific properties or applications of a diagnostic technique rather than to accurately reflect an intrinsic property of the entity (such as a disease) under examination.

diagnostic bias
: Tendency of an observation or conclusion to be influenced by the specific properties or applications of a diagnostic technique rather than to accurately reflect an intrinsic property of the entity (such as a disease) under examination.

age-adjusted
: Referring to an epidemiologic measurement, such as disease incidence or mortality, that has been adjusted to compensate for the age distribution of the population under study, allowing rates to be compared between populations having different age distributions.

mammography
: A clinical procedure using X-rays to detect incipient breast cancers.

steady state
: The condition reached when a series of dynamic, often countervailing processes have placed a complex system in a balanced, relatively constant, unchanging state.

etiology
: (adj., - **ologic**) (1) Mechanism or agent that is responsible for causing a specific pathological state. (2) The study of causative mechanisms of pathology.

2.7 The risks of cancers often seem to be increased by assignable influences, including lifestyle

Evidence that certain kinds of cancers are associated with specific exposures or lifestyles is actually quite old, predating modern epidemiology by more than a century. The first known report comes from the observations of the English physician John Hill, who in 1761 noted the connection between the development of nasal cancer and the excessive use of tobacco snuff. Fourteen years later, Percivall Pott, a surgeon in London, reported that he had encountered a substantial number of skin cancers of the scrotum in adolescent men who, in their youth, had worked as chimney sweeps. Within three years, the Danish sweepers guild urged its members to take daily baths to remove the apparently cancer-causing material from their skin. This practice was likely the cause of the markedly lower rate of scrotal cancer in continental Europe when compared with Britain even a century later.

In 1839, an Italian physician reported that breast cancer was a scourge in the nunneries, being present at rates that were six times higher than among women in the general population who had given birth multiple times. By the end of the nineteenth century, it was clear that occupational exposure and lifestyle were closely connected to and apparently causes of a number of types of cancer.

The range of agents that might trigger cancer was expanded with the discovery in the first decade of the twentieth century that physicians and others who experimented with the then-recently invented X-ray tubes experienced increased rates of cancer, often developing tumors at the site of irradiation.

Perhaps the most compelling association between environmental exposure and cancer incidence was forged in 1949 and 1950 when two groups of epidemiologists reported that individuals who were heavy cigarette smokers ran a lifetime risk of lung cancer that was more than twentyfold higher than that of nonsmokers. The initial results of one of these landmark studies are given in **Table 2.6**. These various epidemiologic correlations proved to be critical for

subsequent cancer research, since they suggested that cancers often had specific, assignable causes, and that a chain of causality might one day be traced between these ultimate causes and the cancerous changes observed in certain human tissues. Indeed, in the half century that followed the 1949–1950 reports, epidemiologists identified a variety of lifestyle factors, infections (**Table 2.7**), and exposures to specific agents (see Table 2.8) that were strongly correlated with the incidence of certain cancers (**Figure 2.19**); in a subset of these cases, researchers have been able to discover the specific biological mechanisms through which these etiologic factors act.

Table 2.6 Relative risk of lung cancer as a function of the number of cigarettes smoked per day[a]

A bar chart describing, for both sexes combined, the extent to various modifiable risk factors contribute to avoidable deaths from cancer. For a given risk factor, the length of the bar gives the percent of all cancer deaths attributable to that factor. Also given, for each risk factor, is the corresponding estimate of the number of avoidable deaths in the United States for the year 2014. For all types of cancer, 45.1 percent of deaths were caused by modifiable factors, implying 265,150 potentially avoidable deaths from cancer in 2014. 28.8 percent of cancer deaths, or 169,180 deaths, were caused by smoking. 6.5 percent of cancer deaths, or 38,230 deaths, were caused by excess body weight. 4.0 percent of cancer deaths, or 23,510 deaths, were caused by alcohol consumption. 2.7 percent of cancer deaths, or 15,940 deaths, were caused by low consumption of fruits and vegetables. 2.2 percent of cancer deaths, or 12,800 deaths, were caused by physical inactivity. The list goes on to include U V radiation, H P V infection, low fiber consumption, processed meat, secondhand smoke, H C V infection, red meat, low calcium, H. pylori infection, H I V infection, H B V infection, and H H V 8 infection. Each of these risk factors caused fewer than 2 percent of deaths from cancer.

Figure 2.19 Percentage of avoidable cancers Epidemiologists have undertaken long-term studies in which the incidence and mortality of various cancers have been correlated with various lifestyle factors and infections. These studies have employed large population cohorts and attempted to factor out extraneous influences that might have otherwise confounded the calculations of the associations of specific cancers with certain assignable

risk factors. A 2018 analysis undertook to determine what effects changes in existing, potentially modifiable lifestyle factors and infections would have had on overall cancer incidence and mortality in the United States in 2014, which totaled ∼587,000 deaths. The numbers on the right are the average calculated avoidable deaths with a lower to upper range of variation that could be stated with 95% confidence. The overall reduction in mortality rate was calculated to be 45% for both sexes; less conservative predictions of avoidable cancer deaths have ranged from 50 to 60%. Smoking, obesity, and alcohol intake together represent the lion's share (39.3%) of this potential reduction. 2.8 Specific chemical agents can induce cancer

Coal tar condensates, much like those implicated in cancer causation by Percivall Pott's work, were used in Japan at the beginning of the twentieth century to induce skin cancers in rabbits. Repeated painting of localized areas of the skin of their ears resulted, after many months, in the outgrowth of carcinomas. This work, first reported by Katsusaburo Yamagiwa in 1915, was little noticed in the international scientific community of the time; instead, the 1926 Nobel Prize in Medicine was given to a Dane whose research on the experimental induction of cancer was soon discredited (**Supplementary Sidebar 2.6**). In retrospect, Yamagiwa's work represented a landmark advance, because it directly implicated chemicals (those in coal tar) in cancer causation. Equally important, Yamagiwa's work, together with that of Peyton Rous (to be described in Chapter 3), demonstrated that cancer could be induced at will in laboratory animals. Before these breakthroughs, researchers had been forced to wait for tumors to appear spontaneously in wild or domesticated animals. Now, cancers could be produced according to a predictable schedule, often involving many months of experimental treatment of animals.

By 1940, British chemists had purified several of the components of coal tar that were particularly carcinogenic (that is, cancer-causing), as demonstrated by the ability of these compounds to induce cancers on the skin of laboratory mice. Compounds such as 3-methylcholanthrene, benzo[*a*]pyrene, and 1,2,4,5-dibenz[*a*,*h*]anthracene were common products of combustion, and some of these hydrocarbons, notably benzo[*a*]pyrene, were subsequently found in the condensates of cigarette smoke as well (**Supplementary Sidebar 2.7**). These findings suggested that certain chemical species that entered into the human body could perturb tissues and cells and ultimately provoke the emergence of a tumor. The same could be said of X-rays, which were also able to produce cancers, ostensibly through a quite different mechanism of action.

While these discoveries were being reported, an independent line of research developed that portrayed cancer as an infectious disease. As described in detail in Chapter 3, researchers in the first decade of the twentieth century found that viruses could cause leukemias and sarcomas in infected chickens. By mid-century, a wide variety of viruses had been found able to induce cancer in rabbits, chickens, mice, and rats. As a consequence, those intent on uncovering the origins of human cancer were pulled in three different directions, since the evidence of cancer causation by chemical, viral, and radioactive agents had become compelling.

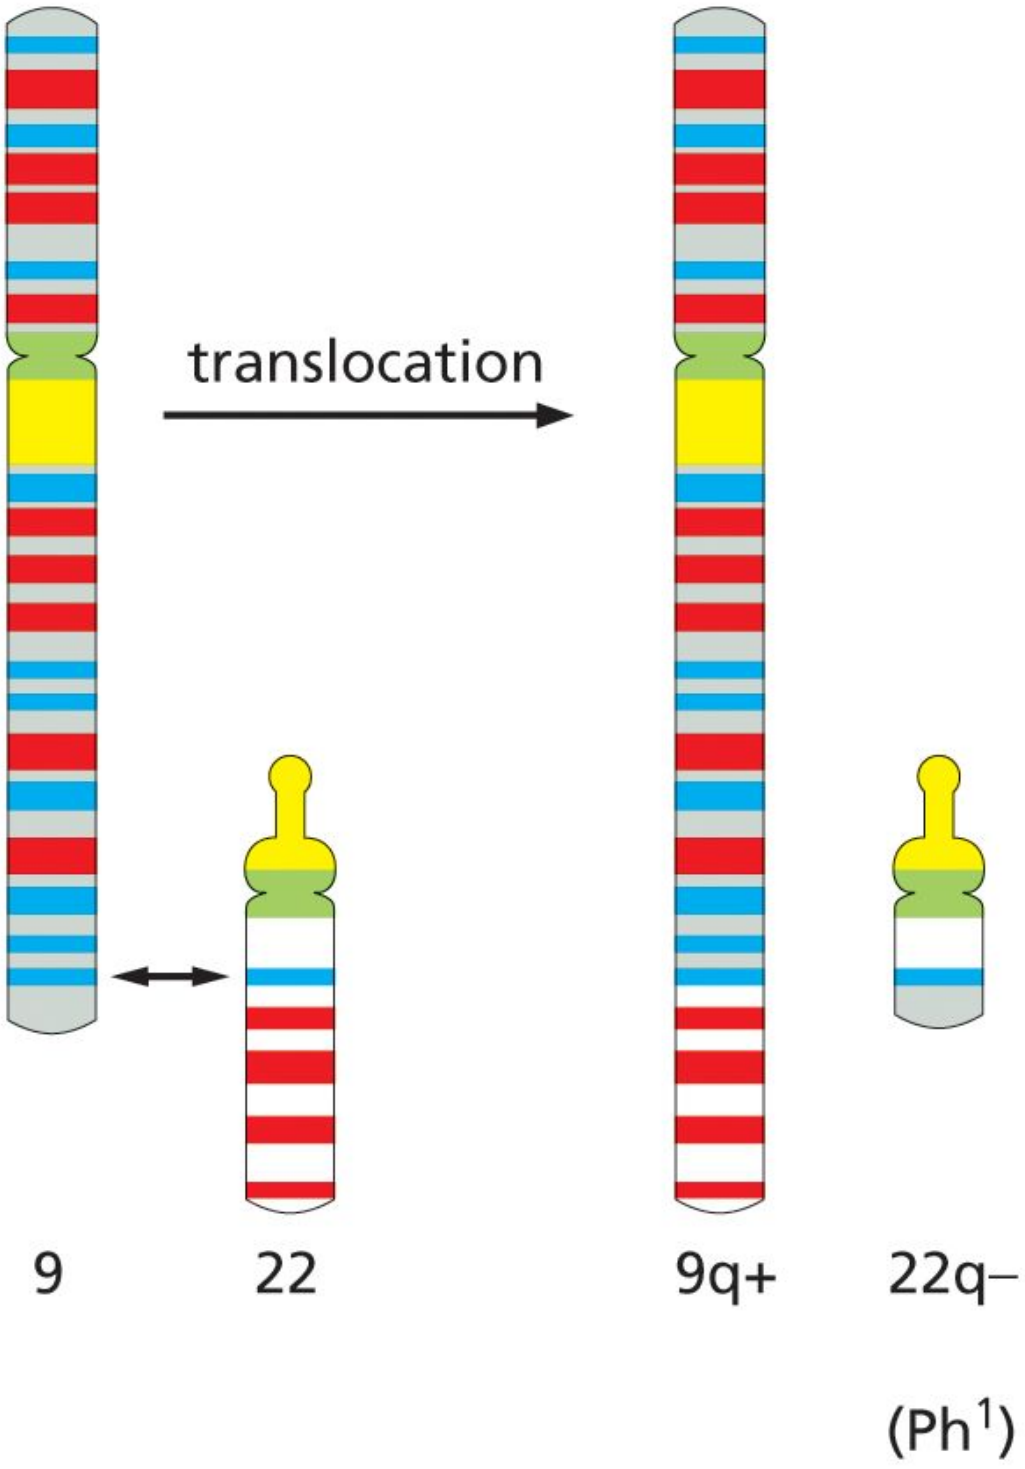
2.9 Both physical and chemical carcinogens act as mutagens

The confusion caused by the three competing theories of carcinogenesis was reduced significantly by discoveries made in the field of fruit fly genetics. In 1927, Hermann Muller discovered that he could induce mutations in the genome of *Drosophila melanogaster* by exposing these flies to X-rays. Most important, this discovery revealed that the genome of an animal was mutable, that is, that its information content could be changed through specific treatments, notably irradiation. At the same time, it suggested at least one mechanism by which X-rays could induce cancer: perhaps radiation was able to mutate the genes of normal cells, thereby creating mutant cells that grew in a malignant fashion.

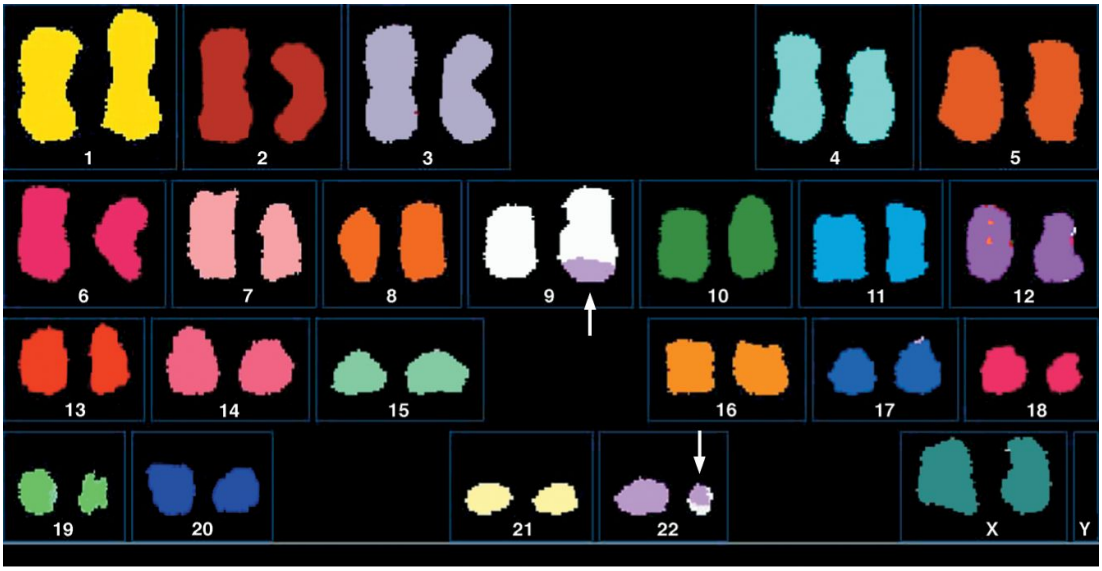
By the late 1940s, a series of chemicals, many of them alkylating agents of the type that had been used in World War I mustard gas warfare, were also found to be mutagenic for fruit flies. Soon thereafter, some of these same compounds were shown to be carcinogenic in laboratory animals. These findings caused several geneticists to speculate that cancer was a disease of mutant genes, and that carcinogenic agents, such as X-rays and certain chemicals, succeeded in inducing cancer through their ability to mutate genes.

These speculations were hardly the first ones of this sort. As early as 1914, the German biologist Theodor Boveri, drawing on yet older observations of others, suggested that chromosomes, which by then had been implicated as carriers of genetic information, were aberrant within cancer cells, and that cancer cells might therefore be mutants. Boveri's notion, along with many other speculations on the origin of cancer, gained few adherents, however, until the discovery in 1960 of an abnormally configured chromosome in a large proportion of cases of chronic myelogenous leukemia (CML). This chromosome, soon called the Philadelphia chromosome after the place of its discovery, was clearly a distinctive characteristic of this type of cancer (**Figure 2.20**). Its reproducible association with this class of tumor cells suggested, but hardly proved, that this genetic alteration played a causal role in tumorigenesis.



Translocation causes a short segment on human chromosome 9 to change places with a long segment on chromosome 22, resulting in a 9 q plus chromosome and a 22 q minus chromosome. Normal 22 is already fairly short, so 22 q minus is very short. This is P h 1, the Philadelphia chromosome.

(A)



A color display of all 22 human chromosome pairs, plus the X Y pair. Pair 9 is white, but one of the two chromosomes, longer than the other, has a purple section. Pair 22 is purple, but one of the two chromosomes, shorter than the other, has a small white section.

(B)

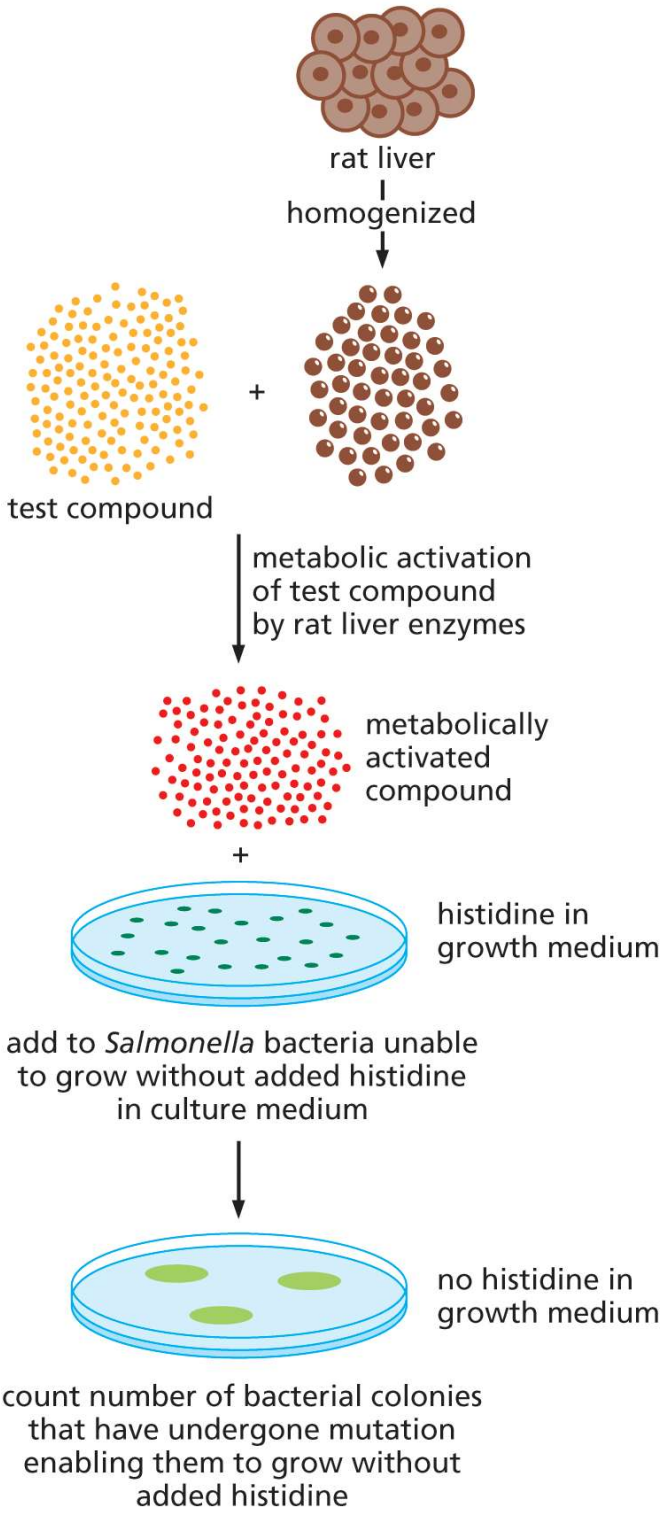
Figure 2.20 Structure of the Philadelphia chromosome Analyses of the banding patterns of stained metaphase chromosomes of chronic myelogenous leukemia (CML) cells first revealed the characteristic tiny chromosome (called the "Philadelphia chromosome" or Ph^1) that is present in the leukemia cells of most CML patients. (A) This banding pattern, determined through light-microscopic surveys, is illustrated here schematically. While the chromosomal translocation generating the two altered chromosomes (9q+ and 22q−) is reciprocal (that is, involving a loss and a gain by both), the sizes of the exchanged chromosomal arms are unequal, leading to the greatly truncated Chromosome 22 (22q−). The small arrow indicates the point of crossing over, known as the translocation breakpoint. Colors are added only to clarify banding patterns of chromosomes. (B) The relatively minor change to the tumor cell karyotype that is created by the CML translocation is apparent in this multicolor spectral karyotype (SKY) analysis, in which chromosome-specific probes are used, together with fluorescent dyes and computer-generated coloring, to visualize the entire chromosomal complement of CML cells. As is apparent, one of the two Chromosomes 9 has acquired a *light purple* segment (a color normally assigned to Chromosome 22) at the end of its long arm. Reciprocally, one of the two Chromosomes 22 has acquired a *white* region (normally characteristic of Chromosome 9) at the end of

its long arm (*arrows*). (A, from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton, 2015. B, courtesy of T. Ried and N. McNeil.)

In 1975 Bruce Ames, a bacterial geneticist working at the University of California in Berkeley, reported experimental results that lent great weight to the theory that carcinogens can function as mutagens. By then, decades of experiments with laboratory mice and rats had demonstrated that chemical carcinogens acted with vastly different potencies, differing by as much as 1 million-fold (per weight unit) in their ability to induce cancers. Such experiments showed, for example, that one microgram of aflatoxin, a compound produced by molds growing on peanuts and wheat, was as potent a carcinogen as was a 10,000 times greater weight of the synthetic compound benzidine. Ames posed the question whether these various compounds were also mutagenic, more specifically, whether compounds that were potent carcinogens also happened to be potent mutagens.

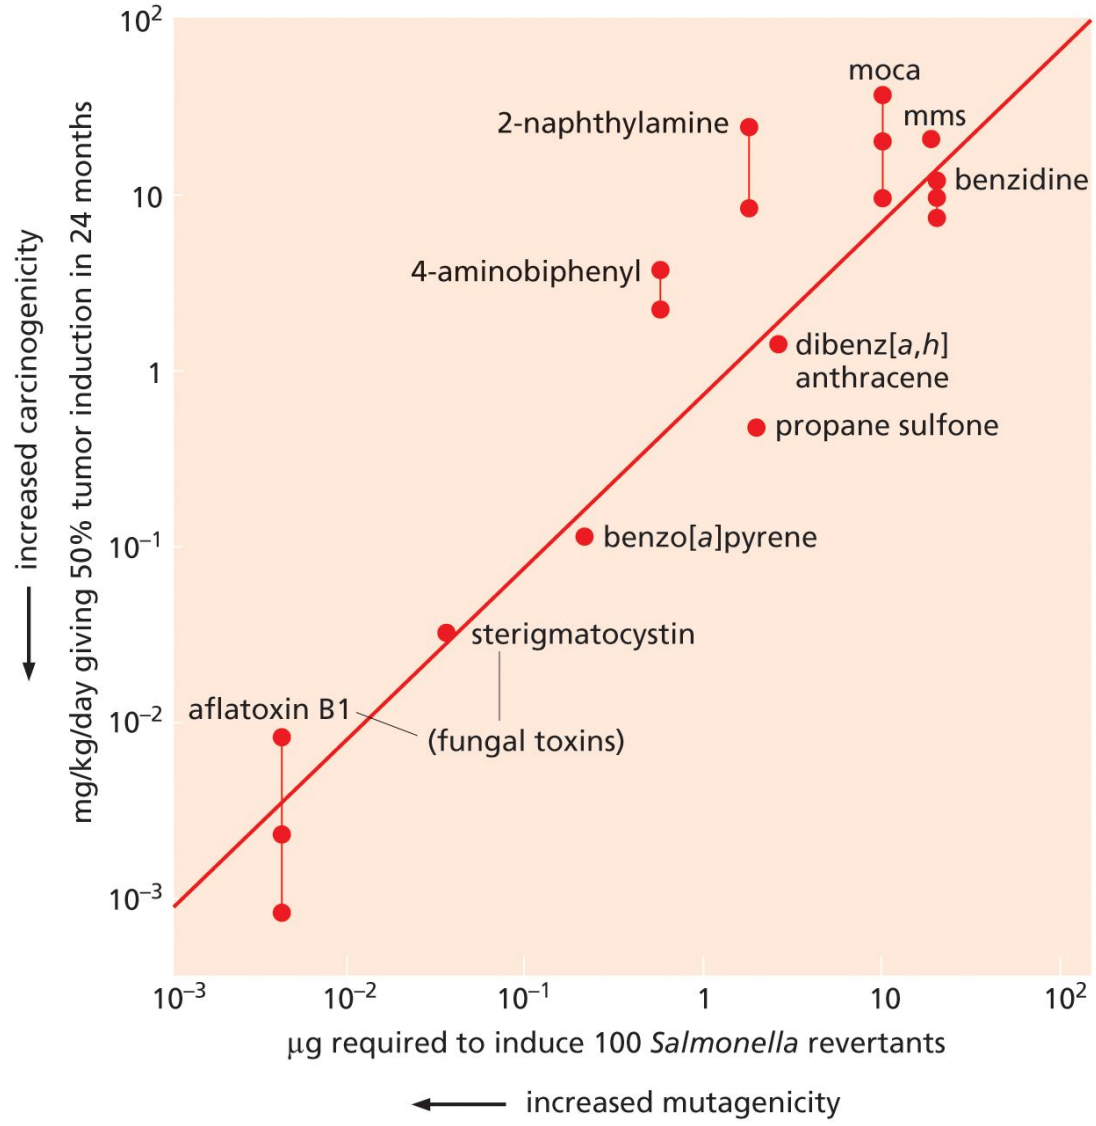
At the time, there were no good ways of measuring the relative mutagenic potencies of various chemical species. So Ames devised his own method. It consisted of applying various carcinogenic chemicals to a population of *Salmonella* bacteria growing in Petri dishes and then scoring for the abilities of these carcinogens to mutate the bacteria. The readout here was the number of colonies of *Salmonella* that grew following exposure to one or another chemical. (Implicit in the design of his experiments was the notion that chemicals that were mutagenic for bacterial genomes, and thus for bacterial DNA, would also act as mutagens for mammalian genomes and DNA.)

In detail, Ames used a mutant strain of *Salmonella* that was unable to grow in medium lacking the amino acid histidine. The mutant allele that caused this phenotype was susceptible to back-mutation to a wild-type allele. Once the wild-type allele had formed in response to exposure to a mutagen, a bacterium carrying this allele became capable of growing in Ames's selective medium, multiplying until it formed a colony that could be scored by eye (**Figure 2.21A**).



The Ames test. Rat liver is homogenized and then combined with a test compound. Rat liver enzymes metabolically activate the test compound. A petri dish has been prepared with enough histidine in the culture medium to grow Salmonella bacteria that are unable to grow without added histidine. The

bacteria grow to form many small spots but stop growing once the histidine is depleted. Now the metabolically activated compound is added to the dish. It cases some bacteria to mutate into a form that does not require added histidine for growth. Where these bacteria are present, the spots grow large enough to be counted with the naked eye. The number of such spots indicates the mutagenic strength of the test compound.
(A)



A log-log plot. On the horizontal axis is quantity required to induce 100 Salmonella revertants. The smaller the quantity, the greater the mutagenicity. On the vertical axis is quantity per day giving 50 percent tumor induction in 24 months. The smaller the quantity, the greater the carcinogenicity. A scatterplot of 10 compounds generally follow a straight trend line that is at a

45 degree angle. The compounds, in order of increasing mutagenicity and carcinogenicity–that is, moving from the upper right to the lower left–are m o c a and m m s, benzidine, 2-naphthylamine, dibenz a h anthracene, propane sulfone, benzo a pyrene, the fungal toxin sterigmatocystin, and the fungal toxin aflatoxin B1.
(B)

Figure 2.21 The Ames test for gauging mutagenicity The Ames test makes it possible to quantitatively assess the mutagenic potency of a test compound. (A) To begin, the liver of a rat (or other species) is homogenized to release its enzymes. The liver homogenate (*brown dots*) is then mixed with the test compound (*orange*), which often results in the liver enzymes metabolically converting the test compound to a chemically activated, mutagenic state (*red*). This mixture (still containing the liver homogenate, *not shown*) is applied to a dish of mutant *Salmonella* bacteria (*small green dots*) that require the amino acid histidine in their culture medium in order to grow. Since histidine is left out of the medium, only those bacteria that are mutated to a histidine-independent genotype (and phenotype) will be able to grow, and each of these will yield a large colony (*green*) that can be counted with the naked eye, indicating how many mutant bacteria (and thus mutant alleles) were generated by the brief exposure to the activated compound. (B) On this log–log plot, the relative carcinogenic potencies of a group of chemicals (*ordinate*) that have been used to treat laboratory animals (rats and mice) are plotted as a function of their mutagenic potencies (*abscissa*), as gauged by the Ames test (panel A). Since both the ordinate and abscissa are plotted as the amount of compound required to elicit an observable effect (yielding tumors in 50% of treated animals or 100 colonies of mutant *Salmonella* bacteria, termed here “revertants”), the compounds that are the most potent mutagens and most potent carcinogens appear in the lower left of this graph. Note that both parameters vary by 5 orders of magnitude. moca, 4,4′-methylenebis(2-chloroaniline), used in manufacture of polyurethane; mms, methyl methanesulfonate, an alkylating mutagen. (Adapted from M. Meselson and K. Russell, in H.H. Hiatt, J.D. Watson, and J.A. Winsten (eds.), Origins of Human Cancer, Book C: Human Risk Assessment. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, 1977. With permission from Cold Spring Harbor Laboratory Press.)

In principle, Ames needed only to introduce a test compound into a Petri dish containing his special *Salmonella* strain and count the bacterial colonies that later appeared. There remained, however, one substantial obstacle to the success of this mutagenesis assay. Detailed studies by other researchers had shown that after carcinogenic molecules entered the tissues of laboratory animals, they were metabolized into yet other chemical species. In many cases, the resulting products of

metabolism, rather than the initially introduced chemicals, seemed to be the agents that were directly responsible for the observed cancer induction. These metabolized compounds were found to be highly reactive chemically and able to form covalent bonds with the various macromolecules known to be present in cells—DNA, RNA, and protein.

The original, unmodified compounds that were introduced into laboratory animals came to be called procarcinogens to indicate their ability to become converted into actively carcinogenic compounds, which were labeled ultimate carcinogens. This chemical conversion complicated the design of Ames's mutagenesis assay. If many compounds required metabolic activation before their carcinogenicity was apparent, it seemed plausible that their mutagenic powers would also be evident only after such conversion. Given the radically different metabolisms of bacteria and mammalian cells, it was highly unlikely that Ames's *Salmonella* would be able to accomplish the metabolic activation of procarcinogens that occurred in the tissues of laboratory animals.

Earlier work of others had shown that a great many chemicals introduced into the body undergo metabolic conversion in the liver. Moreover, many of these conversions could be achieved in the test tube simply by mixing such chemicals with homogenized liver extracts. So Ames mixed rat liver homogenates with his test compounds and only then introduced this mixture into the Petri dishes carrying *Salmonella*. (We now know that the metabolic activation of procarcinogens in the liver is often mediated by enzymes that are normally involved, paradoxically, in the detoxification of compounds introduced into the body.)

With the addition of this extra step, Ames's assay revealed that a number of known carcinogens were also actively mutagenic. Even more important were the correlations that Ames found. Chemicals that were potently mutagenic were also powerful carcinogens. Those that were weakly mutagenic induced cancer poorly. These correlations, as plotted by others, extended over five orders of magnitude of potency (Figure 2.21B).

As we have read, the notion that carcinogens are mutagens predated Ames's work by a quarter of a century. Nonetheless, his analyses galvanized researchers interested in the origins of cancer, since the results addressed the carcinogen–mutagen relationship so directly. Their reasoning went like this: Ames had demonstrated the mutagenic powers of certain chemical compounds in bacteria. Since the genomes of bacterial and animal cells are both made of the same chemical substance—double-stranded DNA—it was likely that the compounds that induced mutations in the *Salmonella* genome were similarly capable of inducing mutations in the genomes of animal cells. Hence, the "Ames test," as it came to be known, should be able to predict the mutagenicity of these compounds in mammals. And in light of the correlation between mutagenic and

carcinogenic potency, the Ames test could be employed to screen various substances for their carcinogenic powers, and thus for their threat to human health. By 1976, Ames and his group reported on the mutagenic potencies of 300 distinct organic compounds (**Supplementary Sidebar 2.8**).

Ames's results led to the next deduction, really more of a speculation: if, as Ames argued, carcinogens are mutagens, then it followed that the carcinogenic powers of various agents derived directly from their ability to induce mutations in the cells of target tissues. As a further deduction, it seemed inescapable that the cancer cells created by chemical carcinogens carried mutated genes. These mutated genes, whatever their identity, must in some way be responsible for the aberrant growth phenotypes of such cancer cells.

This logic was transferable to X-ray carcinogenesis as well. Since X-rays were mutagens and carcinogens, it followed that they also induced cancer through their ability to mutate genes. This convergence of cancer research with genetics had a profound effect on researchers intent on puzzling out the origins of cancer. Though still unproven, it appeared likely that the disease of cancer could be understood in terms of the mutant genes carried by cancer cells.

OceanofPDF.com

Glossary

mutable
: Referring to an entity that is subject to change, notably a genome subject to genetic mutation.

procarcinogen
: A chemical compound that is relatively nonreactive chemically, but can be converted into a highly reactive carcinogen, usually through metabolic processes. *See also* **ultimate carcinogen**.

ultimate carcinogen
: A chemical compound that is able to directly contribute to the induction of cancer without further chemical modification, usually by direct chemical interaction with DNA, thereby altering the chemical structure of the latter. *See also* **procarcinogen**.

Ames test
: An experimental protocol and versions thereof that enable the quantification of the mutagenic potency of candidate chemicals through their ability to induce mutations in bacteria growing in a Petri dish.

detoxify
: To render a previously toxic substance harmless.

mutagenicity
: The property of being mutagenic.

OceanofPDF.com

2.10 Mutagens may be responsible for some human cancers

The connection between carcinogenesis and mutagenesis seemed to shed light on how human tumors arise. Perhaps many of these neoplasms were the direct consequence of the mutagenic actions of chemical and physical carcinogens. The mutagenic chemicals, specifically, procarcinogens, need not derive exclusively from the combustion of carbon compounds and the resulting formation of coal tars. It seemed plausible that chemical species present naturally in foodstuffs (see Table S2.1) or generated during cooking could also induce cancer. Even if many foods did not contain ultimate carcinogens, chemical conversions carried out by liver cells or by the abundant bacteria in the colon might well succeed in creating actively mutagenic and thus carcinogenic chemical species. In the years after Ames's work, a variety of other tests of mutagenic potency have been developed (**Supplementary Sidebar 2.9**).

As this research on the causes of human cancer proceeded, the understanding of carcinogenic agents became more nuanced. Thus, it became apparent that virtually all compounds that are mutagenic in human cells are likely to be carcinogenic as well. However, the converse does not seem to hold: chemical compounds that are carcinogenic are not necessarily mutagenic. By the 1990s, extensive use of the Ames test showed that as many as 40% of the compounds that were known to be carcinogenic in rodents showed no obvious mutagenicity in the *Salmonella* mutation assay. So, the conclusions drawn from the initial applications of Ames's test required major revision: some carcinogens act through their ability to mutate DNA, while others promote the appearance of tumors through nongenetic mechanisms. We will encounter these nonmutagenic carcinogens, often called tumor promoters, again in Chapter 11. Such promoters, including inflammation-inducing factors, may ultimately prove

to be far more important human carcinogens than the much-studied mutagenic agents identified by the Ames test.

Ames and others eventually used his test to catalog the mutagenic powers of a diverse group of chemicals and natural foodstuffs, including many of the plants that are common and abundant in the Western diet. As he argued, the presence of such compounds in foodstuffs derived from plants was hardly surprising, since plants have evolved thousands, possibly millions of distinct toxic chemical compounds in order to defend themselves from predation by insects and larger animals. Some of these naturally toxic compounds, initially developed as anti-predator defenses, might also, as an unintended side effect, be mutagenic (see Table S2.1).

A diverse set of discoveries led to the model that a significant proportion of human cancer is attributable directly to the consumption of foodstuffs that can generate mutagenic compounds and, for this reason, are carcinogenic. This model remains unproven in many of its aspects to this day.

The difficulties in proving this model derive from several sources. Each of the plant and animal foodstuffs in our diet is composed of thousands of diverse chemical species present in vastly differing concentrations. Almost all of these compounds undergo metabolic conversions once ingested, first in the gastrointestinal tract and often thereafter in the liver. Moreover, the hundreds of distinct bacterial species inhabiting our gastrointestinal tract, which together constitute much of our microbiome, have diverse metabolisms and thus powers to generate potentially carcinogenic compounds. Accordingly, the number of distinct chemical species that are introduced into our bodies is incalculable. Each of these introduced compounds may then be concentrated in some cells or quickly metabolized and excreted, creating a further dimension of complexity.

Moreover, the actual mutagenicity of various compounds in different cell types may vary enormously because of metabolic differences in these cells. For example, some cells, such as hepatocytes in the liver, express high levels of biochemical species designed to scavenge and inactivate mutagenic compounds, while others, such as fibroblasts, express far lower levels. In sum, the ability to relate the biological activities of foodstuffs to actual rates of mutagenesis and carcinogenesis in the human body is far

beyond our reach at present—a problem of seemingly intractable complexity. In addition, the limitations of using animal models to detect human carcinogens indicate the profound difficulties of determining in a biological relevant model—a living mammal—how carcinogenic various substances actually are (**Sidebar 2.2**).

Sidebar 2.2 The frustrating search for elusive human carcinogens

Ideally, the identification of important human carcinogens should have been aided by the use of *in vitro* assays, such as the Ames test (see Section 2.9), and *in vivo* tests—exposure of laboratory animals to agents suspected of causing cancer. In truth, however, these various types of laboratory tests have failed to register important human carcinogens. Instead, we have learned about their carcinogenicity in humans because of various epidemiologic studies. For example, the most important known human carcinogen—tobacco smoke—would likely have escaped detection because it is a relatively weak carcinogen in laboratory rodents; and another known human carcinogen—asbestos—would have eluded detection by both *in vitro* and *in vivo* laboratory tests. Conversely, some frequently used drugs, such as phenobarbital and isoniazid, register positive in the Ames test, and saccharin registers as a carcinogen in male laboratory rats, but epidemiologic evidence indicates conclusively that none of these is actually associated with increased cancer risk in humans who have been exposed to these compounds over long periods of time. Moreover, as mentioned, many human carcinogens act through non-mutational mechanisms and therefore do not register in the Ames test or, indeed, in a variety of other laboratory tests. Hence, the development of tests to accurately identify a wide range of human carcinogenic agents still lies in the future.

OceanofPDF.com

Glossary

promoter

(1) An agent that furthers the progression of multi-step tumorigenesis by nongenetic mechanisms, notably those involving inflammation and/or mitogenesis, sometimes termed promoting agent. Tumor promoters are presumed to work by accelerating the rate of clonal expansion of already-mutated cells. (2) The DNA sequence associated with a gene that controls its transcription. *See also* **promotion**.

microbiome

The collection of microbes, largely bacteria, that exist naturally as commensal organisms in normal organs, such as the gastrointestional tract and the skin; each of these and other tissues carries its own spectrum of microbes and thus its own microbiome.

hepatocyte

Epithelial cell type that forms the bulk of the liver and is responsible for virtually all of its metabolic activities.

2.11 Synopsis and prospects

The descriptions of cancer and cancer cells developed during the second half of the nineteenth century and the first half of the twentieth indicated that tumors were nothing more than normal cell populations that had run amok. Moreover, many tumors seemed to be composed largely of the descendants of a single cell that had crossed over the border from normalcy to malignancy and proceeded to spawn the billions of descendant cells constituting these neoplastic masses. This model drew attention to the nature of the cells that founded tumors and to the mechanisms that led to their transformation into cancer cells. If one could understand why a cell multiplied uncontrollably, somehow other pieces of the cancer puzzle were likely to fall into place.

Still, existing observations and experimental techniques offered little prospect of revealing precisely why a cell altered its behavior, transforming itself from a normal into a malignant cell. The carcinogen = mutagen theory seemed to offer some clarification, since it implicated mutant cellular genes as the agents responsible for disease development and, therefore, for the aberrant behavior of cancer cells. Perhaps there were mutant genes operating inside cancer cells that programmed the runaway proliferation of these cells, but the prospects for discovering such genes and understanding their actions seemed remote. No one knew how many genes were present in the human genome and how to analyze them. If mutant genes really did play a major part in cancer causation, they were likely to be small in number and dwarfed by the apparently vast number of genes present in the genome as a whole. They seemed to be the proverbial needles in the haystack, in this case a vast haystack of unknown size.

This theorizing about cancer’s origins was further complicated by two other important considerations. First, many apparent carcinogens failed the Ames test, suggesting that they were nonmutagenic. Second, certain viral infections seemed to be closely connected to the incidence of a small but significant subset of human cancer types. Somehow, their carcinogenic

powers had to be reconciled with the actions of mutagenic carcinogens and mutant cellular genes.

By the mid-1970s, recombinant DNA technology, including gene cloning, began to influence a wide variety of biomedical research areas. While appreciating the powers of this new technology to isolate and characterize genes, cancer researchers were unable, at least initially, to exploit it to track down the elusive mutant genes that were responsible for cancer. One thing was clear, however. Sooner or later, the process of cancer pathogenesis (disease development) needed to be explained and understood in molecular terms. Somehow, the paradigm of DNA, RNA, and proteins, so powerful in elucidating a vast range of biological processes, would need to be brought to bear on the cancer problem.

In the end, the breakthrough came from study of the tumor viruses, which by most accounts were minor players in human cancer development. Tumor viruses were genetically simple, and yet they possessed potent carcinogenic powers. To understand these viruses and their import, we need to move back, once again, to the beginning of the twentieth century and confront another of the ancient roots of modern cancer research. This will be the subject of Chapter 3.

Moving back to the present, we confront an ongoing major challenge for cancer research: how various biological and environmental factors, the latter including lifestyle, contribute to the incidence of cancers, many of them quite common ones. For example, as indicated in part in Table 2.5, the incidence of cancers, such as those of the colon, breast, and prostate, shows enormous geographic variation—dramatic differences that cannot be ascribed to differing genetic susceptibilities. In fact, epidemiologists have uncovered many correlations between the frequencies of these and other cancer types and exposure to various agents. However, with rare exception, our understanding of the biological and biochemical mechanisms by which these factors increase (or reduce) disease incidence is either incomplete or nonexistent (**Table 2.8**). Indeed, these correlations represent one of the major unsolved mysteries confronting contemporary cancer researchers.

Table 2.8 Examples of etiologic mysteries: epidemiologic correlations between environmental/lifestyle factors and cancer incidence that lack

a clear explanation of causal mechanism[a]

Lifestyle, dietary factor, or medical condition	**Altered cancer risk**
High birth weight	premenopausal breast cancer ↑
	infant acute leukemia ↑
Processed red meat[b]	ER+ breast cancer ↑
	squamous cell and adenocarcinoma of lung ↑
Childhood soy consumption	breast cancer ↓
Well-done red meat	prostate cancer ↑
Western diet—high in fat, high in red meat	colorectal, esophageal, liver, and lung cancer ↑
Exercise	hormone-responsive breast cancer ↓
Diet with cruciferous vegetables	prostate cancer ↓

Lifestyle, dietary factor, or medical condition	**Altered cancer risk**
High body-mass index (BMI)	multiple cancer types ↑
Higher ratio of number of daughters to number of sons born to a woman	ovarian carcinoma ↑
Parkinson’s disease	melanoma ↑
Low circulating vitamin D	breast cancer incidence, CRC mortality ↑
Periodontal disease	esophageal carcinoma ↑
Coffee consumption	hepatocellular carcinoma ↓

Abbreviations: ER+= estrogen receptor–positive; CRC = colorectal cancer.

Until we understand how various biological and lifestyle factors succeed in triggering or preventing tumor development, our ability to prevent new cancers (which is usually far more effective than trying to cure them after they have been diagnosed) will be limited. Many of the chapters that follow provide critical information that may ultimately help to unravel these mysteries of cancer etiology.

Key concepts

- The nineteenth-century discovery that all cells of an organism descend from the fertilized egg led to the realization that tumors are not foreign bodies but growths derived from normal tissues. The comparatively disorganized tissue architecture of tumors pointed toward cancer as being a disease of malfunctioning cells.
- Tumors can be either benign (localized, noninvasive) or malignant (invasive, metastatic). The metastases spawned by malignant tumors are responsible for almost all deaths from cancer.
- With some exceptions, most tumors are classified into four major groups according to their origin (epithelial, mesenchymal, hematopoietic, and neuroectodermal).
- Virtually all cell types can give rise to cancer, but the most common human cancers are of epithelial origin—the carcinomas. Most carcinomas fall into two categories: squamous cell carcinomas arise from epithelia that form protective cell layers, while adenocarcinomas arise from secretory epithelia.
- Nonepithelial malignant tumors include (1) sarcomas, which originate from mesenchymal cells; (2) hematopoietic cancers, which arise from the precursors of blood cells; and (3) neuroectodermal tumors, which originate from components of the nervous system.
- If a tumor’s cells have dedifferentiated (lost all tissue-specific traits), its origin cannot be readily identified; such tumors are said to be anaplastic.
- Cancers seem to develop progressively, with tumors demonstrating different gradations of abnormality along the way from benign to metastatic.
- Benign tumors may be hyperplastic or metaplastic. Hyperplastic tissues appear normal except for an excessive number of cells, whereas metaplastic tissues show displacement of normal cells by normal cell types not usually encountered in those tissues. Metaplasias are most frequent in the transition zones between two types of epithelial populations.

- Dysplastic tumors contain cells that are cytologically abnormal. Dysplasia is a transitional state between completely benign and premalignant. Adenomatous growths (adenomas, polyps, papillomas, and warts) are dysplastic epithelial tumors that are considered to be benign because they respect the boundary created by the basement membrane.
- Tumors that breach the basement membrane and invade underlying tissue are malignant. An even further degree of abnormality is metastasis, the seeding of tumor colonies to other sites in the body. Metastasis requires not only invasiveness but also such newly acquired traits as motility and adaptation to foreign tissue environments.
- Biochemical and genetic markers seem to indicate that human tumors are monoclonal (descended from one ancestral cell) rather than polyclonal (descended from multiple ancestral cells, each of which independently spawned a population of cancer cells).
- The incidence of many (but not all) cancers varies dramatically by country, an indication that they cannot be due simply to a normal biologic process gone awry by chance. While differences in either heredity or environment could explain these variations, epidemiologic studies show that environment (including lifestyle factors) is the dominant determinant of the country-by-country variations in cancer incidence.
- Laboratory research supported the epidemiologic studies by directly implicating chemical and physical agents (tobacco, coal dust, X-rays) as causes of cancers. However, the possibility of cancer as an infectious disease arose when viruses were found to cause leukemias and sarcomas in chickens.
- A possible mechanism that supported carcinogenesis by physical and chemical agents surfaced when mutations were induced in fruit flies by exposing them to either X-rays or chemicals, indicating that they were mutagenic. Since these agents were also known to be carcinogenic in laboratory animals, this led to the speculation that cancer was a disease of mutant genes and that carcinogenic agents induced cancer through their ability to mutate genes.
- In 1975 the Ames test provided support for this idea by showing that many carcinogens can act as mutagens. Additional research showed that although almost all compounds that are mutagenic are likely to be

carcinogens, the converse does not hold true. So, some carcinogens act through their ability to mutate DNA, while others promote tumorigenesis through nongenetic mechanisms. Such nonmutagenic carcinogens are called tumor promoters.

OceanofPDF.com

Thought questions

1. What types of observation allow a pathologist to identify the tissue of origin of a tumor? And why are certain tumors extremely difficult to assign to a specific tissue of origin?
2. Under certain circumstances, all tumors of a class can be traced to a specific embryonic cell layer, while in other classes of tumors, no such association can be made. What tumors would fit into each of these two groupings?
3. What evidence persuades us that a cancer arises from the native tissues of an individual rather than invading the body from outside and thus being of foreign origin?
4. How compelling are the arguments for the monoclonality of tumor cell populations, and what logic and observations undermine the conclusion of monoclonality?
5. How can we estimate what percentage of cancers in a population are avoidable (through virtuous lifestyles) and what percentage occur independently of lifestyle?
6. What limitations does the Ames test have in predicting the carcinogenicity of various agents?
7. In the absence of being able to directly detect mutant genes within cancer cells, what types of observation allow one to infer that cancer is a disease of mutant cells?

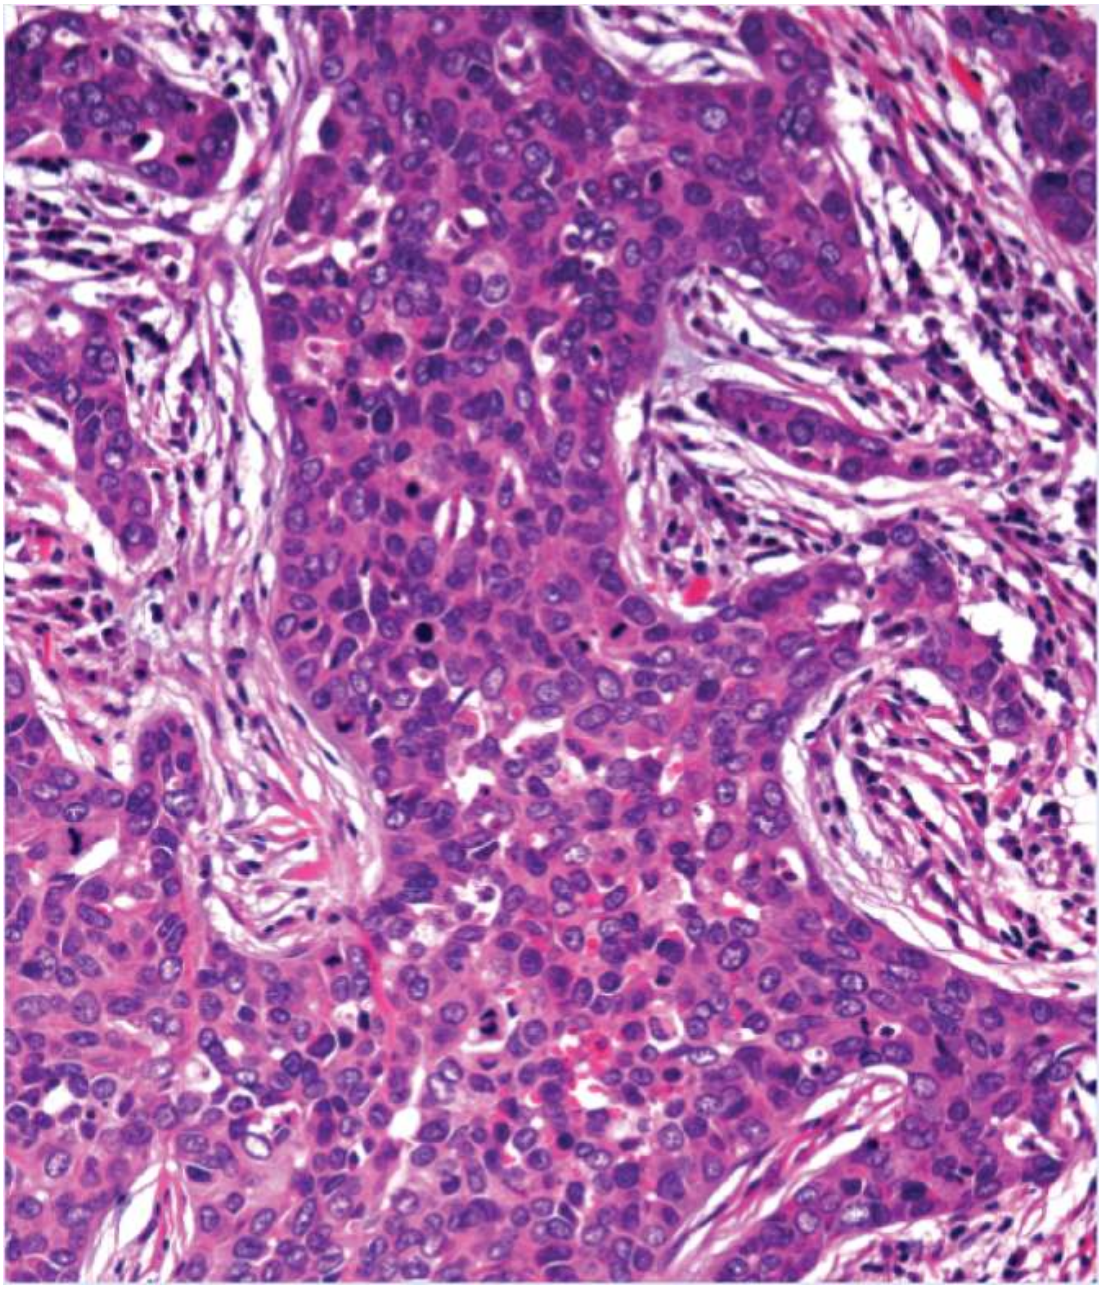
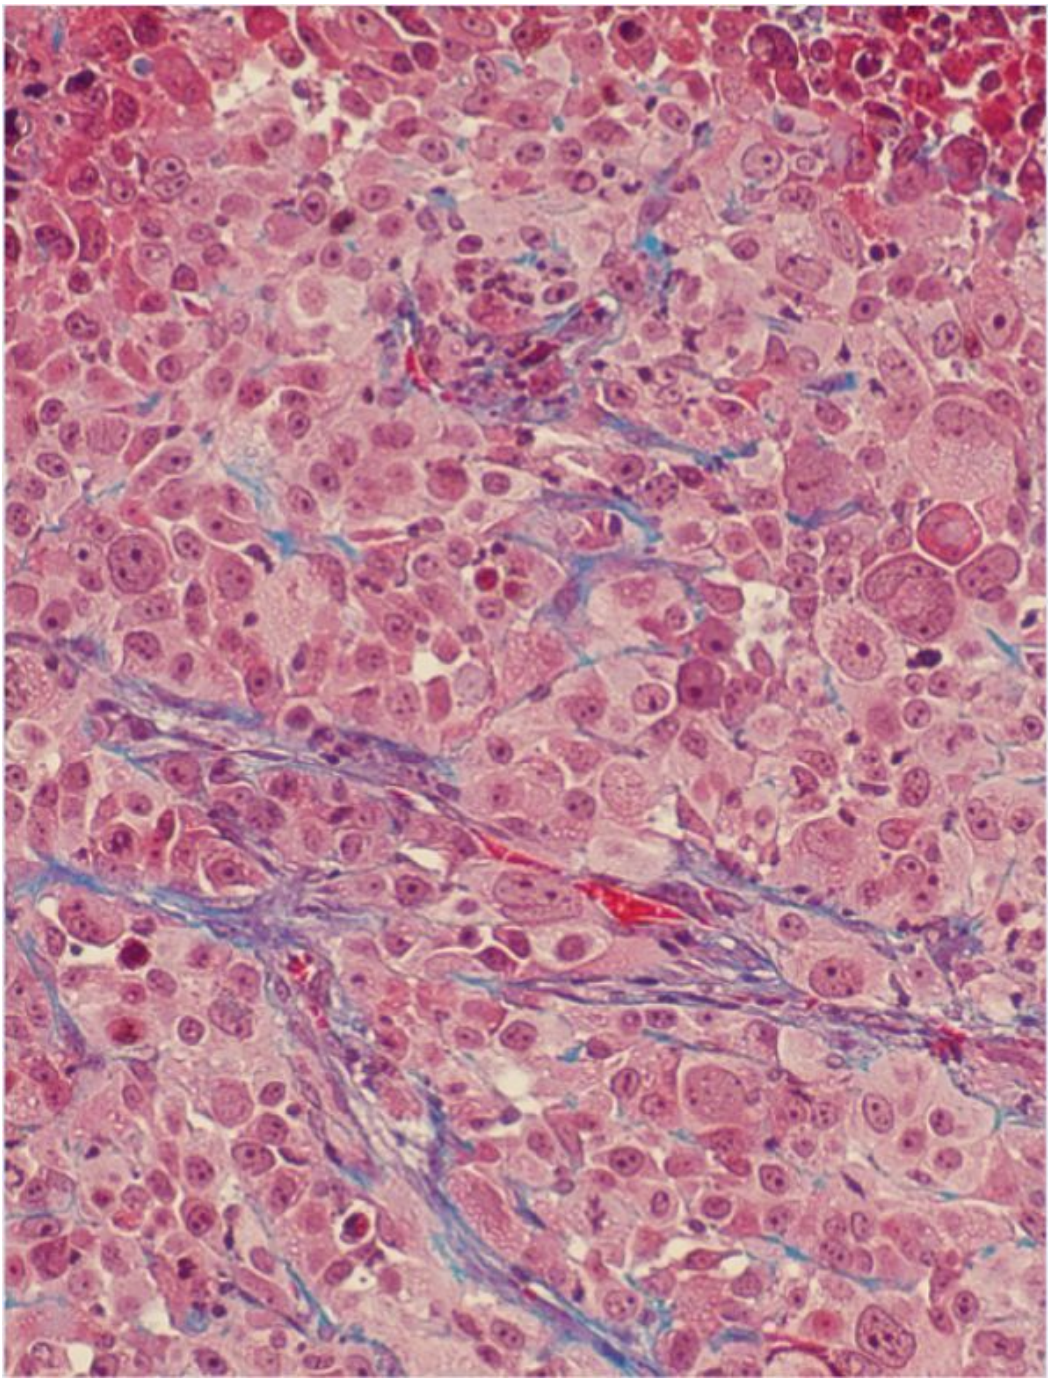
Supplementary Sidebars

Supplementary Sidebar 2.1 Commonly used histopathological techniques

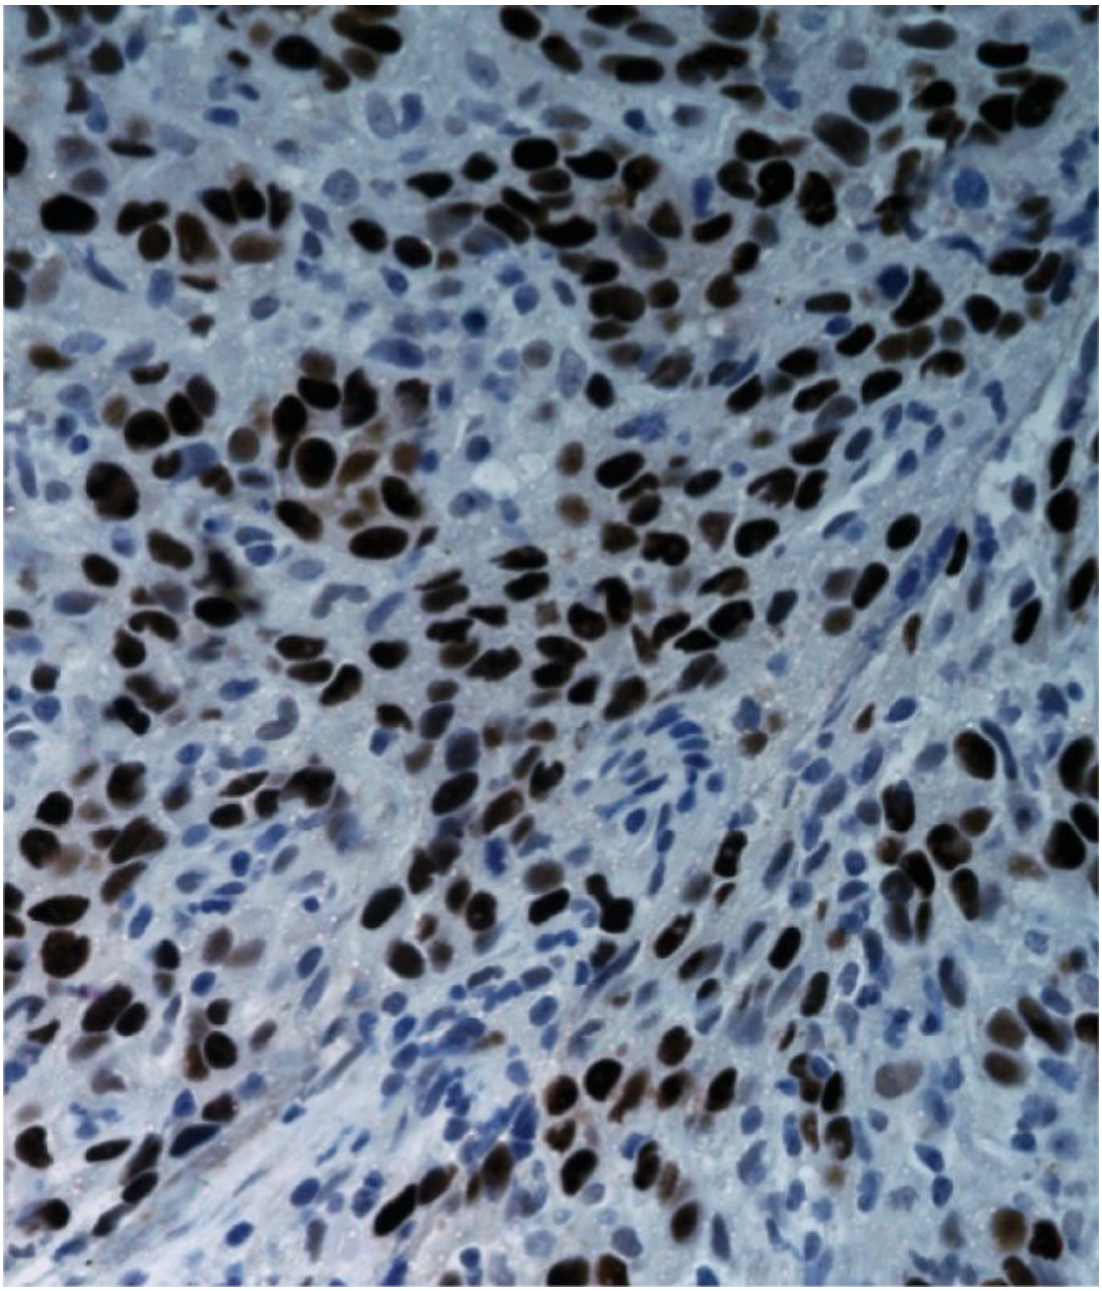
Several techniques are used frequently to mark structures in the fields viewed through a light microscope in order to resolve tissue architecture, the subcellular structures within individual cells, proteins that form these various structures, and even specific genes borne by chromosomal DNA (**Figure S2.1**).



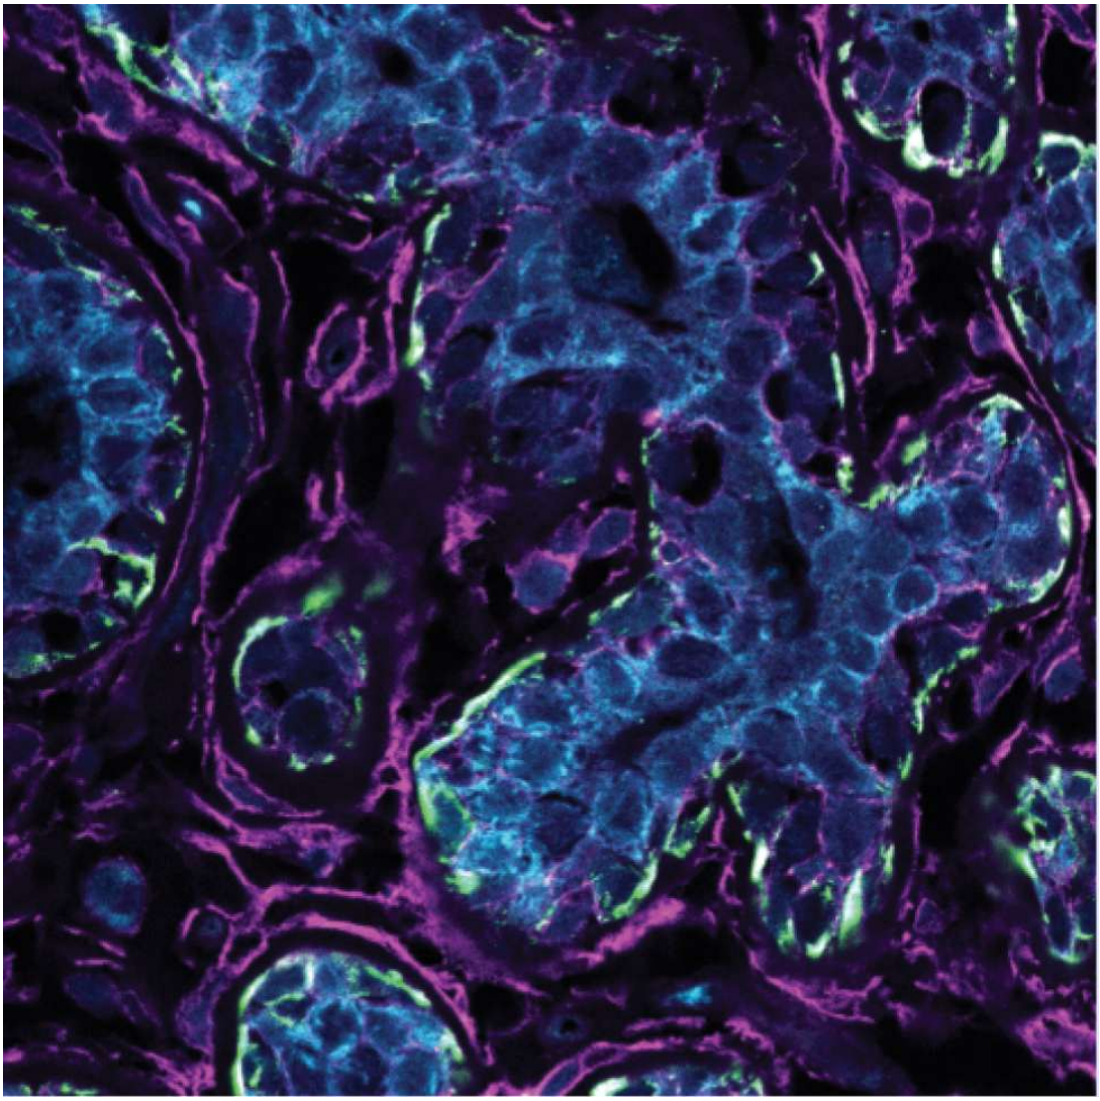
(A)



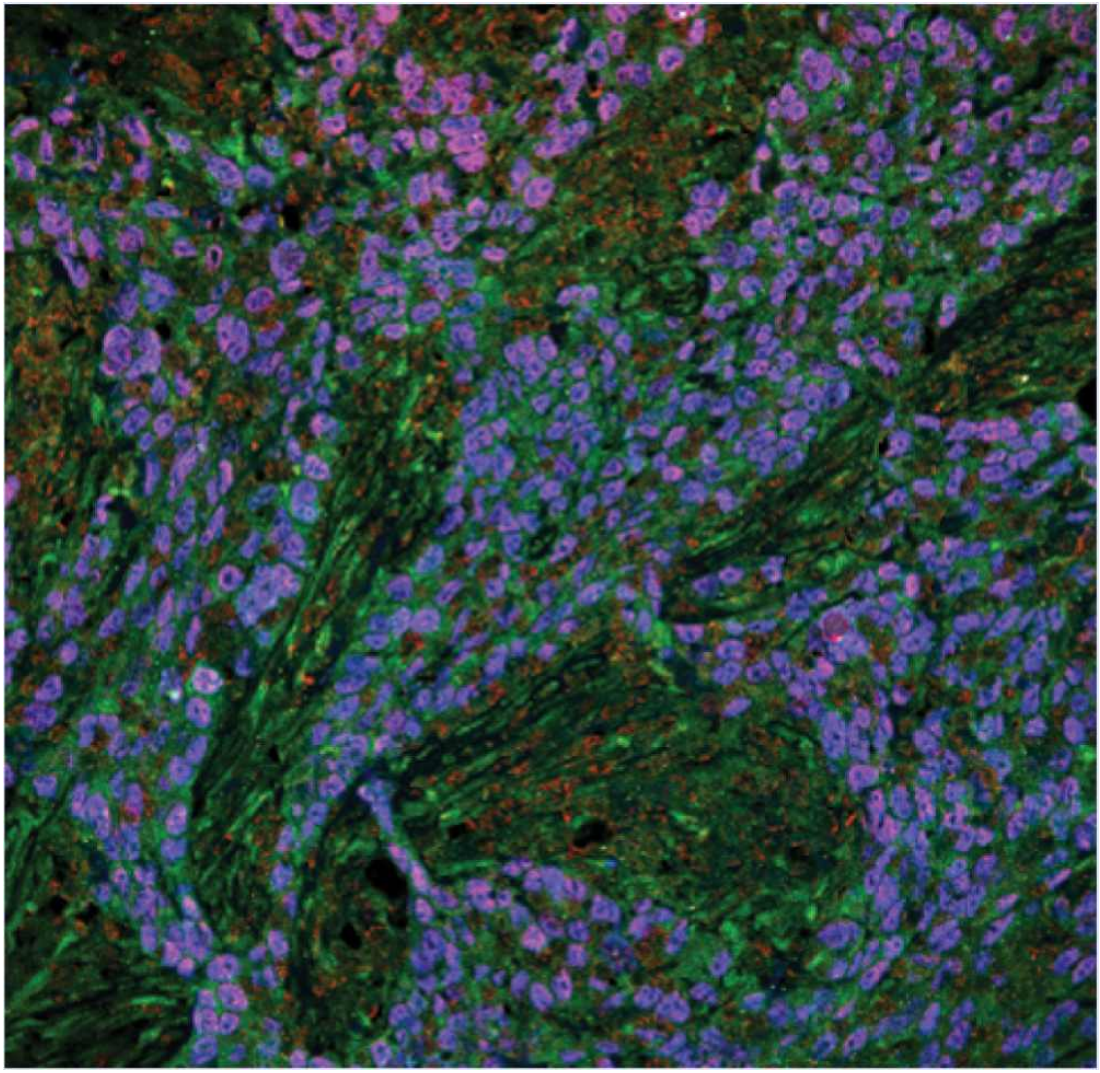
(B)



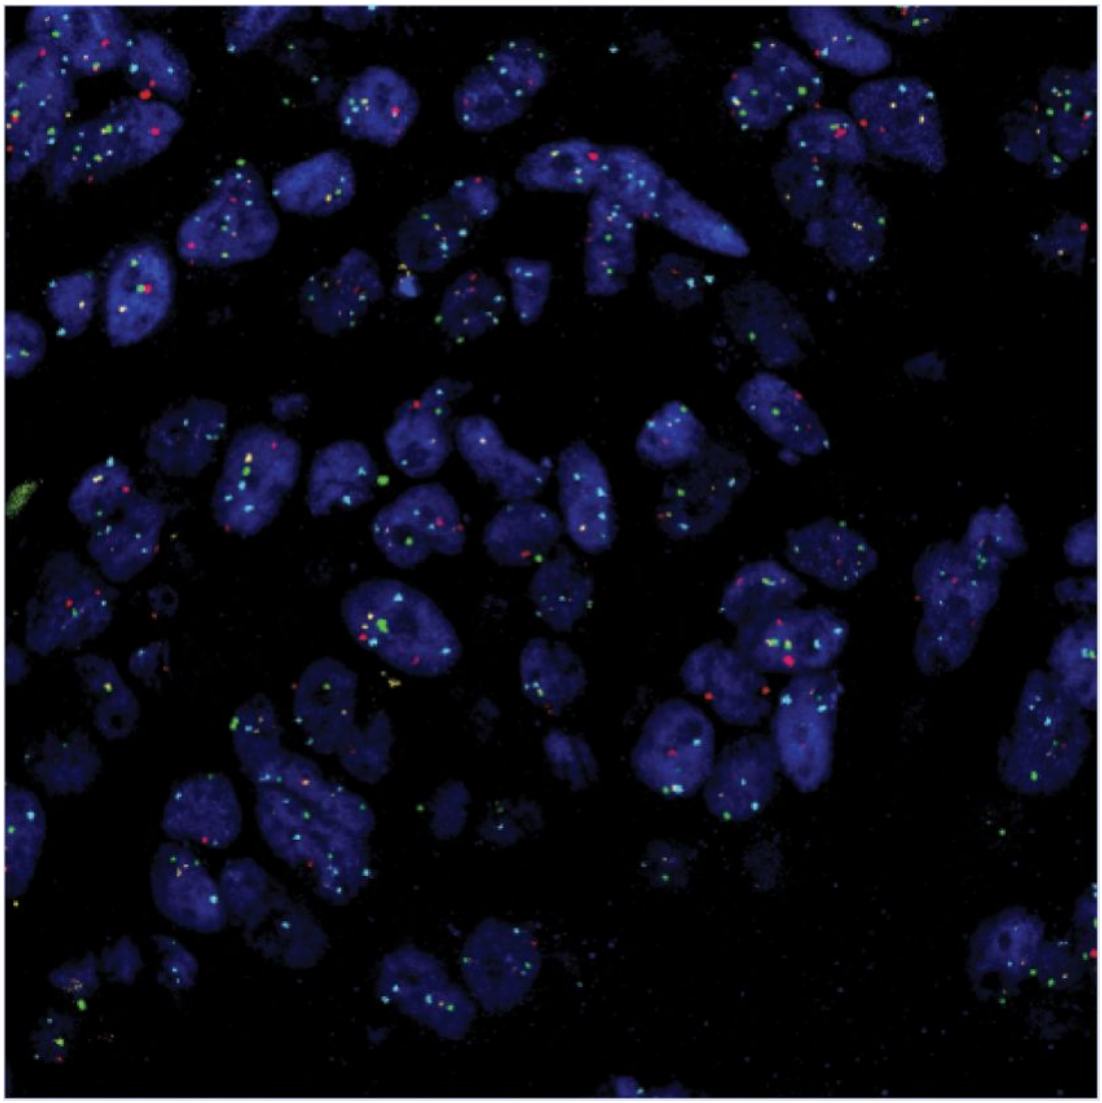
(C)



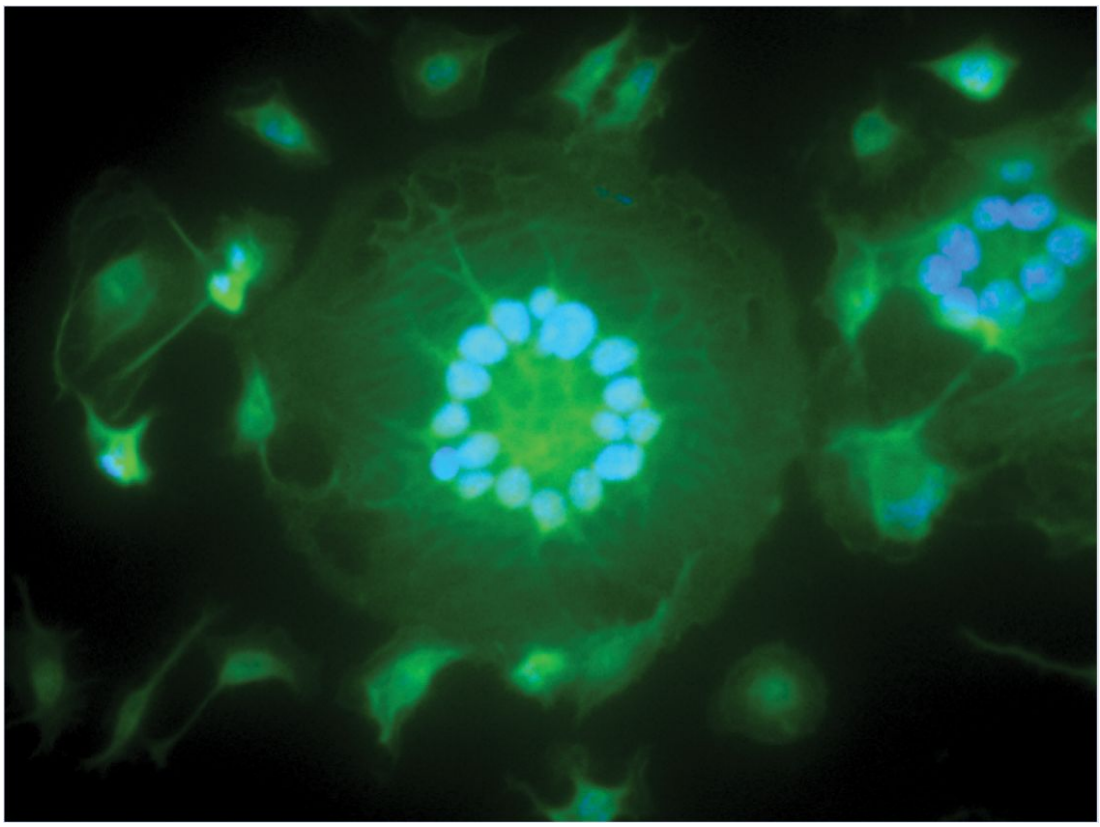
(D)



(E)



(F)



(G)

Figure S2.1 Some frequently used techniques for staining histopathological sections While certain modern microscopic techniques allow visualization of tissues at various depths of focus (sometimes termed the “z-axis”), the great majority are limited to viewing at a single depth, either in cell monolayers or in tissue sections. The latter are prepared by sectioning tissues that have been stabilized by certain fixatives, such as formaldehyde, glutaraldehyde, or ethanol, which permeabilize cells and cross-link molecules in the biological sample prior to its being embedded in paraffin wax and sectioned; this embedding increases the mechanical strength of the sample, thereby facilitating sectioning. Alternatively, a tissue sample may be frozen and sectioned. In both cases, the resulting tissue sections are then deposited on glass slides. The magnification of the images (e.g., 20×) is then represented as the size of an object in an image of a microscopic field divided by its actual size; this factor may then be further increased or decreased as the initially viewed image is printed or presented in digital form. (A) Hematoxylin and eosin (H&E) staining reveals complex tissue architecture in this section of a human basal-like carcinoma of the breast (40×). Hematoxylin stains nuclear structures, notably the histones in the chromatin, *blue*; in contrast, eosin stains cytoplasm, connective tissue, and extracellular structures, such as extracellular matrix, *pink*. Note the two major types of tissue organization here: the carcinoma

cells have large, *dark purple* nuclei and are assembled in continuous aggregates while the non-neoplastic cells forming the loose, fibrous stroma have small, *very dark* nuclei. (B) Use of Masson's trichrome stain allows a variety of structures to be visualized with a single staining procedure. In this micrograph (20×) of experimentally transformed human mammary epithelial cells growing as a tumor *xenograft* in a mouse, erythrocytes (red blood cells) appear *bright red*, collagen appears *blue*, cytoplasms appear *light pink*, and cell nuclei appear *dark pink*. (C) Immunohistochemistry (IHC) depends on the ability to conjugate (link) an antigen-specific antibody with an enzyme, usually horseradish peroxidase; this enzyme uses added hydrogen peroxide (H_2O_2) to oxidize an added chemical substrate, usually generating a *dark brown* or *black* product. In this image (40×), a section of a human basal-like breast tumor has been immunostained using an antibody that binds the p53 tumor suppressor protein, which, in mutant form, accumulates in high concentrations in cell nuclei, revealing them here as *dark ovals*. The section was then stained with hematoxylin, which was used here as a *counterstain* to reveal remaining structures in the tumor, seen here as *light blue*. Nuclei stained with hematoxylin but not with the anti-p53 peroxidase-conjugated antibody are mostly normal, non-neoplastic cells of the tumor-associated stroma. (D) Normal human mammary gland tissue has been stained here using the technique of immunofluorescence (IF), in which antigen-specific antibodies have been conjugated to fluorescent dyes (sometimes termed fluorophores) that emit light at various wavelengths after being excited with light of different, specific wavelengths. This allows the staining with multiple distinct antigen-specific antibodies (in this case three) that enables the concomitant visualization of multiple distinct antigens and thus the cells that express them. In this micrograph (63×), cells expressing the CD44 antigen have been stained with a conjugated antibody that generates a *pink/purple* signal, cells expressing the CD24 antigen have been stained with an antibody that generates a *blue* signal, while cells expressing α-smooth muscle actin have been stained with an antibody that generates a *green* signal. The *blue* mammary epithelial cells are arrayed as the lining of ducts that have a dark lumen (cavity) in their center. (E) An alternative combination of antibodies allows this visualization of human basal-like breast cancer at 40× magnification. In this case, the anti-p53 antibody has been conjugated to a fluorescent dye emitting a *blue* signal, and an antibody recognizing the BRCA1 protein has been conjugated with a dye emitting a *red* signal (yielding small *red dots* in cell nuclei), while an antibody recognizing the PTEN tumor suppressor protein has been stained with an antibody that emits *green* light. This image indicates that the neoplastic cells with *pinkish blue* nuclei generally have lower levels of the BRCA1 protein than do the non-neoplastic cells of the tumor stroma, which lack mutant p53 protein and thus the *pinkish blue* nuclei. (F) In this micrograph (63×), immunofluorescence staining has been combined with fluorescence *in situ* hybridization (FISH), which allows the

detection of DNA sequences in the section by annealing (hybridizing) sequence-specific DNA probes that have been coupled with specific fluorescent dyes; the combined staining is sometimes termed *immunoFISH*. Here, an anti-p53 antibody stains carcinoma cell nuclei *dark blue*, while specific DNA probes have detected DNA sequences associated with the centromeres of Chromosome 10 (CEP10, *red*) and Chromosome 17 (CEP17, *green*), as well as the genes encoding the PTEN (*yellow*) and BRCA1 (*light blue*) proteins. (G) Monkey kidney cells growing in monolayer culture were forced to express a protein that caused them to undergo cell–cell fusion, generating a multi-nucleated cell, sometimes termed a polykaryon or syncytium (*center*). The nuclei were stained with DAPI (4′,6′-diamidino-2-phenylindole), a dye that emits *blue* fluorescence when it binds to dsDNA (double-stranded DNA), while the actin cytoskeleton was stained with phalloidin, which binds actin filaments and in this case has been linked to the *green* fluorescent dye FITC (fluorescein isothiocyanate). (A, C–F, courtesy of F. Martins and K. Polyak.B, courtesy of S. McAllister. G, courtesy of S. Rozenblatt.)

Supplementary Sidebar 2.2 Early embryonic cell layers generate distinct cell types

The early embryos of chordates form three distinct cell layers, each of which in turn generates distinct sets of differentiated cell types in the later embryo and newborn (**Figure S2.2**). Moreover, most adult tissues are formed from cells deriving from more than one early embryonic cell layer. For example, in the majority of adult epithelial tissues, the epithelial cells derive from either the ectoderm or the endoderm, while the underlying mesenchymal cells arise from the mesoderm. Notable exceptions to this involve the kidneys and reproductive organs, in which the multiple cell types forming each of these tissues originate entirely from the mesoderm. Hence, epithelial cells can actually arise from the endoderm, mesoderm, or ectoderm.

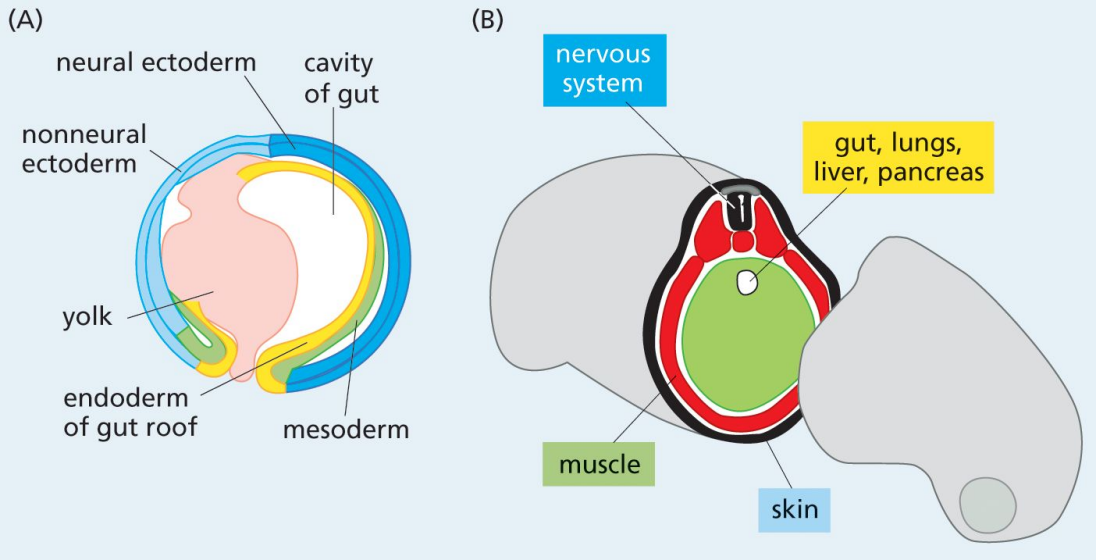


Figure S2.2. Embryonic cell layers (A) The tissues of more complex metazoa develop from three embryonic cell compartments—ectoderm (*blue*), mesoderm (*green*), and endoderm (*yellow*). Each of the three embryonic cell layers is precursor to distinct types of differentiated cells. (B) In an early-stage tadpole, the skin and nervous system develop from the ectoderm (*black*), while the connective tissue, including bone, muscle, and blood-forming cells, develops from the mesoderm (*red*). The gut and derived outpouchings, including lung, pancreas, and liver, develop from the endoderm (*green*). The development of all chordates follows this plan. (Adapted from T. Mohun et al., *Cell* 22:9–15, 1980.)

Supplementary Sidebar 2.3 Anaplastic tumors

Much of the profession of pathology involves analyses of microscopic sections of neoplastic growths, with attempts to determine the grade of tumor, that is, how far it has progressed to a state of aggressive malignancy and, in the case of metastases, the tissue-of-origin in the event that the primary tumor that spawned the metastases cannot be readily detected. Identification of tissue-of-origin is usually aided by the fact that the cells of high-grade malignancies retain many of the biological features that are present in the corresponding normal cells-of-origin. However, as seen in **Figure S2.3**, occasionally the malignant progression of a tumor can effectively erase the morphological traits that usually enable pathologists to readily identify the origins of a tumor under study. Such anaplastic tumors are often highly aggressive and difficult to treat effectively. With the development of (1) monoclonal antibodies directed against tissue-specific marker proteins, (2) large-scale systematic surveys of transcriptomes (see, as examples, Figure 1.14), and (3) the bioinformatics required to process the resulting complex data sets, the assignment of a specific biopsied tumor to one or

another subtype of cancer became almost routine. Hence, the previous reliance exclusively on the morphologic features provided by histopathology was replaced by multi-parameter tests that could categorize tumors routinely, including the great majority of metastatic tumors whose morphology had previously caused them to be relegated to the category of cancers of unknown primary (CUPs).

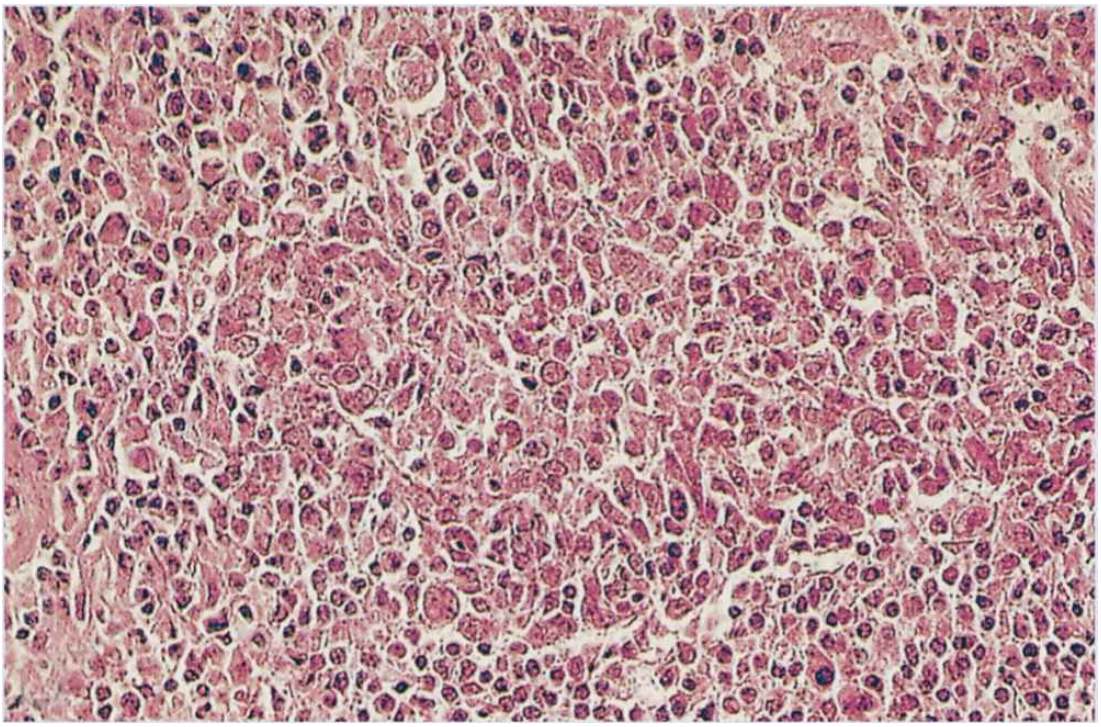

Figure S2.3 Anaplastic tumors of obscure origin The histological appearance of an anaplastic tumor, such as that shown here, gives little indication of its tissue-of-origin. Attempts to determine the origin of these cells with an antibody stain that specifically recognizes one or another tissue-specific protein marker may also prove uninformative. However, more recently developed procedures, including gene expression analyses and sequence analyses of tumor genomes, usually yield an unambiguous assignment of tissue-of-origin. (From A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier.)

Supplementary Sidebar 2.4 Some principles involved in classifying tumors

Many of the principles associated with tumor classification are associated with the need to make useful clinical decisions involving the diagnosis of a tumor (assigning it to a well-defined type or subtype of cancer by enumerating its various characteristics) and prognosis (predicting the future course of the disease). The latter includes a judgment of the responsiveness of a diagnosed tumor to various types of contemplated

therapy including surgery, in addition to the long-term course of a patient's disease. Thus, each type and subtype of tumor has a characteristic course that can be described and predicted with some accuracy by the decades-long experiences of oncologists.

The task of classifying tumors has in recent years become both easier and more difficult. In decades past, almost all of the diagnosis depended simply on histopathological examination of the tissue structure of the tumor under the microscope, doing so using histochemical stains, such as the widely used H&E (hematoxylin and eosin) stain for a wide spectrum of tissue and cancer types (for example, see Figure S2.1A) or more specialized histochemical stains for specific cellular or tissue structures. In addition, macroscopic examination of a tumor, which was usually possible only upon exposing it through surgery, provided further information about its size, degree of progression, and origins. (For example, larger tumors of a given cancer type such as breast cancers generally hold a worse prognosis than smaller tumors.)

The last of these judgments—the origin of the tumor—usually provided the most useful diagnostic decision. The differentiation programs of the cells in various normal tissues continue to influence cell behavior after cells in those tissues undergo neoplastic transformation and become the cells-of-origin of tumor cell populations arising in those tissues. Stated differently, major components of normal differentiation programs persist robustly in tumor cells in spite of the widespread changes in cell physiology that occur in association with the transformation of a normal cell into a tumor cell. This explains why pathologists examining microscopic sections of tumors could successfully classify the tissue origins of >95% of tumors simply by the histomorphology of a cancerous tissue, including aspects of its cytology—the shape and form of individual cells. The remaining tumors, cancers/carcinomas-of-unknown-primary (CUPs), typically were tumors that were ostensibly metastases from a primary tumor that could not be identified at the time of diagnosis; such primary tumors may have disappeared following the seeding of the CUP (see Chapter 14) or remained small, unobtrusive, and thus not readily located.

In addition, microscopic examination of the lymph nodes connected to the organ site in which the tumor was growing would reveal, following their isolation during surgery, the extent to which the tumor had begun to release cells into the lymphatic system, presumably doing so in parallel with releasing cells into the venous system draining the tumor site; hence, lymph node status, including the number of affected lymph nodes, could reveal the degree of metastatic progression, a topic that will be addressed in Chapter 14.

Finally, karyotypic analysis would provide one view of the disorder of the cancer cells' genomes, which in turn could be associated with the staging of the tumor—that is, when considered together with the above-mentioned characteristics, rendering a

judgment of how far the tumor had progressed through the course of multi-step tumor development (see Chapter 11). Together, the various parameters could be integrated into an overall classification of the tumor, placing it in a particular subtype. Reference thereafter to the massive body of clinical oncology experience would then allow a reasonably accurate prediction of the responsiveness of the tumor to surgery, radiotherapy, and chemotherapy, as well as the subsequent eventual course of clinical development, that is, prognosis.

The invention of monoclonal antibodies in 1975 (see **Supplementary Sidebar 16.1**) led in the ensuing decades to an explosion of antigen-specific reagents that made possible the visualization of specific proteins using these antibodies, which were, in turn, often chemically coupled either to enzymes or to a fluorescent protein that generated a specific microscopically visible product (see **Supplementary Sidebar 2.1**). An often-used antibody-coupled enzyme is horseradish peroxidase (HRP), which can react with added chromagenic substrate molecules to generate a pigment that is readily visualized in the microscope. A commonly used fluorescent protein is green fluorescent protein (GFP). At present, the traditional H&E staining suffices for histopathological diagnosis in ∼80% of tumor samples, while the newer immunostaining is often employed in the remaining 20% of cases. In recent years, use of the antibody-based histological techniques has made it possible to properly identify the origins of CUPs as well as tumors that have become quite anaplastic, that is, have shed most of the histomorphological features that enable the identification of the origins of a tumor.

In the same year, the technology was invented that led to the development of DNA microarrays, in which large assemblies of gene-specific DNA molecules could be affixed to glass slides or other substrates, which enabled in turn the surveys of the RNA transcriptomes of cells and tissues. Such microarrays could be used in subsequent decades to stratify tumor samples, that is, to segregate them into distinct subsets that share in common certain transcriptional patterns (see Figure 1.14A). Such stratification allowed tumors that were superficially similar, as judged by histopathology, to be divided into tumor subtypes that carried very different prognoses and behaved very differently in the oncology clinic in response to therapy.

Supplementary Sidebar 2.5 Demonstrations of monoclonality of tumors

The first experiments designed to measure the clonality of tumor cell populations actually relied on a naturally occurring, nongenetic (epigenetic) marking event. As described in Chapter 1, in the somatic cells of early embryos of female placental mammals, one of the two X chromosomes in each cell is selected randomly for silencing. This silencing causes almost all genes on one X chromosome in a cell to be repressed transcriptionally and is manifested karyotypically through the condensation

of the silenced X chromosome into a small particle termed the Barr body. Once an X chromosome (of maternal or paternal origin) has been inactivated in a cell, all descendant cells in adult tissues appear to respect this decision and thus continue to inactivate the same X chromosome.

Thus, the lineage of a cell can be followed *in vivo* from its embryonic ancestor, a process called lineage tracing. The gene for glucose-6-phosphate dehydrogenase (G6PD) is located on the X chromosome, and more than 30% of African American women are heterozygous at this locus. Thus, they carry two alleles specifying forms of this enzyme that can be distinguished either by starch gel electrophoresis or by susceptibility to heat inactivation. Because of X-chromosome silencing, each of the cells in these heterozygous women will express only one or the other allele of the *G6PD* gene, which is manifested in turn in the variant of the G6PD protein that these cells synthesize (**Figure S2.4**). In most of their tissues, half of the cells make one variant enzyme, while the other half make the other variant. In 1965, observations were reported on a number of leiomyomas (benign tumors of the uterine wall) in African American heterozygotes. Each leiomyoma invariably expressed either one or the other variant form of the G6PD enzyme. This meant that, with great likelihood, its component cancer cells all descended from a single founding progenitor that expressed only that particular allele of the *G6PD* gene.

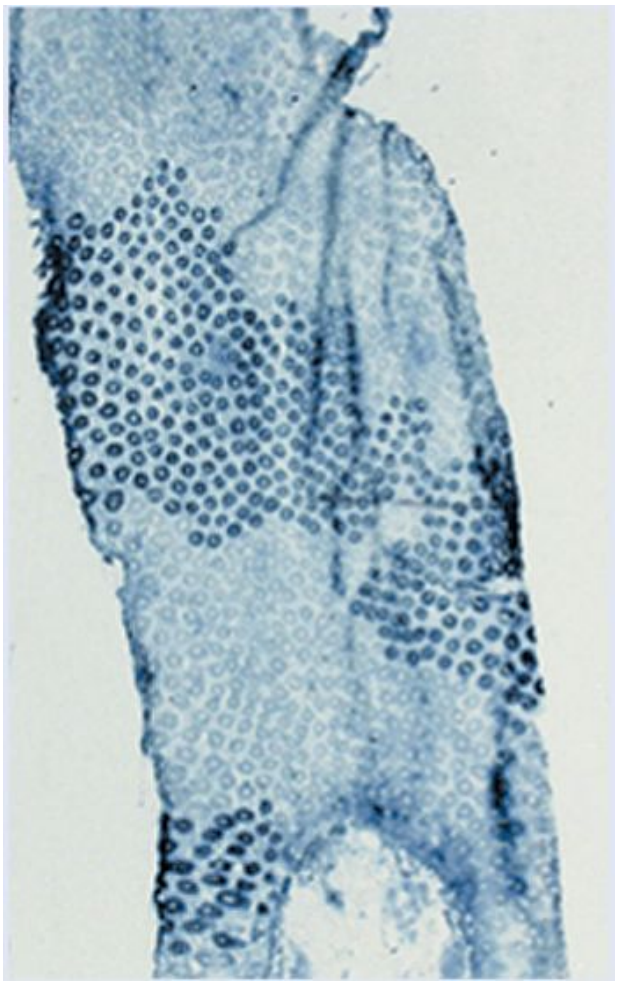
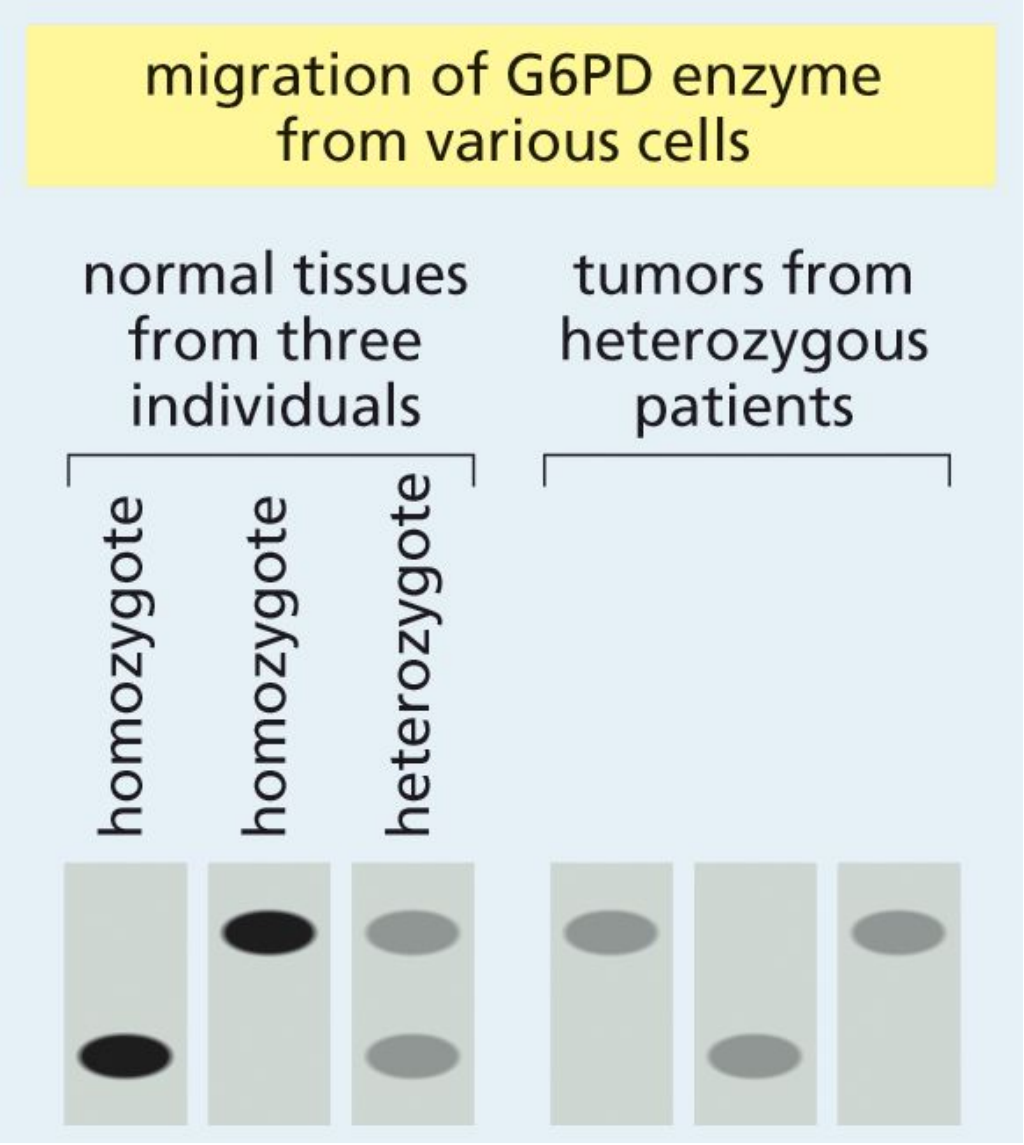
(A)



(B)



(C)

Figure S2.4 X-chromosome inactivation patterns and the monoclonality of tumors (A) The female embryo begins with both X chromosomes in an equally active state. At a very early stage of development, the embryonic cells individually undergo random inactivation of either the X chromosome inherited from the mother (M) or the one from the father (P); expression of almost all genes on a cell's inactivated chromosome becomes silenced. In the adult female, all the lineal descendants of any particular embryonic cell continue to exhibit inactivation of the same X chromosome as their ancestor. Hence, the adult female body is made of patches (clones) of cells of the type Mp and patches of the type mP, where the lowercase letter denotes an inactivated state. (B) The two allelic forms of glucose-6-phosphate dehydrogenase (G6PD), which is encoded by a gene on the X

chromosome, have differing sensitivities to heat inactivation. Hence, gentle heating of tissue from a heterozygote—in this case a section of intestine—reveals patches of cells that carry the heat-resistant, still-active enzyme variant (*dark blue spots*) among patches that do not. The cells in any given patch are the descendants of an embryonic cell that had inactivated either its maternal or its paternal X chromosome. (C) Use of starch gel electrophoresis to resolve the two forms of G6PD showed all of the cancer cells in a tumor from a G6PD-heteozygous patient expressing the same version of this enzyme. This indicated their likely descent from a common ancestral cell that already had this particular pattern of X-inactivation, suggesting that the cancer cells within a tumor mass constitute a monoclonal growth. (B, from M. Novelli et al., *Proc. Natl. Acad. Sci. USA* 100:3311–3314, 2003. With permission from National Academy of Sciences, U.S.A. C, adapted from P.J. Fialkow, *N. Engl. J. Med.* 291:26–35, 1974.)

Demonstrations of the monoclonality of human tumors have taken many forms. One of particular interest came from observations of myelomas, which derive from the B-cell precursors of antibody-producing plasma cells. Normally, the pool of these B-cell precursors consists of hundreds of thousands, likely millions of distinct subpopulations, each expressing its own specific antibody molecules as a consequence of a particular immunoglobulin (antibody) gene rearrangement. In contrast, all the myeloma cells in a patient produce the identical antibody molecule, indicating their descent from a single, common ancestor that was present years earlier in this complex, heterogeneous cell population (**Figure S2.5**).

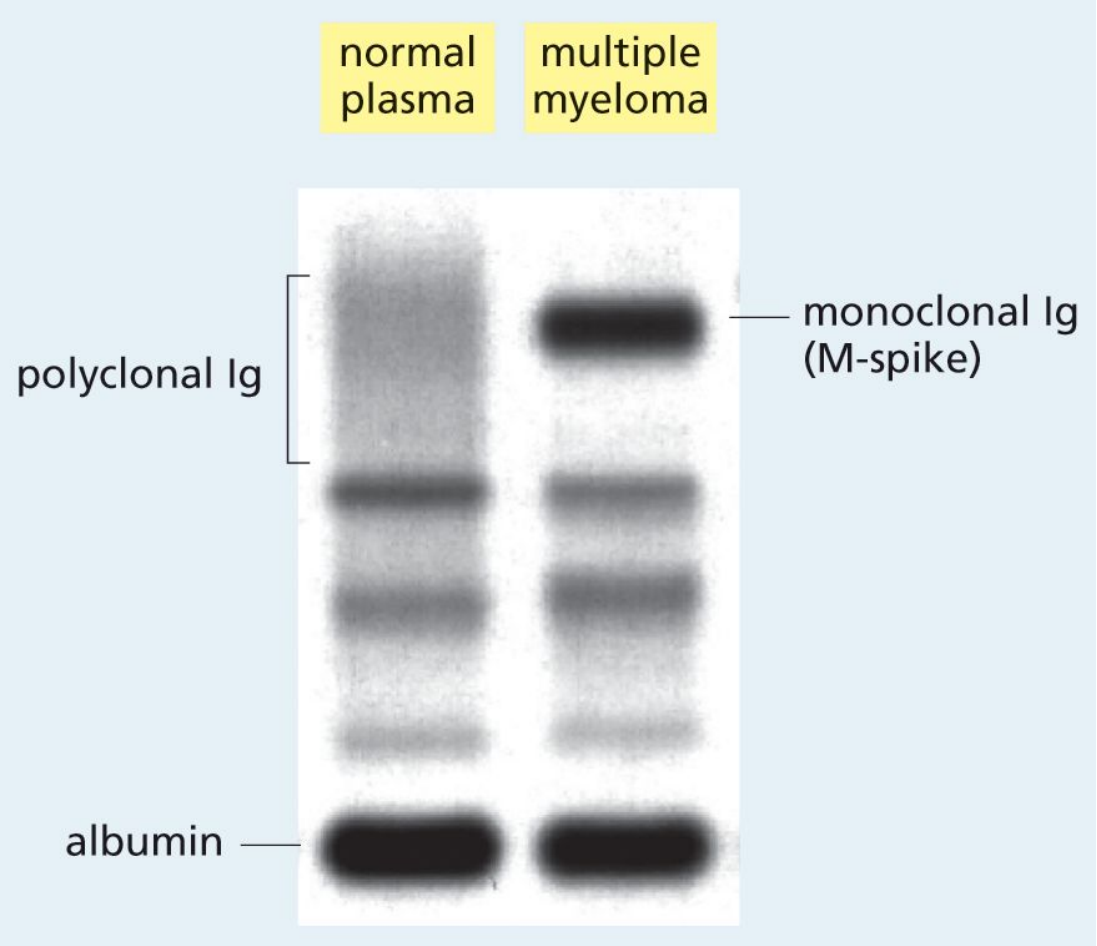


Figure S2.5 Additional proofs of tumor monoclonality In normal plasma, the immunoglobulin (Ig) molecules (e.g., antibodies) migrate as a heterogeneous collection of molecules upon gel electrophoresis (polyclonal Ig, *top of left channel*); this heterogeneity is indicative of the participation of a diverse spectrum (a polyclonal population) of plasma cells in antibody production. However, in multiple myeloma, this heterogeneity is replaced by a single antibody species (termed an M-spike) that is produced by a single clonal population of antibody-secreting tumor cells. (Courtesy of S. Chen-Kiang and S. Ely.)

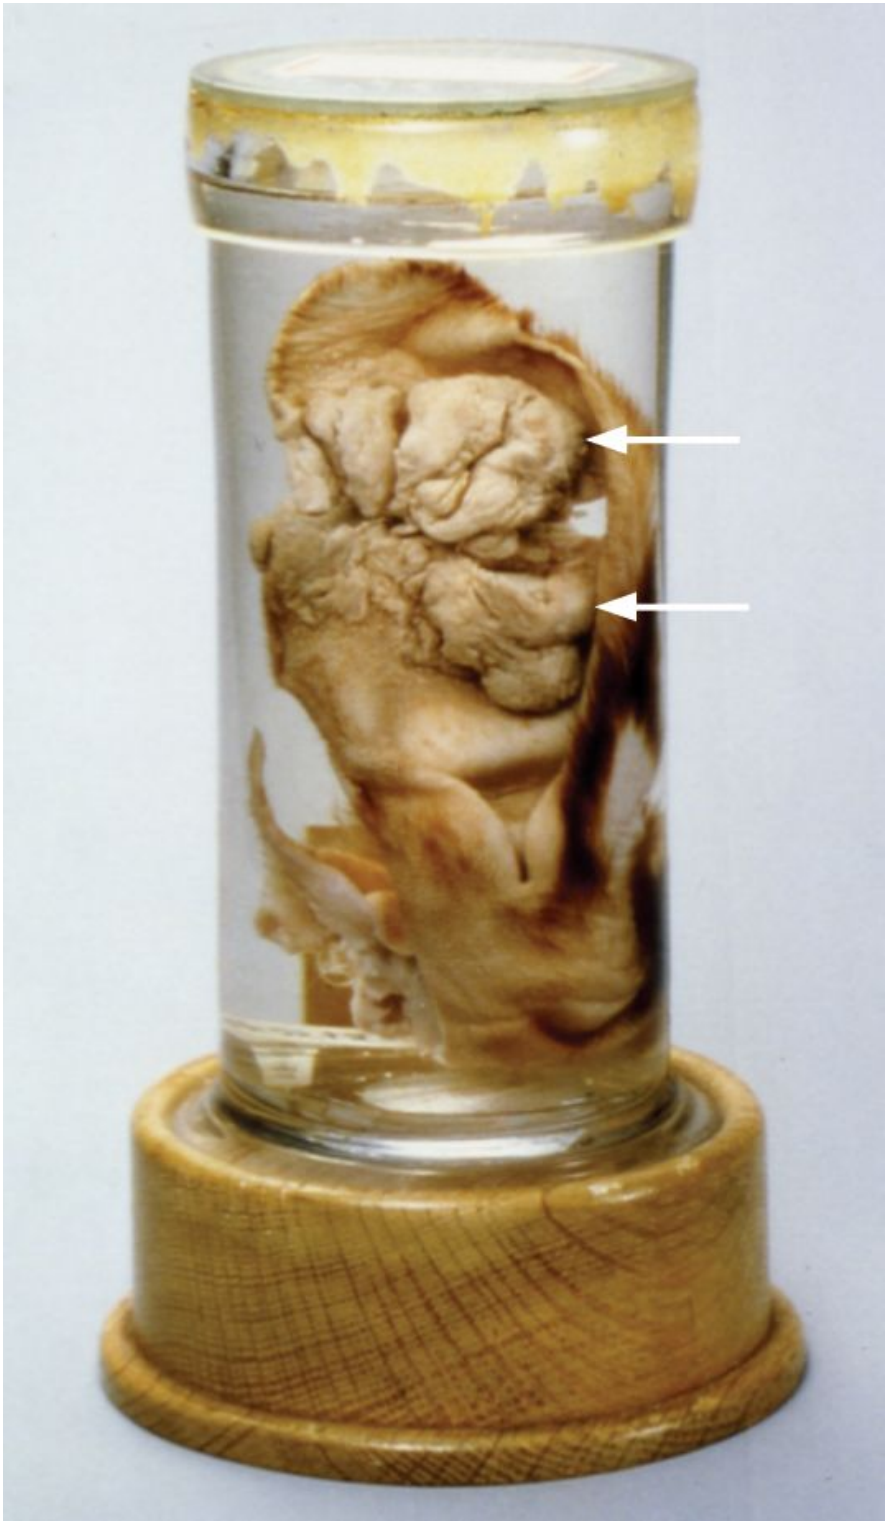
Supplementary Sidebar 2.6 Katsusaburo Yamagiwa and the origins of experimental carcinogenesis

Working at the University of Tokyo, Katsusaburo Yamagiwa undertook to induce tumors by applying agents that were suspected at the time to be potent carcinogens. Others before him had attempted to induce tumors using some of the same coal tar chemicals that Percivall Pott's earlier research had implicated in inducing scrotal cancers in men who had worked as chimney sweeps in London; these attempts all

failed. Yamagiwa, in contrast, undertook to repeatedly apply coal tar carcinogens to the skin of rabbit ears, doing so over a period of many months and finally succeeding (1915) in inducing tumors (**Figure S2.6**). This work effectively launched the field of chemical carcinogenesis research that flourished during most of the twentieth century.

(A)



(B)

Figure S2.6 The first induction of tumors by chemical carcinogens In 1915, Katsusaburo Yamagiwa (A) reported the first successful induction of cancer by repeated treatment of rabbit ears with a chemical carcinogen, in this case coal tars. (B) The skin carcinomas (*arrows*) that he induced on the ears of these rabbits are preserved to this day in the Medical Museum of the University of Tokyo. This particular carcinoma was harvested and fixed following 660 days of painting with coal tar. (Courtesy of University of Tokyo Graduate School of Medicine.)

In faraway Denmark, Johannes Grib Fibiger had reported two years earlier that stomach cancers in rats could be traced to *Spiroptera* worms that they harbored. His work, for which he received the 1926 Nobel Prize in Physiology or Medicine, represented direct and strong validation of the idea, first indicated by Peyton Rous's work (described in Section 3.1), that cancer was yet another example of an infectious disease. Indeed, although their work was mechanistically quite unrelated, the Nobel Committee regarded Yamagiwa's research as a validation of Fibiger's research and therefore awarded the Nobel Prize only to Fibiger.

A year after Fibiger's 1926 Nobel award, he passed away and his scientific opus began to disintegrate. The stomach tumors that he had described were not tumors at all. Instead, they were found to be metaplastic stomach epithelia that were the result of the profound vitamin deficiencies suffered by these rats; they lived in sugar refineries and ate sugar cane almost exclusively. Fibiger's Nobel Prize became an embarrassment to the still-small community of cancer researchers. They threw the proverbial baby out with the bathwater, discrediting both his work and the notion that cancer could ever be caused by infectious agents. Another 40 years would pass before the Nobel Committee once again awarded a prize for cancer research (by recognizing Peyton Rous for his discovery of Rous sarcoma virus).

Yamagiwa's fundamental contribution earned him much respect in Japan but was essentially overlooked in the rest of the world during his lifetime. Only with the advent in the 1940s of intensive experimental study of skin carcinogenesis by Isaac Berenblum, first at Oxford University and later at the Weizmann Institute in Israel (described in Section 11.13), did Yamagiwa's pioneering work become widely appreciated internationally.

Supplementary Sidebar 2.7 Structures of carcinogenic coal tar molecules

While work of Yamagiwa (see **Supplementary Sidebar 2.6**) and others demonstrated experimentally that coal tar chemicals were potently carcinogenic, the chemical species within the highly complex mixture of coal tar condensate chemicals that were specifically responsible for the observed effects on cancer induction were unresolved.

By the late 1930s, using complex analytical tools of organic chemistry, chemists had deciphered the molecular structures of many of these compounds (**Figure S2.7**).

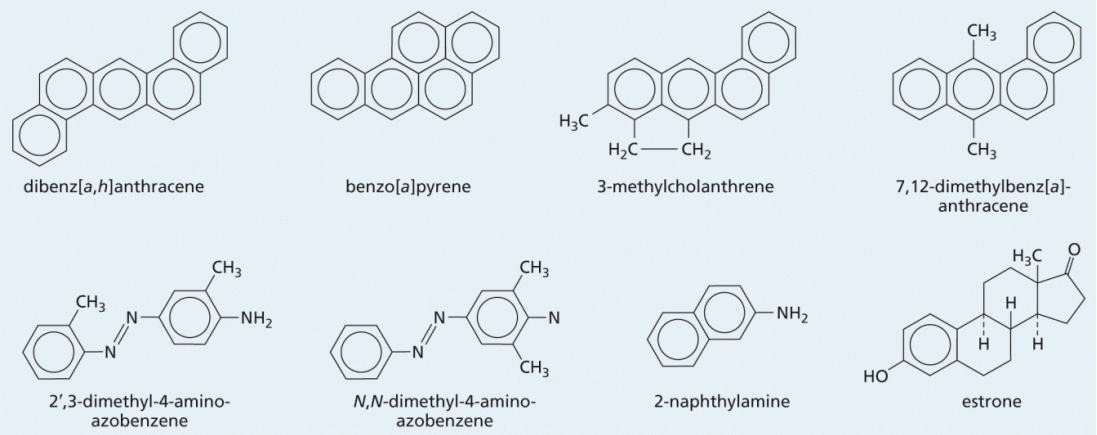


Figure S2.7 Structures of carcinogenic hydrocarbons These chemical species arise from the incomplete combustion of organic (carbon-containing) compounds. Each of the chemical structures shown here, which were already determined before 1940, represents a chemical species thatwas found, following purification, tobe potently carcinogenic. The four compounds shown in the top row are all polycyclic aromatic hydrocarbons (PAHs). (From E.C. Miller, *Cancer Res.* 38:1479–1496, 1978. With permission from American Association for Cancer Research.)

Supplementary Sidebar 2.8 Use of the Ames test to detect mutagenic and thus potentially carcinogenic compounds

The Ames test was applied extensively in the years after its initial employment to detect a wide diversity of mutagens, many of which are present in the food supply and many of which are the products of natural biosynthesis. In the great majority of cases, these “natural” compounds are present in minute quantities in the food chain and therefore do not present significant risk of developing various types of cancer. Nevertheless, they suggest the possibility that the vast majority of mutagenic compounds to which humans are exposed are products of natural/organic biosynthesis rather than being products of synthetic chemical processes (**Table S2.1**).

Table S2.1 A sampling of Bruce Ames’s roster of carcinogens identified in the normal diet[a]

Foodstuff	Compound	Concentration in foodstuff
Black pepper	piperine	100 mg/g
Common mushroom	agaritine	3 mg/g
Celery	furocoumarins, psoralens[b]	1 µg/g, 0.8 µg/g
Rhubarb	anthraquinones	varies
Cocoa powder	theobromine	20 mg/g
Mustard, horseradish	allyl isothiocyanate	varies
Alfalfa sprouts	canavanine[c]	15 mg/g
Burnt materials[d]	large number	varies
Coffee	caffeic acid	11.6 mg/g

Adapted from B.N. Ames, *Science* 221:1256–1264, 1983; B.N. Ames and L.S. Gold, *Proc. Natl. Acad. Sci. USA* 87:7777–7781, 1990; and L.S. Gold, B.N. Ames and T.H. Slone, Misconceptions about the causes of cancer, in D. Paustenbach, ed., Human and Environmental Risk Assessment: Theory and Practice, New York: John Wiley & Sons, 2002, pp. 1415–1460.

Supplementary Sidebar 2.9 Other tests for mutagenicity help assess possible carcinogenicity

The Ames test is only one of a number of biological assay systems that can be used to assess the mutagenic potency of suspected carcinogenic chemicals. Many of these other assays depend upon exposing mammalian cells directly to the chemical compounds being tested and the subsequent use of a diverse array of biological readouts. For example, (1) a test for sister chromatid exchange (SCE) measures crossing over between the two paired chromatids that are formed by DNA replication during the S phase and persist in paired form during the late (that is, G_2) phase of a cell's growth-and-division cycle. Many mutagenic agents have been shown to provoke this SCE. (2) Mutagenic agents may also register as being capable of inducing the formation of fragmented cell nuclei, that is, micronuclei. (3) Use of genetics has made it possible to select mammalian cells that have lost by mutation their thymidine kinase or HGPRT (hypoxanthine guanine phosphoribosyl transferase) enzymes. (4) The ability to examine under the light microscope the chromosomal array (that is, the karyotype; see Figure 1.9) of cells in metaphase of mitosis makes it possible to screen for chromosomal aberrations inflicted by test compounds. (5) Yet another assay gauges the degree of DNA labeling in those cells that are in the G_1 or G_2 phase of the cell cycle (described in Chapter 8); since cellular DNA synthesis normally occurs in the S phase, such non-S-phase labeling, which is sometimes referred to as "unscheduled DNA synthesis," has also been shown to be a good indicator of the genomic damage that has been inflicted on a cultured cell, since this type of DNA synthesis represents one key step in the process used by cells to repair damaged DNA.

None of these tests has proven to be ideal as a predictor of the carcinogenicity of a test substance. The Ames test, as an example, has been found by some to have a sensitivity (% of established carcinogens identified as mutagens) of about 54% and a specificity (% of noncarcinogens identified as nonmutagens) of 70%.

OceanofPDF.com

Glossary

cell-of-origin
: The fully normal cell that serves as the ancestor of all the neoplastic cells within a tumor, i.e., their last common normal ancestor.

micronucleus
: (1) A small fragment of a nucleus that has its own nuclear membrane and results from certain aberrations in cell division or from damage inflicted on a cell; micronuclei often carry only a single chromosome and arise when this chromosome fails to be incorporated into the previously formed mitotic spindle, thereby escaping inclusion in the normal karyotypic array of a daughter cell. (2) Smaller of the two nuclei in many ciliate cells, which is used to carry and transmit the ciliate genome to progeny cells.

immunoglobulin
: An antibody molecule assembled from two heavy and two light chains.

epigenetic
: (1) Referring to a process that affects phenotype without the involvement of heritable changes in the nucleotide sequence of the genome. (2) Referring to a mechanism enabling the transmission of a heritable trait from a cell or organism to its progeny that does not depend directly on changes of specific nucleotide sequences in its genome. (3) Referring to a mechanism that creates a cell-heritable trait, as in (2), and maintains expression of this trait in the absence of ongoing exposure to the stimulus that initially induced the expression of this trait. *See also* **epigenetics**, **genetic**.

leiomyoma
: Benign tumor of the mesenchymal cells forming the wall of the uterus.

myeloma
: A malignancy of the antibody-producing cells of the bone marrow, often called multiple myeloma to indicate the large number of osteolytic lesions that are encountered in patients with advanced disease.

lineage
: A continuous, linear succession of cells extending from an ancestral cell via multiple intervening generations to its most recent

descendants.

anaplastic

(Referring to a tumor) having a tissue and cellular architecture lacking the differentiated characteristics of an identifiable tissue-of-origin or tumor type.

anaplastic

(Referring to a tumor) having a tissue and cellular architecture lacking the differentiated characteristics of an identifiable tissue-of-origin or tumor type.

prognosis

A prediction about the future clinical course of a disease, often influenced by detailed analyses of its existing attributes such as histopathology and biochemical markers.

staging

A determination of the extent to which a tumor has progressed to a specific stage of multi-step tumor progression, involving consideration of an array of gross/macroscopic, histopathological, and karyotypic parameters.

chromogenic

A chemical that generates a visible pigment upon enzymatic alteration; *sometimes called* **chromagenic**.

stratify

(n., **stratification**) To classify superficially similar entities (e.g., a group of tumors) into several distinct categories or subclasses based on the shared properties of the entities within a given subclass.

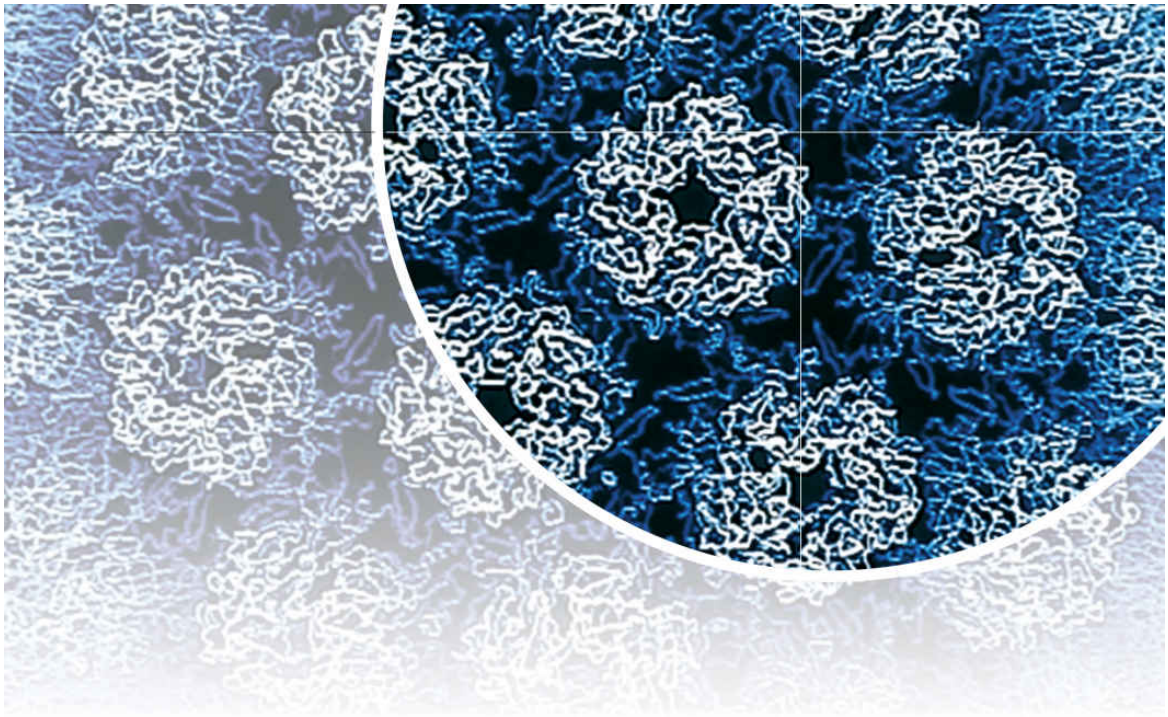
Chapter 3
Cancer as an Infectious Disease



A color micrograph of the S V 40 virus. It is coated with cylidrical protrusions.

A tumor of the chicken ... has been propagated in this laboratory since October, 1909. The behavior of this new growth has been throughout that of a true neoplasm, for which reason the fact of its transmission by means of a cell-free filtrate assumes exceptional importance.

Francis Peyton Rous, cancer biologist, 1911

Viruses are capable of causing a wide variety of human diseases, ranging from rabies to smallpox to the common cold and the acute respiratory syndrome triggered by the COVID-19 virus. The great majority of these infectious agents do harm through their ability to multiply inside infected host cells, to kill these cells, and to release progeny virus particles that proceed to infect other hosts

nearby. The cytopathic (cell-killing) effects of viruses, together with their ability to spread rapidly throughout a tissue, enable these agents to leave wide swaths of destruction in their wake.

But the peculiarities of certain viral replication cycles may on occasion yield quite another outcome. Rather than killing infected cells, some viruses may, quite paradoxically, force their cellular hosts to thrive, indeed, to proliferate uncontrollably. In so doing, such viruses—often called tumor viruses—can create cancer.

At one time, beginning in the early 1970s, tumor viruses were studied intensively because they were suspected to be the cause of many common human cancers. This notion was eventually rejected based on the evidence subsequently gathered during that decade, which indicated that virus-induced cancers represent only a minority of the cancer types afflicting humans. Nonetheless, this line of research proved to be invaluable for cancer biologists: study of various tumor viruses provided the key for opening many of the long-hidden secrets of human cancers, including the great majority of cancers that have no connection with infectious agents.

As we will see, tumor virus research had a highly variable history over the course of the last century. These infectious agents were discovered in the first decade of the twentieth century and then retreated from the center stage of science. Half a century later, interest in these agents revived, culminating in the frenetic pace of tumor virus research during the 1970s.

The cancer-causing powers of tumor viruses drove many researchers to ask precisely how they succeed in creating disease. Most of these viruses possess relatively simple genomes containing only a few genes, yet some were found able to overwhelm an infected cell and its vastly more complex genome and to redirect cell growth. Such behavior indicated that tumor viruses have developed extremely potent genes to perturb the complex regulatory circuitry of the host cells that they infect.

By studying tumor viruses and their mechanisms of action, researchers changed the entire mindset of cancer research. Cancer became a disease of genes and thus a condition that was susceptible to analysis by the newly invented tools of molecular biology and genetics. When this story began, no one anticipated how obscure tumor viruses would one day revolutionize the study of human cancer pathogenesis.

3.1 Peyton Rous discovers a chicken sarcoma virus

In the last two decades of the nineteenth century, the research of Louis Pasteur and Robert Koch uncovered the infectious agents that were responsible for dysentery, cholera, rabies, and a number of other diseases. By the end of the century, these agents had been placed into two distinct categories, depending on their behavior upon filtration. Solutions of infectious agents that were trapped in the pores of filters were considered to contain bacteria. The other agents, which were small enough to pass through the filters, were classified as viruses. On the basis of this criterion, the agents responsible for rabies, foot-and-mouth disease, and smallpox were categorized as viruses.

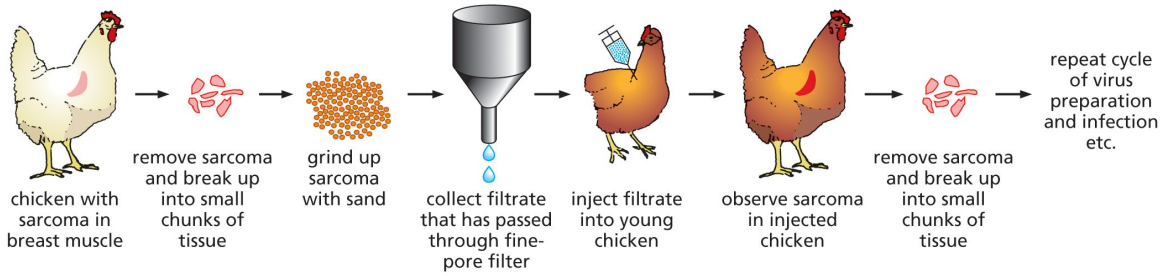
Cancer, too, was considered a candidate infectious disease. As early as 1876, a researcher in Russia reported the transmission of a tumor from one dog to another: chunks of tumor tissue from the first dog were experimentally implanted into the second, whereupon a tumor appeared several weeks later. This success was followed by many others using rat and mouse tumors.

The significance of these early experiments remained controversial. Some researchers interpreted these outcomes as proof that cancer was a transmissible disease. Yet others dismissed these transplantation experiments, since in their eyes, such work showed only that tumors, like normal tissues, could be excised from one animal and forced to grow as a graft in the body of a second animal.

In 1908, two researchers in Copenhagen reported extracting a filterable agent from chicken leukemia cells and transmitting this agent to other birds, which then contracted the disease. The two Danes did not follow up on their initial discovery, and it remained for Peyton Rous, working at the Rockefeller Institute in New York, to found the discipline of tumor virology (**Supplementary Sidebar 3.1**).

A year later, Rous began his study of a sarcoma that had appeared in the breast muscle of a hen. In initial experiments, Rous succeeded in transmitting the tumor by implanting small fragments of it into other birds of the same breed. Later, as a variation of this experiment, he ground up a sarcoma fragment in sand and filtered the resulting homogenate under conditions in which only subcellular particles could pass through the filter (**Figure 3.1**). When he injected the resulting

filtrate into young birds, they too developed tumors, sometimes within several weeks. He subsequently found that these induced tumors could also be homogenized to yield, once again, an infectious agent that could be transmitted, following filtration, to yet other birds, which also developed sarcomas at the sites of injection.



Rous's protocol for inducing sarcomas in chickens begins with a chicken that already has sarcoma in the breast muscle. The sarcoma tissue is removed and broken up into small chunks, which are then ground up with sand. The resulting homogenate is passed through a fine-pore filter. The collected filtrate is injected into a young chicken. Some time later, a sarcoma is observed in the injected chicken. Now the cycle of virus preparation and infection can be repeated: the sarcoma tissue is removed and broken up into small chunks, and so on.

Figure 3.1 Rous's protocol for inducing sarcomas in chickens Rous removed a sarcoma from the breast muscle of a chicken, ground it with sand, and passed the resulting homogenate through a fine-pore filter. He then injected the filtrate (the liquid that passed through the filter) into the wing web of a young chicken and observed the development of a sarcoma many weeks later. He then ground up this new sarcoma and repeated the cycle of homogenization, filtration, and injection, once again observing a tumor in another young chicken. These cycles could be repeated indefinitely; after repeated serial passaging, the virus produced sarcomas far more rapidly than the original viral isolate.

These serial passages of the sarcoma-inducing agent from one animal to another yielded a number of conclusions that are obvious to us now but at the time were nothing less than revolutionary. The carcinogenic agent, whatever its nature, was clearly very small, since it could pass through a filter. Hence, it was a virus (**Sidebar 3.1**). This virus could cause the development of a sarcoma in an injected chicken, doing so on a predictable timetable. Such an infectious agent offered

researchers the unique opportunity to induce cancers at will rather than relying on the spontaneous and unpredictable appearance of tumors in animals or humans. In addition to its ability to induce cancer, this agent, which came to be called Rous sarcoma virus (RSV), was capable of multiplying within the tissues of the chicken; far more virus could be recovered from an infected tumor tissue than was originally injected.

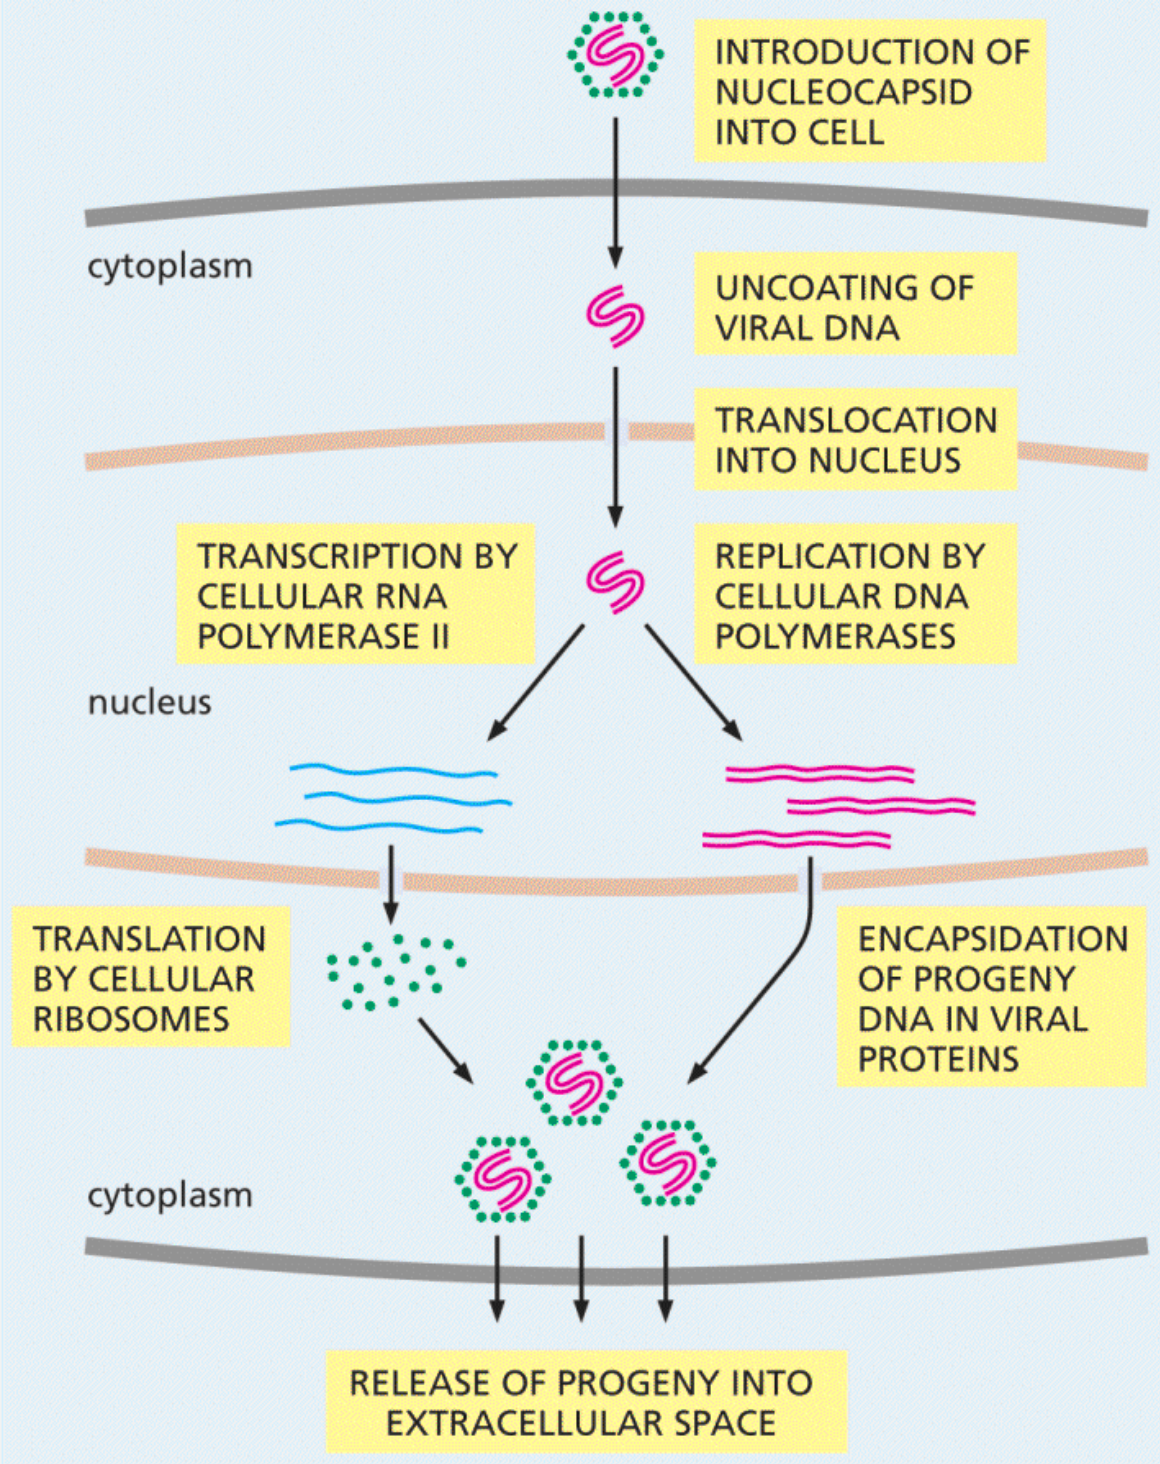
Sidebar 3.1 Viruses have simple life cycles

The term “virus” refers to a diverse array of particles that infect and multiply within a wide variety of cells, ranging from bacteria to the cells of plants and metazoa. Relative to the cells that they infect, individual virus particles, often termed virions, are tiny. This explains the original experimental definition of a virus: an infectious particle that could pass through a filter that was designed to trap larger infectious particles, namely bacteria. Virions are generally simple in structure, with a nucleic acid (DNA or RNA) genome wrapped in a protein coat (a capsid) and, in some cases, a lipid membrane surrounding the capsid. In isolation, viruses are metabolically inert. They can multiply only by infecting and parasitizing a suitable host cell. The viral genome, once introduced into the cell, provides instructions for the synthesis of progeny virus particles. The host cell, for its part, provides the low–molecular-weight precursors needed for the synthesis of viral proteins and nucleic acids, the protein-synthetic machinery, and, in many cases, the polymerases required for replicating and transcribing the viral genome.

The endpoint of the resulting infectious cycle is the production of hundreds, even thousands of progeny virus particles that can then leave the infected cell and proceed to infect other susceptible cells. The interaction of the virus with the host cell can be either a virulent one, in which the host cell is destroyed during the infectious cycle, or a persistent one, in which the host cell survives for extended periods, all the while harboring the viral genome and releasing progeny virus particles.

Many viruses carrying double-stranded DNA (dsDNA) genomes replicate in a fashion that closely parallels the macromolecular metabolism of their host cells (**Figure 3.2**). These viruses use host-cell DNA polymerases to replicate their DNA, host-cell RNA polymerases to transcribe the viral mRNAs from viral dsDNA templates, and host ribosomes to translate the resulting viral mRNAs. Once synthesized, viral proteins are used to coat (encapsidate) the newly

synthesized viral genomes, resulting in the assembly of complete progeny virions, which then are released from the infected cell.



The life cycle of a virus. It begins when a nucleocapsid is introduced into the cytoplasm of a cell. The viral D N A undergoes uncoating and translocation

into the cell nucleus. Now two processes occur in parallel. One process is transcription by cellular R N A polymerase 2. The other process is replication by cellular D N A. Ribosomes translate the products of the transcription process out of the nucleus. The progeny D N A produced by replication undergo encapsidation by the viral proteins produced through transcription. The new, complete progeny particles are released into extracellular space.
Figure 3.2 Life cycle of viruses with dsDNA genomes The life cycle of viruses with double-stranded DNA (dsDNA) genomes closely parallels that of the host cell. Almost all of the steps leading to the synthesis of viral DNA, RNA, and proteins can be achieved by using the synthetic machinery provided by the infected host cell. (Adapted from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W. W. Norton & Company, 2015.)

Since cells do not express enzymes that can replicate RNA molecules, the genomes of most RNA-containing virus particles encode their own RNA-dependent RNA polymerases to replicate their genomes. Poliovirus, as an example, makes such an enzyme, as does rabies virus. RNA tumor viruses like Rous sarcoma virus, as we will learn later in this chapter, follow a much more circuitous route for replicating their viral RNA.

In 1911, when Rous finally published his work, yet another report appeared on a transmissible virus of rabbit tumors, called myxomas. Soon thereafter, Rous and his collaborators found two other chicken viruses, and yet another chicken sarcoma virus was reported by others in Japan. Four years later, Rous himself gave up his research on the virus he had discovered, since human cancer did not seem to behave like an infectious disease. Then, research on tumor viruses languished for two decades until other novel tumor viruses were discovered. The molecular nature of viruses and the means by which they multiplied would remain mysteries for more than half a century after Rous's initial discovery.

Still, his finding of a sarcoma virus reinforced the convictions of those who believed that virtually all human diseases were provoked by infectious agents. In their eyes, cancer could be added to the lengthening list of diseases, such as cholera, tuberculosis, rabies, and sepsis, whose causes could be associated with a specific microbial agent. Like many others, however, Rous focused his research in the decades that followed on chemicals as causes of human cancer. As described in Section 2.8, the field of chemical carcinogenesis to which Rous turned was established in the early twentieth century following the discovery of chemicals that were clearly carcinogenic. The research community turned its back

on Rous sarcoma virus and the other tumor viruses for decades after his initial discoveries.

Glossary

filtrate
: Liquid that has passed through a filter.

virion
: Virus particle including a capsid (coat) and the viral genome.

capsid
: Protein coat of a virus particle that envelops and protects the viral genome.

virulent
: Referring to an infectious agent, such as a virus, that exhibits toxicity and creates damage in an infected host cell or organism. *See also* **temperate**.

encapsidation
: Process of packaging a viral genome in a capsid.

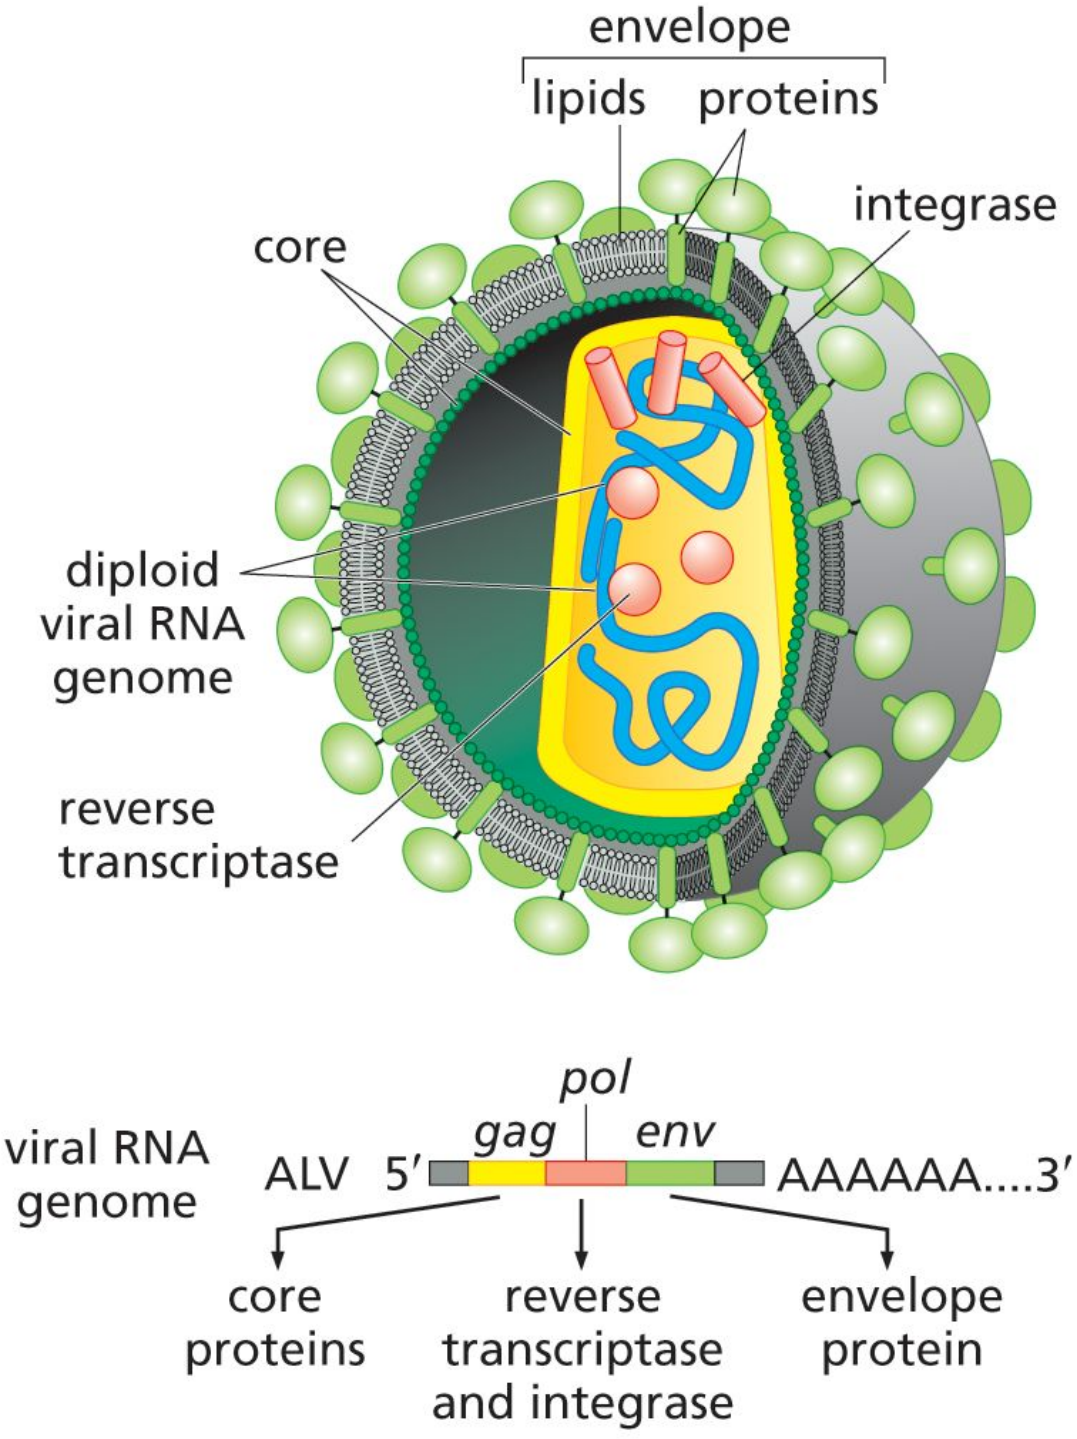
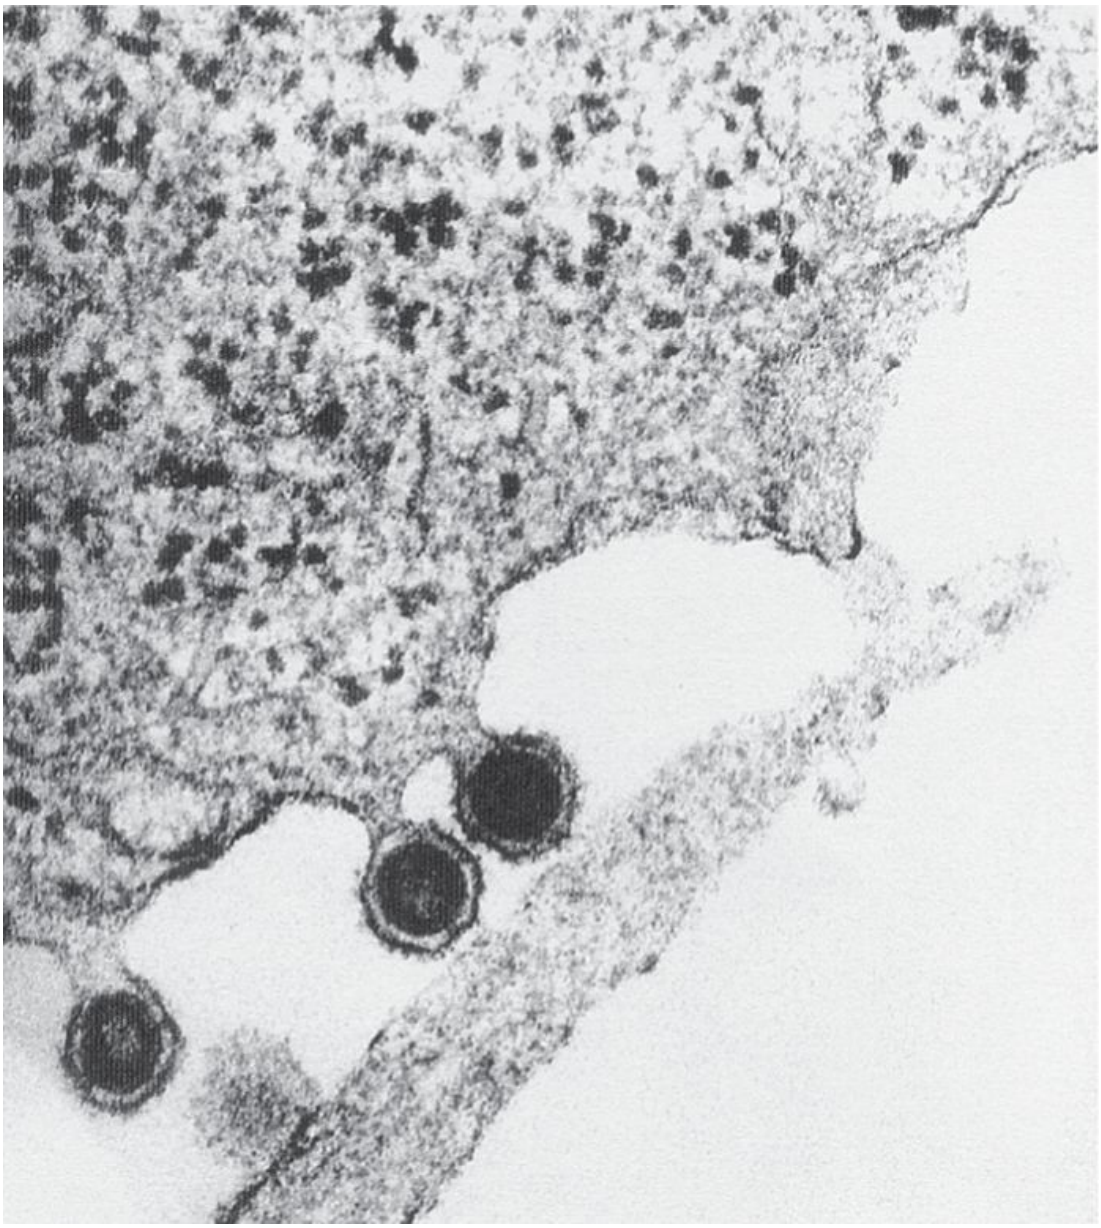
3.2 Rous sarcoma virus is discovered to transform infected cells in culture

The rebirth of Rous sarcoma virus research began largely at the California Institute of Technology in Pasadena, in the virology laboratory of Renato Dulbecco. This group found that when stocks of RSV were introduced into Petri dishes carrying cultures of chicken embryo fibroblasts, the RSV-infected cells survived, apparently indefinitely. (These experiments depended on the then-recently developed procedures of tissue culture, that is, the ability to propagate cells in culture dishes outside of living tissues; **Supplementary Sidebar 3.2.**) It seemed that RSV parasitized these cells, forcing them to produce a steady stream of progeny virus particles for many days, weeks, even months (**Figure 3.3A, B**). Most other viruses, in contrast, were known to enter into host cells, multiply, and quickly kill their hosts; the multitude of progeny virus particles released from dying cells could then proceed to infect yet other susceptible cells in the vicinity, repeating the cycle of infection, multiplication, and cell destruction (see Sidebar 3.1).



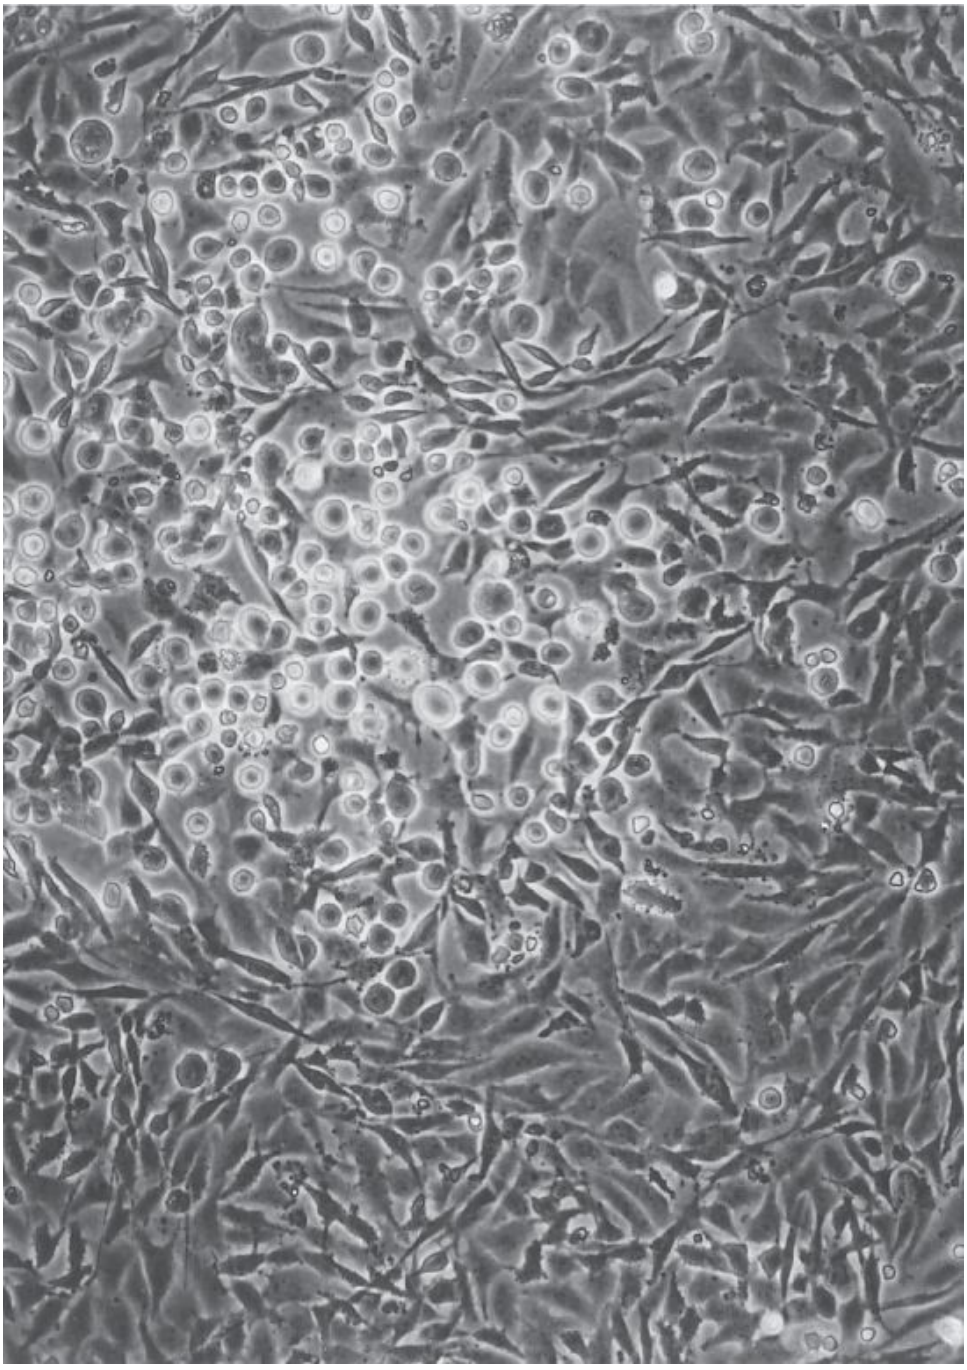
The structure of the R S V virion. The spherical outer shell consists of a layer of lipids penetrated by rodlike proteins that have a bulbous attachment on the outward-facing end. The core is also spherical, but at its center is an oblong structure containing short, rod-shaped pieces of integrase; long, wormlike pieces of of diploid viral R N A genome; and small, spherical pieces of reverse

transcriptase. Below the virion is a diagram of the structure of the viral R N A genome for A L V, with a 5 prime end on the left and a 3 prime end on the right. At the 5 prime end, from left to right, are a gag gene that encodes core proteins, a pol gene that encodes reverse transcriptase and integrase, and an evn gene that encodes envelope protein.
(A)



A transmission electron micrograph shows virus particles budding from the surface of an infected cell.

(B)



A micrograph shows a dense cluster of rounded cells surrounded by less densely packed elongated cells.

(C)

Figure 3.3 The virion of RSV and transformation of infected cells (A) An artist’s reconstruction of the structure of a retrovirus virion, such as that of Rous sarcoma virus, which has four major types of viral proteins. The glycoprotein

spikes (encoded by the viral *env* gene) that protrude from the lipid bilayer membrane enable the virion to *adsorb* to the surface of a cell and to introduce its contents into the cytoplasm. Beneath this lipid membrane lies a protein shell formed by the several core proteins encoded by the viral *gag* gene. Within this protein shell are two identical copies of the viral genomic RNA and a number of reverse transcriptase and integrase molecules specified by the viral *pol* gene. (B) Transmission electron micrograph showing murine leukemia virus (MLV) particles budding from the surface of a chronically infected cell; avian leukosis virus (ALV) particles behave identically. As the nucleocapsid cores (containing the viral gag proteins, the virion RNA, and the reverse transcriptase and integrase enzymes) push through the plasma membrane of the infected cell, they wrap themselves with a patch of lipid bilayer taken from the plasma membrane of the infected cell. (C) This phase-contrast micrograph reveals a focus of Rous sarcoma virus–transformed chicken embryo fibroblasts surrounded by a monolayer of uninfected cells. The focus stands out because it is composed of rounded, refractile cells that are beginning to pile up on one another, in contrast to the flattened morphology of the surrounding normal cells, which stop proliferating after they have produced a layer of cells one cell thick. (A, adapted from H. Fan et al., The Biology of AIDS. Boston: Jones and Bartlett Publishers, 1989. With permission of Jones and Bartlett. B, reprinted from *Cell Press*, Vol. 107, 55–65, Jennifer E. Garrus, Uta K. von Schwedler, Owen W. Pornillos, Scott G. Morham, Kenton H. Zavitz, Hubert E. Wang, Daniel A. Wettstein, Kirsten M. Stray, Mélanie Côté, Rebecca L. Rich, David G. Myszka, Wesley I. Sundquist, Tsg101 and the Vacuolar Protein Sorting Pathway Are Essential for HIV-1 Budding, 55-65, Copyright (2001), with permission from Elsevier. C, courtesy of P.K. Vogt.)

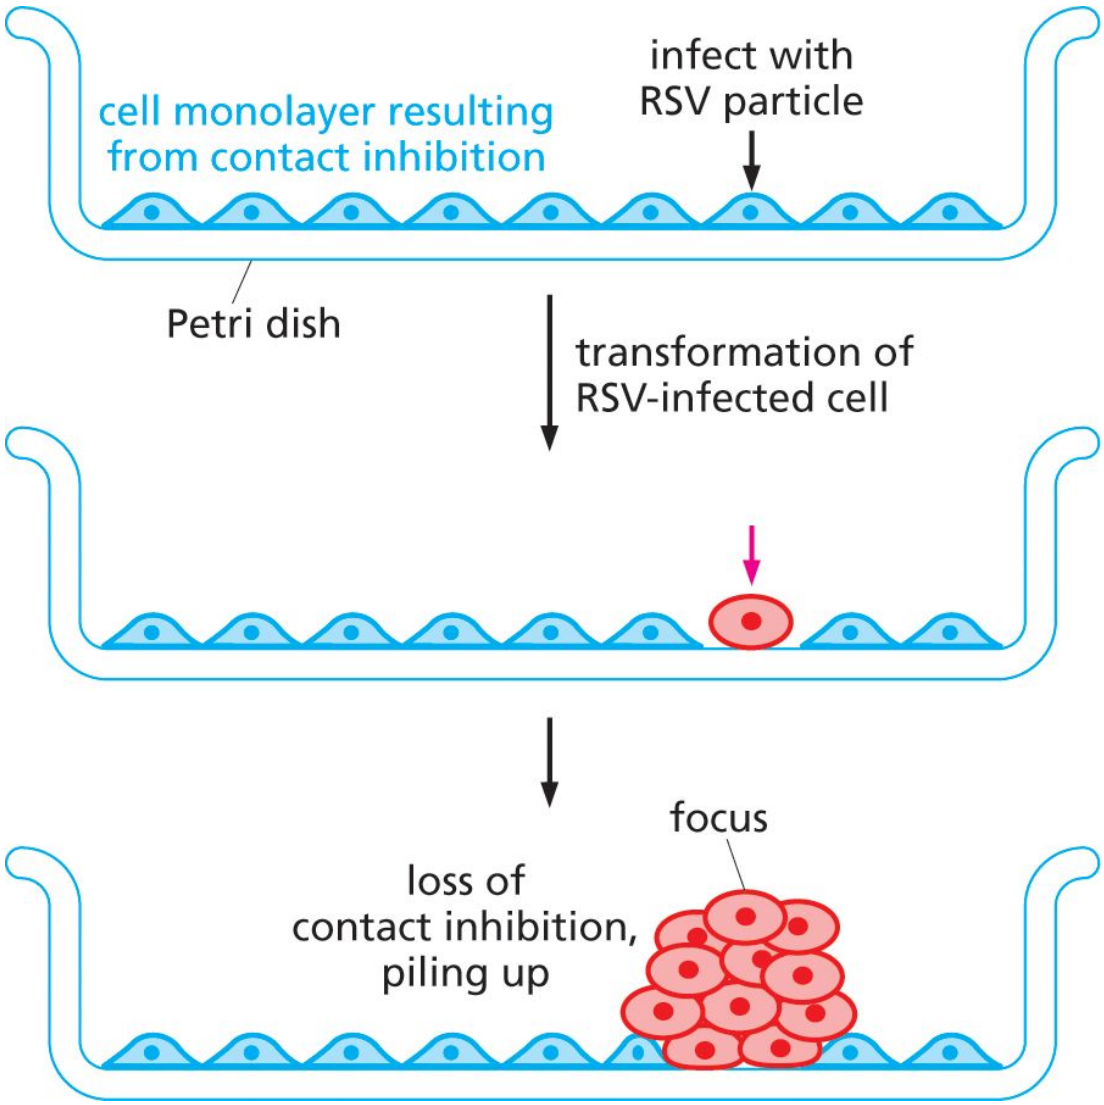
Most important, the RSV-infected cells in these cultures displayed many of the traits associated with cancer cells. Thus, foci (clusters) of cells appeared after infection. Under the microscope, these cells strongly resembled the cells isolated from chicken sarcomas, exhibiting the characteristic rounded morphology of cancer cells (Figure 3.3C). They also had a metabolism reminiscent of that seen in cells isolated from tumors. This resemblance led Howard Temin (a student in Dulbecco's laboratory; **Supplementary Sidebar 3.3**) and Harry Rubin (a post-doctoral fellow) to conclude that the process of cell transformation—conversion of a normal cell into a tumor cell—could be accomplished within the confines of a Petri dish, not just in the complex and difficult-to-study environment of a living tissue.

These simple observations radically changed the course of twentieth-century cancer research, because they clearly demonstrated that cancer formation could be studied at the level of individual cells whose behavior could be tracked closely under the microscope. This insight suggested the further possibility that the entire complex biology of tumors could one day be understood by studying the transformed cells

forming tumor masses. So, an increasing number of biologists began to view cancer as a disease of malfunctioning cells rather than abnormally developing tissues.

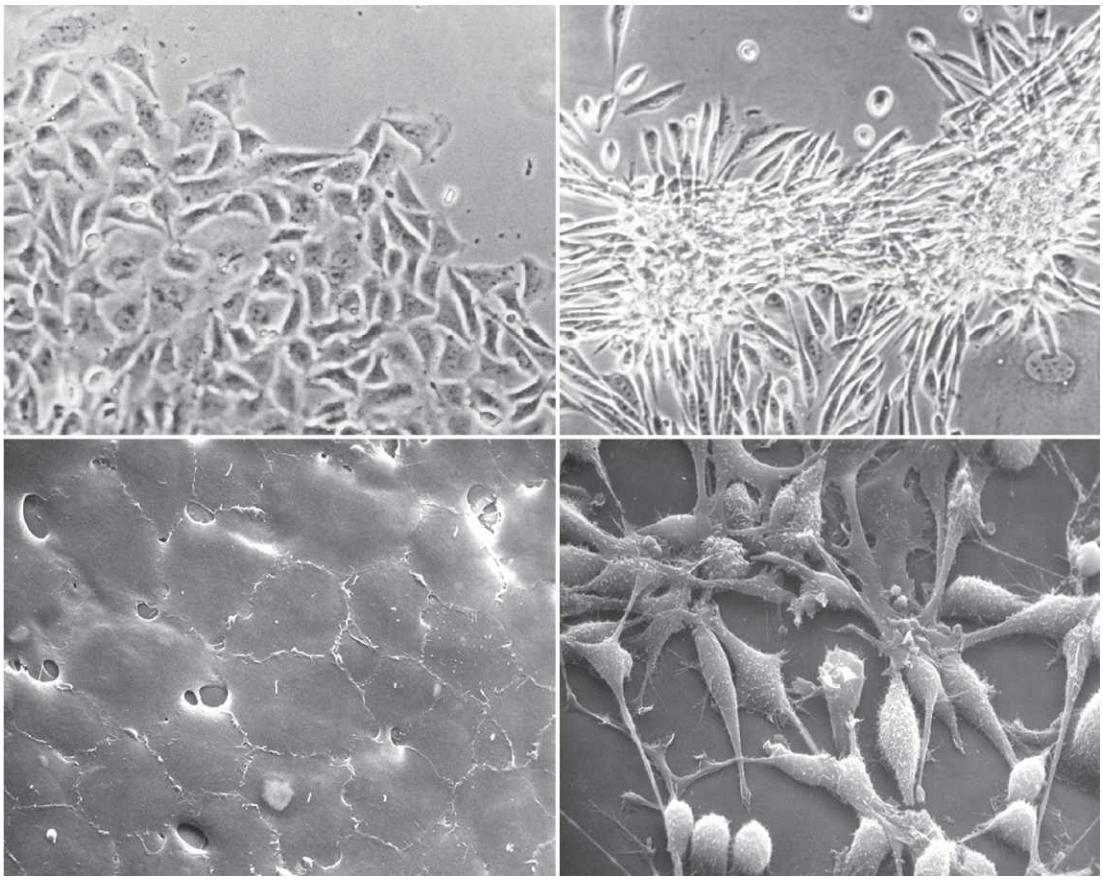
Temin and Rubin, soon followed by many others, used this experimental model to learn some basic principles about cell transformation. They were interested in the fate of a cell that was initially infected by RSV. How did such a cell proliferate when compared with uninfected neighboring cells? After exposure of cells to a solution of virus particles (often called a virus stock), the two researchers would place a layer of agar above the cell layer growing at the bottom of the Petri dish, thereby preventing free virus particles from spreading from initially infected cells to uninfected cells in other parts of the dish. Hence, any changes in cell behavior were the direct result of the initial infection by virus particles of chicken embryo fibroblasts.

The foci that Temin and Rubin studied revealed dramatic differences in the behavior of normal versus transformed cells. When first introduced into a Petri dish, normal cells formed islands scattered across the bottom of the dish. They then proliferated and eventually filled up all the space in the bottom of the dish, thereby creating confluent cultures. Once they reached confluence, however, these normal cells stopped proliferating, resulting in a one-cell-thick (or slightly thicker) layer of cells, often called a cell monolayer (**Figure 3.4A**).



A diagram of the behavior of R S V infected cells. Initially, normally elongated cells grow on the bottom of a Petri dish. Because of contact inhibition, they form a monolayer. Once cell is then infected with a R S V particle, and thereby transformed into an abnormally round cell. The infected cell multiplies, and due to loss of contact inhibition it forms a thick cluster, multiple cells deep, called a focus.

(A)



Four micrographs. In the two on the left, normally elongated and flattened cells form a monolayer. In the two on the right, rounded cells form multilayered clumps with extentions from the cells connecting them.

(B)

Figure 3.4 Transformed cells forming foci (A) Normal chicken embryo fibroblasts (*blue*) growing on the bottom of a Petri dish form a layer one cell thick —a monolayer. This is formed because these cells cease proliferating when they touch one another—the behavior termed *contact inhibition*. However, if one of these cells is infected by RSV prior to reaching confluence, this cell (*red*) and its descendants acquire a rounded morphology and lose contact inhibition. As a consequence, they continue to proliferate in spite of touching one another and eventually accumulate in a multilayered clump of cells (a *focus*) visible to the naked eye. (B) The effects of RSV infection and transformation can be observed through both phase-contrast microscopy (*upper panels*) and scanning electron microscopy (*lower panels*). Normal chicken embryo fibroblasts are spread out and form a continuous monolayer (*left panels*). However, upon transformation by RSV, they round up, become refractile (*white halos, upper right panel*), and pile up on one another (*right panels*). (B, courtesy of L.B. Chen.)

The cessation of growth of these normal cells after forming confluent monolayers was the result of a process that came to be called contact inhibition, density inhibition, or topoinhibition. Somehow, high cell density or contact with neighbors caused these cells to stop dividing. This behavior of normal cells contrasted starkly with that of the transformants within the RSV-induced foci (Figure 3.4B). The latter clearly had lost contact (density) inhibition and consequently continued to proliferate, piling up on top of one another and creating multilayered cell foci so thick that they could often be seen with the naked eye.

Under certain experimental conditions, it could be shown that all the cells within a given focus were the descendants of a single progenitor cell that had been infected and presumably transformed by an RSV particle. Today, we would term such a flock of descendant cells a cell clone, and the focus as a whole, a clonal outgrowth.

The behavior of these foci gave support to one speculation about the possible similarities between the cell transformation triggered by RSV in the Petri dish and the processes that led to the appearance of tumors in living animals, including humans: maybe all the cells within a spontaneously arising human tumor mass also constitute a clonal outgrowth and therefore are the descendants of a single common progenitor cell that somehow underwent transformation and then launched a program of replication that led eventually to the millions, even billions, of descendant cells that together formed the mass. As discussed earlier (see Section 2.5), detailed genetic analyses of human tumor cells were required, in the end, to test this notion in a truly definitive way.

Glossary

tissue culture
: Procedure of propagating cells outside of living tissues in various types of vessels including flasks and Petri dishes.

transformation
: (1) Process of converting a normal mammalian cell into a cell having some or many of the attributes of a cancer cell. (2) Alteration of a cell through the introduction of a genetic element, usually referring to a process occurring in prokaryotic cells.

virus stock
: A solution of virus particles used experimentally to infect cells or organisms.

monolayer
: A population of cells growing *in vitro* as a layer one cell thick.

contact inhibition
: Behavior exhibited by cells propagated in monolayer culture, reflecting the halt in cell proliferation when adjacent cells touch one another. *Also termed* **density inhibition**.

density inhibition
: Behavior exhibited by cells propagated in monolayer culture, reflecting the halt in cell proliferation when adjacent cells touch one another. *Also termed* **contact inhibition**.

topoinhibition
: Behavior exhibited by cells propagated in monolayer culture, reflecting the halt in cell proliferation when adjacent cells touch one another. *Also termed* **contact inhibition**.

transformant
: A neoplastic cell that is formed by the experimental transformation of a non-neoplastic cell. *See* **transformation**.

clone
: (adj., **clonal**) (1) Copy of a gene that has been isolated by recombinant DNA procedures and amplified into a large number of identical copies. (2) Population of cells, all of which descend from a common progenitor cell. (3) Offspring of a procedure of asexual reproduction in which the genome of a somatic diploid cell of an organism is used to

form a cell that functions equivalently to a fertilized egg that may itself develop thereafter into an entire organism.

confluence

State reached when cells in monolayer culture proliferate until they fill available space at the bottom surface of a Petri dish.

OceanofPDF.com

3.3 The continued presence of RSV is needed to maintain transformation

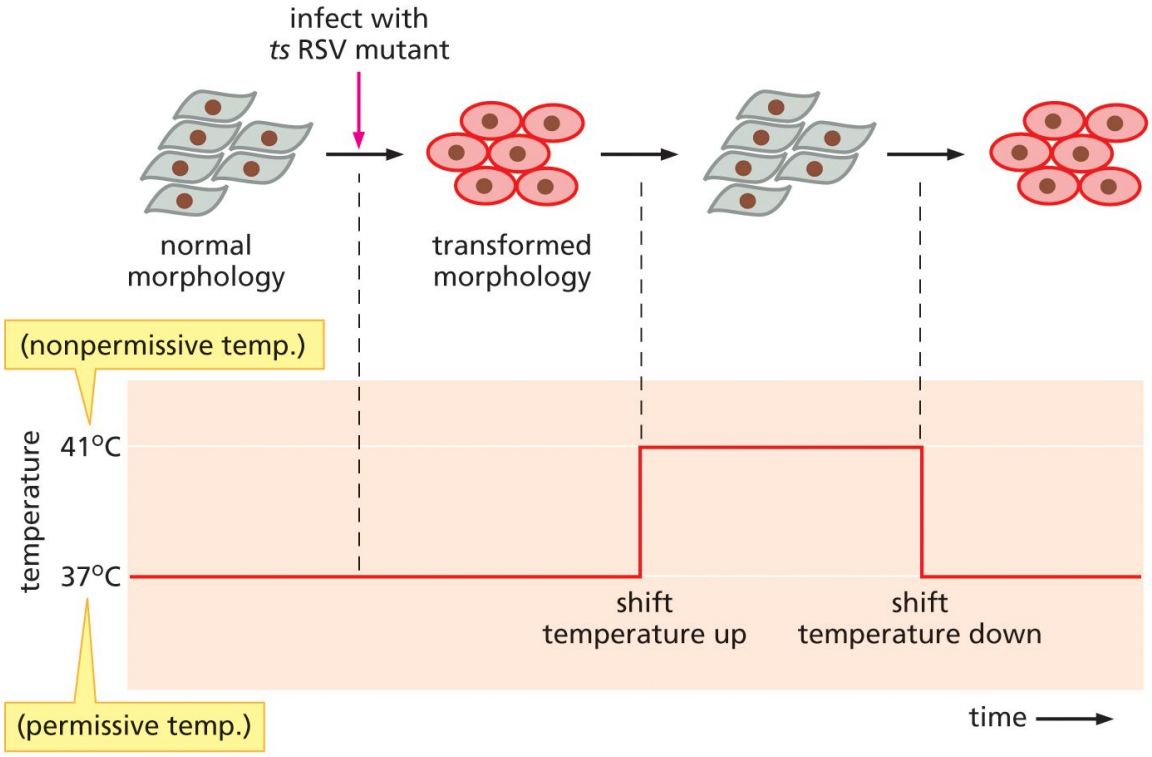
The behavior of the cells within an RSV-induced focus indicated that the transformation phenotype was transmitted from an initially infected, transformed chicken cell to its direct descendants. This transmission provoked another set of questions: Did an RSV particle infect and transform the progenitor cell of the focus and, later on, continue to influence the behavior of all of its direct descendants, ensuring that they also remained transformed? Or, as an alternative, did RSV act in a “hit-and-run” fashion by striking the initially infected progenitor cell, altering its behavior, and then leaving the scene of the crime? According to this second scenario, the progenitor cell could somehow transmit the phenotype of cancerous growth to its descendants without the continued presence of RSV.

Temin and Rubin’s work made it clear that the descendants of an RSV-infected cell continued to harbor copies of the RSV genome, but that evidence, on its own, settled little. The real question was: Did the transformed state of the descendant cells actually depend on some continuing influence exerted by the RSV genomes that they carried?

An experiment performed in 1970 at the University of California, Berkeley, settled this issue unambiguously. A mutant of RSV was developed that was capable of transforming chicken cells when these cells were cultured at 37°C but not at 41°C (the latter being the normal temperature at which chicken cells grow). Temperature-sensitive (ts) mutants like this one were known to encode partially defective proteins, which retain their normal structure and function at one temperature and lose their function at another temperature, presumably through thermal denaturation of the structure of the mutant protein.

After the chicken embryo fibroblasts were infected with the ts mutant of RSV, these cells became transformed if they were subsequently cultured at the lower (permissive) temperature of 37°C, as anticipated. Indeed, these cells could be propagated for many cell generations at this lower temperature and continued to grow and divide just like cancer cells, showing their characteristic transformed morphology. But weeks later, if the temperature of these infected cultures was

raised to 41°C (the nonpermissive temperature), these cells lost their transformed shape and quickly reverted to the shape and growth pattern of cells that had never experienced an RSV infection. If these RSV-infected cells were again returned to the permissive temperature, they regained their transformed appearance (**Figure 3.5**).



A timeline of transformation in a temperature sensitive mutant. Morphologically normal, elongated cells maintained at 37 degrees Celsius are transformed into morphologically abnormal, rounded cells by infection with the t s R S V mutant. When the temperature is shifted from 37 degrees, which is a permissive temperature, up to 41 degrees, which is a non-permissive temperature, the morphology reverts to normal. However, when the temperature is shifted back down to 37, the abnormal morphology reasserts itself.

Figure 3.5 A temperature-sensitive mutant and the maintenance of transformation by RSV When chicken embryo fibroblasts were infected with a temperature-sensitive mutant of RSV and cultured at a *permissive* temperature of 37°C, the viral transforming function could be expressed and the cells became transformed. However, when the cultures containing these infected cells were shifted to a *nonpermissive* temperature of 41°C, the cells

reverted to a normal, nontransformed morphology. Many cell generations later, with a shift of the cultures back to the permissive temperature, the cells once again exhibited a transformed morphology. The loss of the transformed phenotype upon temperature shift-up demonstrated that the continuous action of some temperature-sensitive viral protein was required in order to maintain this phenotype. The reacquisition of the transformed phenotype after temperature shift-down to the permissive temperature many cell generations later indicated that the viral genome continued to be present in these cells at the high temperature in spite of their normal appearance.

The Berkeley experiments led to simple and yet profoundly important conclusions. Since the cells that descended from a ts RSV–infected cell continued to show the temperature-sensitive growth trait, it was obvious that copies of the genome of the infecting virus persisted in these cells for weeks after the initial infection. These copies of the RSV genome in the descendant cells continued to make some temperature-sensitive protein (whose precise identity was not known). Most important, the continuing actions of this protein were required in order to maintain the transformed growth phenotype of the RSV-infected cells.

This work showed that cell transformation, at least that induced by RSV, was not a hit-and-run affair. In the language of the tumor virologists, the viral transforming gene was required to both initiate and maintain the transformed phenotype of virus-infected cells.

OceanofPDF.com

Glossary

temperature-sensitive
: Describing a phenotype that is apparent when cells or viruses grow at one temperature but not at another.

denaturation
: Process that causes a molecule, such as a macromolecule (DNA, RNA, or protein), to lose its natural three-dimensional structure.

permissive
: (1) Describing a physiological state that allows the survival and/or proliferation of a cell or infectious agent, such as a temperature-sensitive virus. (2) Describing a type of host or host cell that allows cells or infectious agents to proliferate. *See also* **nonpermissive**.

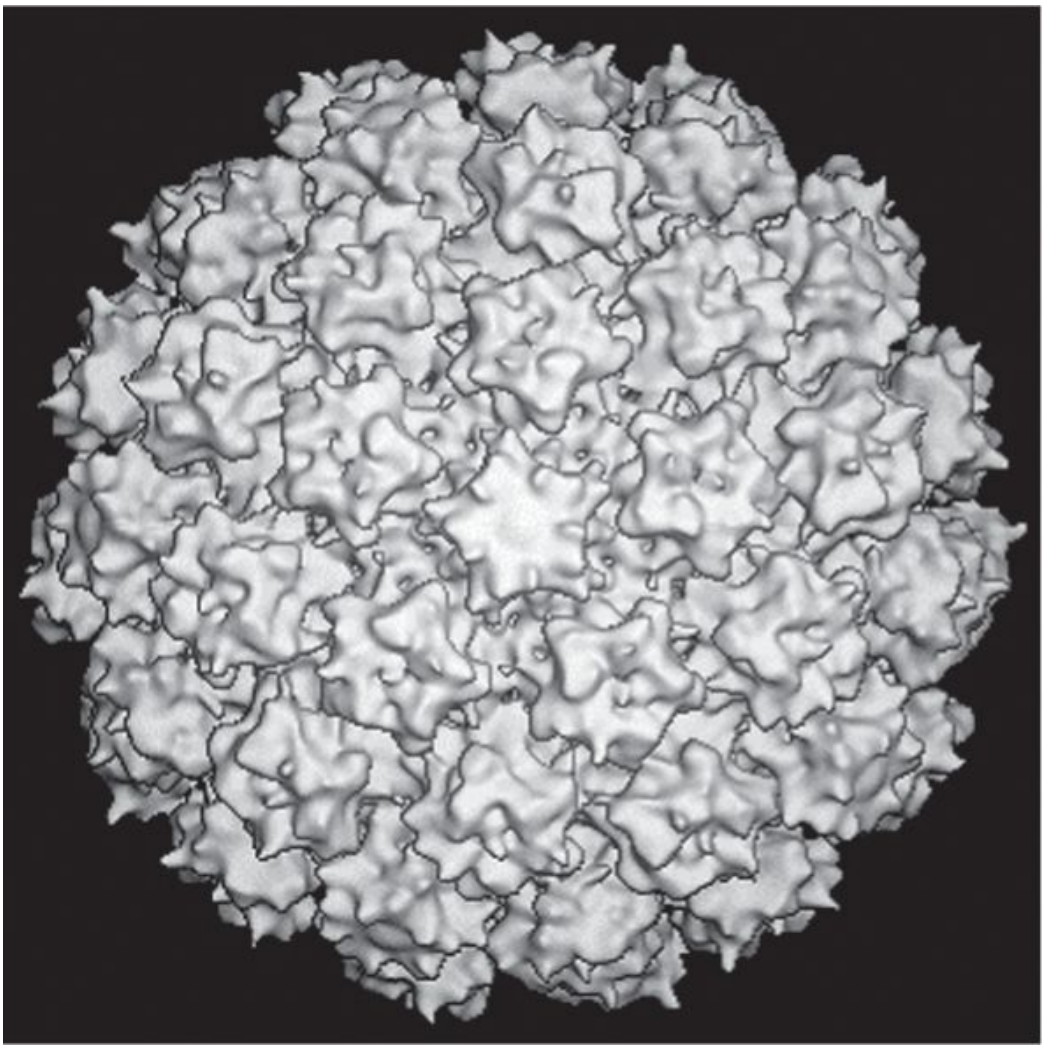
3.4 Viruses containing DNA molecules are also able to induce cancer

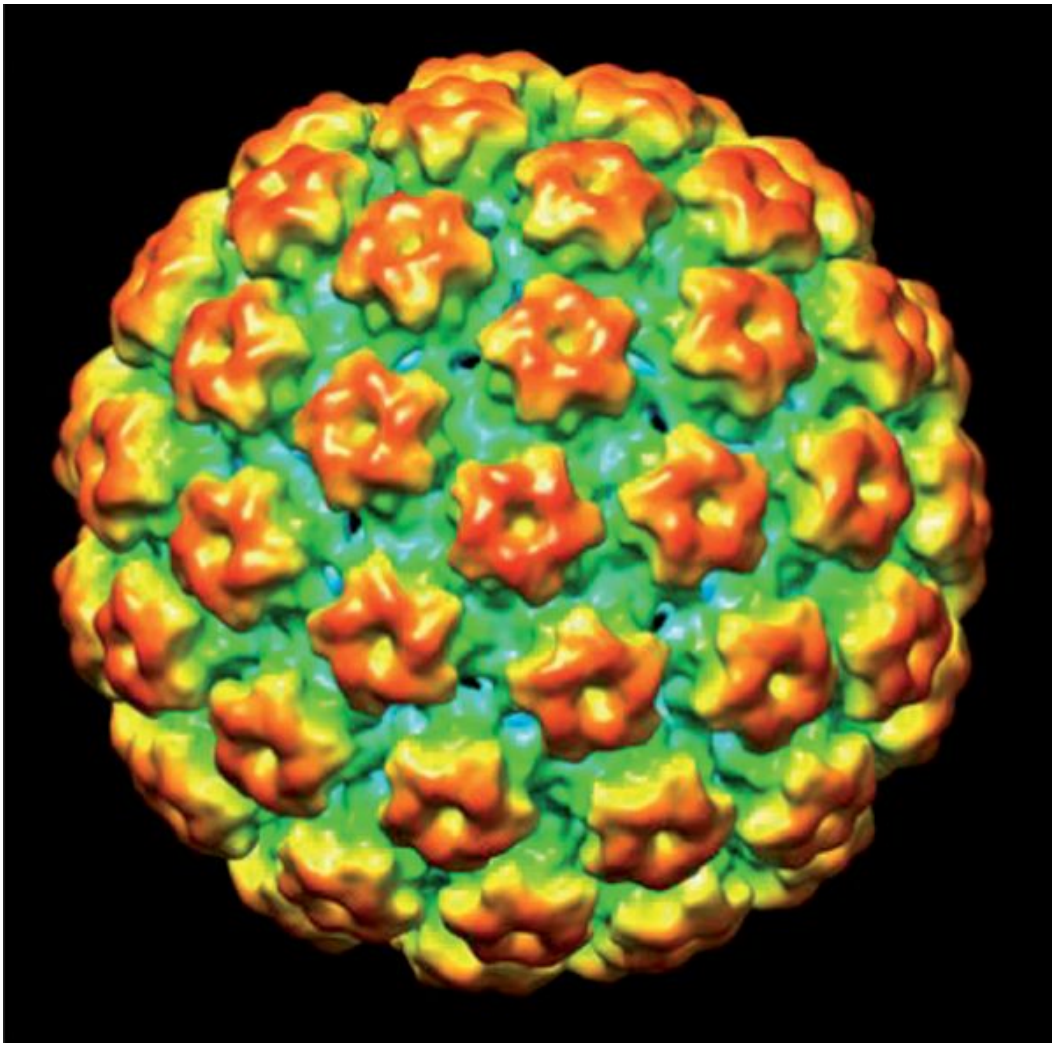
RSV was only one of a disparate group of viruses that were found able to induce tumors in infected animals. By 1960, four other classes of tumor viruses had become equally attractive agents for study by cancer biologists. One of them was a tumor virus that was discovered almost a quarter century after Rous's pioneering work. This virus, discovered by Richard Shope in rabbits, caused papillomas (warts) on the skin. These were actually benign lesions, which on rare occasions progressed to true cancers—squamous cell carcinomas of the skin.

By the late 1950s, it became clear that the Shope papillomavirus was constructed very differently from RSV. The papillomavirus particles carried DNA genomes, whereas RSV particles were known to carry RNA molecules. Also, the Shope virus particles were sheathed in a protein coat (**Figure 3.6**), whereas RSV clearly had, in addition, a lipid membrane coating on the outside (see Figure 3.3A and B). In the decades that followed, more than 100 distinct human papillomavirus (HPV) types, all related to the Shope virus, would be discovered.



The papillomavirus virion appears in a grayscale micrograph as a ball with a complex, spiky surface.

(A)



The papillomavirus virion appears in a color-enhanced micrograph. It looks like a spherical blue-green bush with five-petaled orange flowers.

(B)

Figure 3.6 Papillomavirus virion (A) A cryogenic electron microscopy 3D reconstruction and (B) a cryoelectron micrograph, together with image enhancement, reveal the structure of papillomavirus particles. (A, from B.L. Trus et al., *Nat. Struct. Biol*. 4:413–420, 1997. With permission from Springer Nature. B, Hyunwook Lee, Sarah A. Brendle, Stephanie M. Bywaters, Jian Guan, Robert E. Ashley, Joshua D. Yoder, Alexander M. Makhov, James F. Conway, Neil D. Christensen, Susan Hafensteinl. *Journal of Virology*, 2015 Jan 15; 89(2): 1428–1438. doi: 10.1128/JVI.02898-14. Reproduced with permission from American Society for Microbiology.)

In the 1950s and 1960s, various other DNA tumor viruses were isolated (**Table 3.1**). The murine polyomavirus (MPyV), named for its ability to induce a variety of distinct tumor types in newborn mice, was discovered in 1953. Closely related to MPyV in its size and chemical makeup was SV40 virus (the 40th simian virus in a series of isolates). This monkey virus had originally been discovered as a contaminant of the poliovirus vaccine stocks prepared in the mid- and late 1950s (**Figure 3.7A**). Clever virological sleuthing revealed that SV40 particles often hid out in cultures of the rhesus and cynomolgus monkey kidney cells used to propagate poliovirus during the preparation of vaccine. In fact, the presence of SV40 was not initially apparent in these cell cultures. However, when poliovirus stocks that had been propagated in these monkey cells were later used to infect African green monkey kidney (AGMK) cells, SV40 revealed itself by inducing a very distinctive cytopathic effect—numerous large vacuoles (fluid-filled bubble-like structures) in the cytoplasm of infected cells (Figure 3.7B). Within a day after the vacuoles formed in an SV40-infected cell, this cell would lyse, releasing tens of thousands of progeny virus particles. (Because of SV40 contamination, occurring during the course of poliovirus vaccine production, some poliovirus-infected cell cultures yielded far more SV40 virus particles than poliovirus particles! See **Supplementary Sidebar 3.4**.)

Table 3.1 Tumor virus genomes

	Virus family	**Approximate size of genome (kb)**
DNA viruses		
Hepatitis B virus (HBV)	hepadna	3
SV40/murine polyomavirus (MPyV)	polyoma	5
Human papillomavirus 16 (HPV) / Shope papillomavirus (SPV)	papilloma	8
Human adenovirus 5	adenovirus	35

	Virus family	Approximate size of genome (kb)
DNA viruses		
Human herpesvirus 8 (HHV-8; KSHV) / Human herpesvirus 4 (HHV-4; EBV)	herpesviruses	165
Shope fibroma virus (SFV)	poxviruses	160
RNA viruses		
Human T-cell leukemia virus (HTLV-I)	retrovirus	8.2
Rous sarcoma virus (RSV)	retrovirus	9.3
Hepatitis C virus (HCV)	flavivirus	9.6

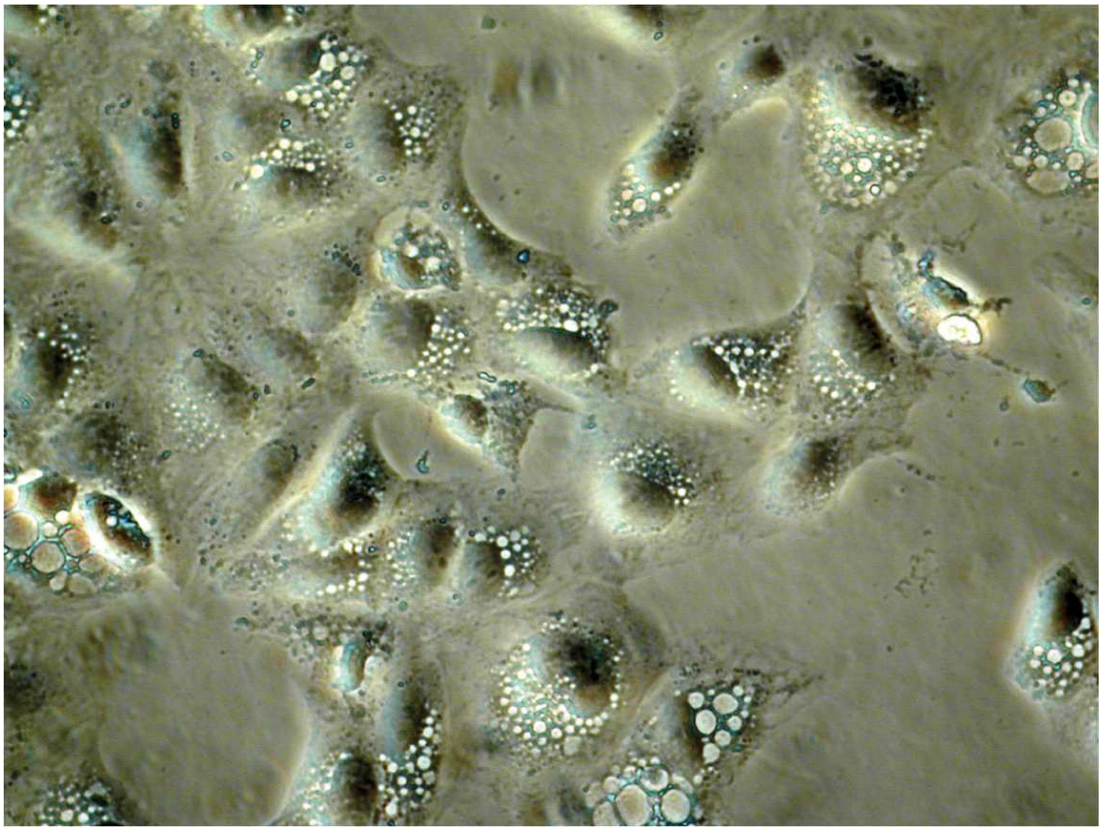
A color micrograph of the S V 40 virus. It appears as a fuzzy blue sphere with many tuftlike protrusions.

(A)



Smooth gray tissue is pockmarked by irregular depressions containing round, white nodules of varying size.

(B)

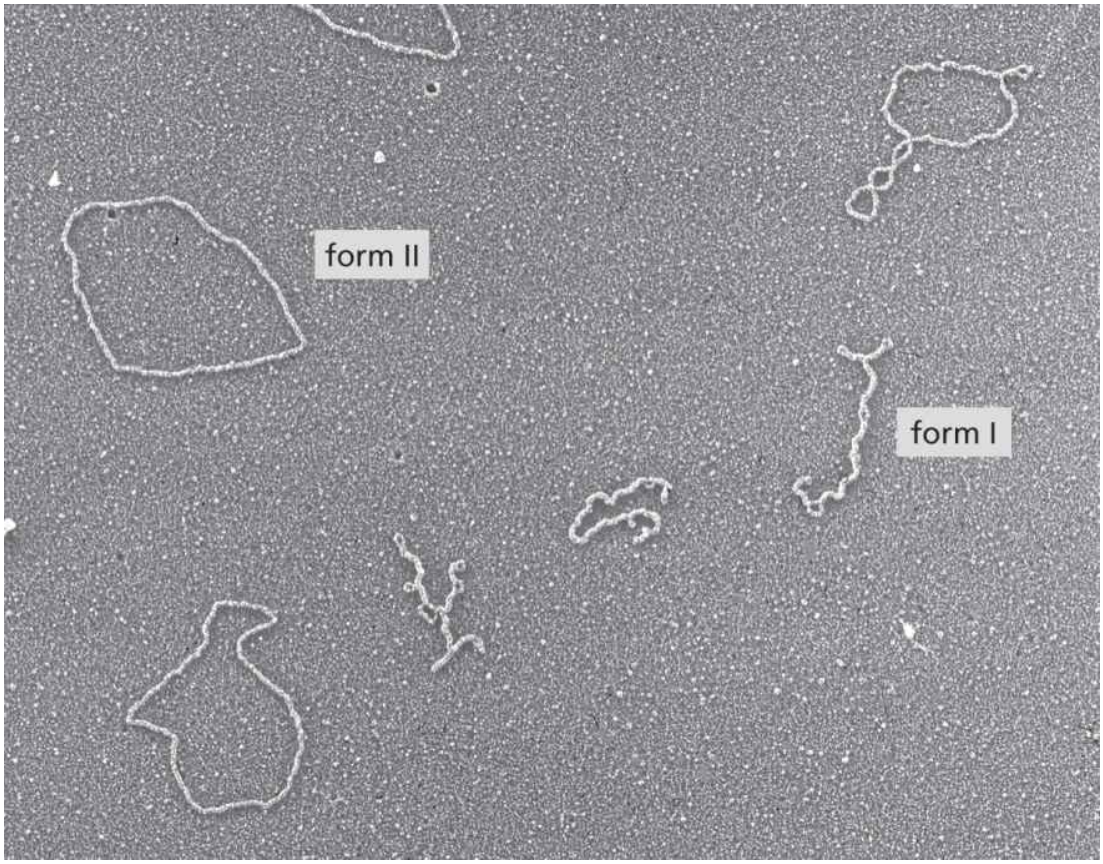
Figure 3.7 SV40 virus (A) As determined by X-ray diffraction, the protein capsid of the SV40 DNA tumor virus consists of three virus-encoded proteins that are assembled into pentamers and hexamers that assemble to create a virion organized via icosahedral symmetry. The circular dsDNA genome of SV40 is carried within this capsid. (B) SV40 launches a lytic cycle in permissive host cells, such as the kidney cells of several monkey species. The resulting cytopathic effect, seen here, involves the formation of large cytoplasmic vacuoles prior to the death of the cell and the release of tens of thousands of progeny virus particles. (A, courtesy of R. Grant, S. Crainic, and J.M. Hogle. B, courtesy of A. Oppenheim.)

This lytic cycle of SV40 in monkey cells contrasted starkly with its behavior in cells prepared from mouse, rat, or hamster embryos. SV40 was unable to replicate in these rodent cells, which were therefore considered to be nonpermissive hosts. But on occasion, in one cell out of thousands in a nonpermissive infected cell population, a transformant grew out that shared many characteristics with RSV-transformed cells,

that is, the cell had undergone changes in morphology and loss of contact inhibition, and had acquired the ability to seed tumors *in vivo*. On the basis of this, SV40 was classified as a tumor virus.

By some estimates, between one-third and two-thirds of the polio vaccines—the oral, live Sabin vaccine and the inactivated, injected Salk vaccine—administered between 1955 and 1963 contained SV40 virus as a contaminant, and between 10 and 30 million people were exposed to this virus through vaccination. In 1960, the fear was first voiced that the SV40 contaminant might trigger cancer in many of those who were vaccinated. Reassuringly, epidemiologic analyses conducted over the succeeding four decades indicated little, if any, increased risk of cancer among those exposed to these two vaccines.

Shope's papillomavirus, the mouse polyomavirus, and SV40 were initially grouped together as the papovavirus class of DNA tumor viruses, the term signifying papilloma, polyoma, and the vacuoles induced by SV40 during its lytic infection. In 2000, these viruses were recategorized as two distinct families, the first including HPV and the Shope papillomavirus as part of the papillomavirus family, and the second including SV40 and the murine polyomavirus as part of the polyomavirus family. By the mid-1960s, it was apparent that the genomes of the papillomavirus and polyomavirus were all formed from circular double-stranded DNA molecules (**Figure 3.8**). This represented a great convenience for experimenters studying the viral genomes, since there were several techniques in use at the time that made it possible to separate these relatively small, circular DNA molecules [about 5–8 kilobases (kb) in length] from the far larger, linear DNA molecules present in the chromosomes of infected host cells.



A grayscale micrograph of several circular coils of D N A lying on a flat surface. Some coils appear more or less linear, because they are twisted around themselves like twisted rubber bands. These are labeled form 1. Other coils lie in open loops, like rubber bands that are not twisted. These are labeled form 2.

Figure 3.8 Papillomavirus and polyomavirus genomes Electron-microscopic analyses revealed the structure of DNA genomes of both the papillomavirus and the polyomavirus to be double-stranded and circular. Shown here are the closed-circular, supercoiled form of SV40 DNA (form I; kinked DNAs) and the relaxed, nicked circular form (form II; open, spread circles). Form III, which is a linear form of the viral DNA resulting from a double-strand DNA break, is not shown. (Courtesy of J.D. Griffith, University of North Carolina.)

The group of DNA tumor viruses grew further with the discovery that human adenovirus, known to be responsible for upper respiratory infections in humans, was able to induce tumors in infected hamsters. Here was a striking parallel with the behavior of SV40. The two viruses could multiply freely in their natural host cells, which were therefore considered to be permissive. During the resulting lytic cycles of the virus, permissive host cells were rapidly killed in concert with the release of

progeny virus particles. But when introduced into nonpermissive rodent cells, both adenovirus and SV40 failed to replicate and instead left behind, albeit at very low frequency, clones of transformants.

Other entrants into the class of DNA tumor viruses were members of the herpesvirus group. While human herpesvirus types 1 and 2 were apparently not tumorigenic (capable of inducing tumors), a distantly related herpesvirus of Saimiri monkeys provoked rapid and fatal lymphomas when injected into monkeys from several other species. Another distantly related member of the herpesvirus family—Epstein–Barr virus (EBV)—was discovered to play a causal role in provoking the development of Burkitt's lymphomas in young children in Equatorial Africa and New Guinea as well as nasopharyngeal carcinomas in Southeast Asia. Finally, at least two members of the poxvirus class, which includes smallpox virus, were found to be tumorigenic: Shope fibroma virus (SFV) and Yaba monkey virus cause benign skin lesions in rabbits and rhesus monkeys, respectively. The tumorigenic powers of poxviruses, which have very large genomes (135–160 kb), remain poorly understood to this day.

Researchers found that adenovirus and herpesvirus particles contain long, linear double-stranded DNA (dsDNA) molecules, which, like the genomes of RSV, carry the information required for both viral replication and virus-induced cell transformation. Compared with the papillomavirus and polyomavirus, the herpesviruses had genomes of enormous size (see Table 3.1), suggesting that they carried a proportionately larger number of genes. In the end, it was the relatively small sizes of papillomavirus and polyomavirus genomes that made them attractive objects of study.

Most of the small group of genes in a papillomavirus and polyomavirus genome were apparently required to program viral replication; included among these were several genes specifying the proteins that form the capsid coat of the virus particle. This dictated that papillomaviruses and polyomaviruses could devote only a small number of their genes to the process of cell transformation.

This realization offered the prospect of greatly simplifying the cancer problem by reducing the array of responsible genes and causal mechanisms down to a very small number. Without such simplification, cancer biologists were forced to study the cancer-causing genes that were thought to be present in the genomes of cells transformed by nonviral mechanisms. Cellular genomes clearly harbored large arrays of genes, possibly more than a hundred thousand. At the time, the ability to analyze genomes of such vast complexity and to isolate individual genes from these genomes was a distant prospect.

OceanofPDF.com

Glossary

papilloma
: Benign, adenomatous proliferation of epithelial cells; term often used to describe benign lesions of the skin.

cytopathic
: Causing damage or death to a cell. *See also* **cytocidal**, **cytostatic**, **cytotoxic**.

vacuoles
: Small, fluid-filled, bubble-like structures, often seen in the cytoplasm of cells that are under physiological stress and in cells infected by certain viruses.

lytic cycle
: Cycle of viral infection and replication that results ultimately in the death of the infected host cell.

nonpermissive
: (1) Describing a physiological state that does not permit the survival and/or proliferation of a cell or infectious agent such as a temperature-sensitive virus. (2) Describing a type of host or host cell that does not permit cells or infectious agents to proliferate. *See* **permissive**.

permissive
: (1) Describing a physiological state that allows the survival and/or proliferation of a cell or infectious agent, such as a temperature-sensitive virus. (2) Describing a type of host or host cell that allows cells or infectious agents to proliferate. *See also* **nonpermissive**.

tumorigenic
: (1) Referring to the ability of cells to form tumors when introduced into appropriate animal hosts. (2) Less commonly, pertaining to an agent such as a tumor virus that imparts this ability to cells.

OceanofPDF.com

3.5 Tumor viruses induce multiple changes in cell phenotype including acquisition of tumorigenicity

Like RSV-transformed chicken cells, the rodent cells transformed by SV40 showed profoundly altered shape and piled up on one another. This loss of contact inhibition was only one of a number of changes exhibited by virus-transformed cells (**Table 3.2**). As discussed later in this book (in Chapter 5), normal cells in culture will not proliferate unless they are provided with serum and serum-associated growth-stimulating factors. Cells transformed by a variety of tumor viruses were often found to have substantially reduced requirements for these factors in their culture medium.

Table 3.2 Properties of transformed cells

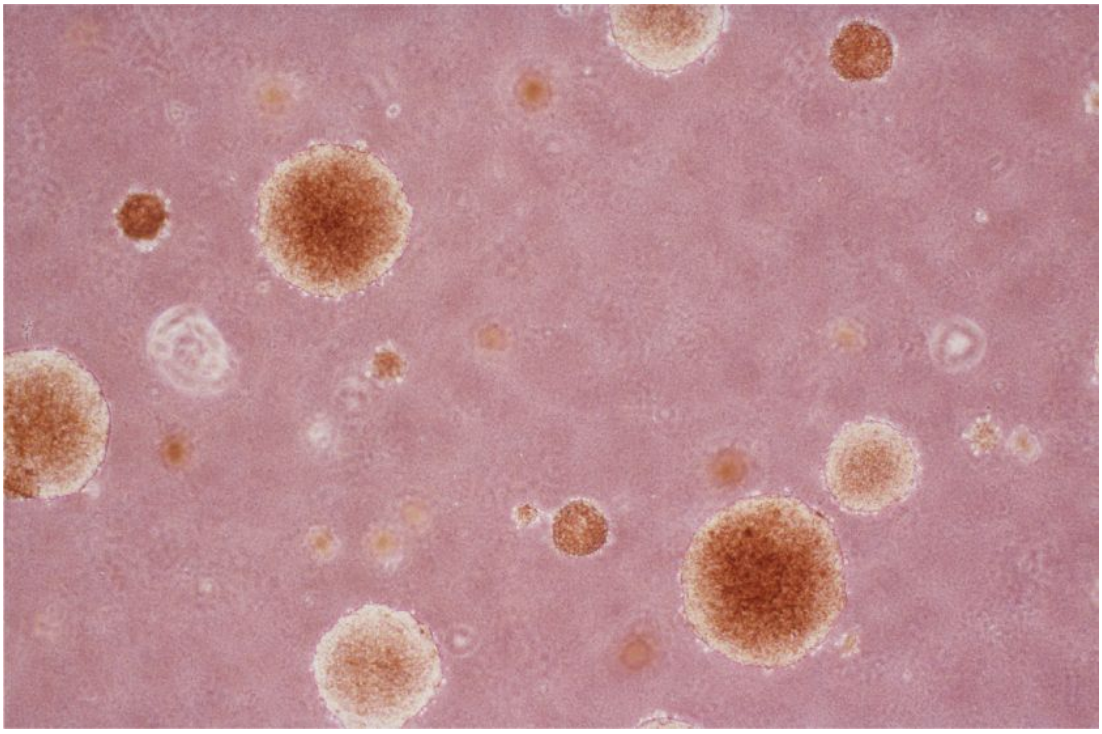
Altered morphology (rounded shape, refractile in phase-contrast microscope)
Loss of contact inhibition (ability to grow over one another)
Ability to grow without attachment to solid substrate (anchorage independence)
Ability to proliferate indefinitely (immortalization)
Reduced requirement for exposure to mitogenic growth factors
High saturation density (ability to accumulate large numbers of cells in culture dish)
Inability to halt proliferation in response to deprivation of growth factors

Increased import of glucose
Glycolysis in presence of oxygen
Tumorigenicity

Adapted in part from S.J. Flint, L.W. Enquist, R.M. Krug et al., Principles of Virology. Washington, DC: ASM Press, 2000.

Yet another hallmark of the transformed state is an ability to proliferate in culture for unusually long time periods. Normal cells have a limited proliferative potential in culture and ultimately stop multiplying after a certain, apparently predetermined number of cell divisions. Cancer cells seemed to be able to proliferate indefinitely in culture, and thus to undergo immortalization (as discussed in Chapter 10).

When transformed cells were suspended in an agar gel, they were able to proliferate into spherical colonies containing dozens, even hundreds of cells (**Figure 3.9A**). This ability to multiply without attachment to the solid substrate at the bottom of the Petri dish was termed the trait of anchorage independence. Normal epithelial cells and fibroblasts, in contrast, demonstrated an absolute requirement for tethering to a solid substrate before they would grow and were therefore considered to be anchorage-dependent. The ability of cells to grow in an anchorage-independent fashion *in vitro* usually served as a good predictor of their ability to form tumors *in vivo* following injection into appropriate host animals (Figure 3.9B).



A color micrograph showing spherical tumor cell colonies growing in a transparent medium, not attached to anything solid.

(A)

A photo of a hairless mouse with a large tumor growing on its back, under the skin.

(B)

Figure 3.9 Anchorage-independent growth and tumorigenesis (A) A photomicrograph of colonies of cells growing in an anchorage-independent fashion. (Each of the larger colonies seen here may contain several hundred cells, all the descendants of a single transformed ancestor.) This test is usually performed by suspending cells in a semi-solid medium, such as agarose or methylcellulose, to prevent their attachment to a solid substrate, specifically, the bottom of the Petri dish. The ability of cells to proliferate while held in suspension —the phenotype of anchorage independence—is usually a good (but hardly infallible) predictor of their ability to form tumors *in vivo*. (B) Mice of the Nude strain offer two advantages in tests of tumorigenicity. Lacking a thymus, they are highly immunocompromised and therefore relatively receptive to engrafted cells from genetically unrelated sources (i.e., xenografts), including those from foreign species. In addition, because these mice are hairless, it is easy to monitor closely the progress of tumor formation (*arrow*) after transformed cells have been injected under their skin. (A, courtesy of A. Orimo. B, courtesy of X.G. Wang and E. Dadachova; see also X.G. Wang et al., *PLoS ONE* 2(10): e1114, 2007.)

This tumor-forming ability—the phenotype of tumorigenicity—represented the acid test of whether cells were fully transformed, that is, had acquired the full repertoire of neoplastic traits. One test for tumorigenicity could be performed by injecting mouse cells prepared from one strain of mice and then transformed in an *in vitro* transformation experiment into host mice of the same strain (**Sidebar 3.2**). Since the host and injected cells came from the same genetic strain, the immune systems of such syngeneic host mice would not recognize the transformed cells as being foreign bodies and therefore would not attempt to eliminate them—the process of tumor rejection (a process to which we will return in Chapter 15). This allowed injected cells to survive in their animal hosts, enabling them to multiply into large tumors if, indeed, they had acquired the tumorigenic phenotype. (Populations of injected non-tumorigenic cells, in contrast, might survive in a syngeneic host as small clumps for weeks, even months, without increasing in size.)

Sidebar 3.2 The powers of the immune system dictate whether transformed cells can form tumors

Over the past century, repeated cycles of inbreeding have been used to create distinct strains of mice and rats that are genetically identical within a strain (aside from the gender-specific differences created by the Y chromosome). Included among these mouse strains are, for example, the BALB/c, C3H, and C57/BL6 strains. The shared genetic identity of all individuals within a strain means that tissue fragments (including tumors) from one animal of a strain can be transplanted to other animals of that strain and become established in the recipient animals. The transplanted cells are not rejected by the immune systems of these animals because they are not recognized as foreign, since they express proteins that are identical to those of their hosts.

This ability to transplant tissues from one individual to another does not exist in outbred populations, such as humans and natural populations of mice. Except for the rare instances of identical twins, tissues that are introduced from one animal (or human) to another are recognized as being foreign by the recipient's immune system. The immune system then attempts to eliminate the foreign tissue and usually succeeds in doing so rapidly. This means that true tests of the tumorigenicity of *in vitro* transformed mouse cells can be undertaken only when such cells derive from the same strain of mice as the hosts into which these cells are introduced. As an aside, the lack of inbred strains of chickens severely limited the type of cancer research that could be carried out with these birds.

This barrier to transplantation can be circumvented in several ways. Often the immune system of a very young animal is more tolerant of genetically foreign tissue than the more robust, well-developed immune system of an adult. This allowed Rous to carry out some of his experiments. More common and practical, however, is the use of

immunocompromised strains of mice, which lack fully functional immune systems and therefore tolerate engrafted tissues of foreign genetic origin, including cells and tissues originating in other species (termed xenografts). Frequently used strains of immunocompromised mice include the Nude, RAG, and NOD/SCID mice, each of which has a defect in one or more key components of its immune system.

Often, it was impossible to test the tumorigenicity of tumor virus–infected cells in a syngeneic host animal, simply because the cells being studied came from a species in which inbred syngeneic hosts were not available. This forced the use of immunocompromised hosts whose immune systems were defective and thus tolerant of a wide variety of foreign cell types, including those from other species (see Sidebar 3.2). Mice of the Nude strain soon became the most commonly used hosts to test the tumorigenicity of a wide variety of cells, including those of human origin. Quite frequently, candidate tumor cells are injected subcutaneously, that is, directly under the skin of these animals. Since they also happen to lack the ability to grow hair, Nude mice provide the additional advantage of allowing the experimenter to closely monitor the behavior of implanted tumor cells, specifically the growth of any tumors that they may spawn (see Figure 3.9B).

As mentioned, the small size of the genomes of RNA tumor viruses (for example, RSV) and the papillomavirus and polyomavirus dictated that each of these employ only a small number of genes (perhaps as few as one) to elicit multiple changes in the cells that they infect and transform. Recall that the ability of a gene to concomitantly induce a number of distinct alterations in a cell is termed pleiotropy. Accordingly, though little direct evidence about gene number was yet in hand, it seemed highly likely that the genes used by tumor viruses to induce cell transformation were acting pleiotropically on a variety of molecular targets within cells.

OceanofPDF.com

Glossary

anchorage independence
: Ability of a cell to proliferate without attachment to a solid substrate.

syngeneic
: (1) Referring to two organisms that share the identical genetic background, such as two members of an inbred strain of mice. (2) Describing the relationship between two sets of cells or tissues, or between a set of cells and an organism, deriving from identical genetic backgrounds.

tumor rejection
: Process by which an organism prevents the formation of a tumor (including tumor formation by engrafted cells), usually achieved through the action of its immune system.

xenograft
: A normal or neoplastic tissue derived from one species that has been implanted into a host animal from another species.

immunocompromised
: Describing an organism lacking a fully functional immune system. *Also termed* **immunodeficient**.

anchorage dependence
: Requirement of cells for tethering to a solid substrate before they will grow.

subcutaneous
: Beneath the skin.

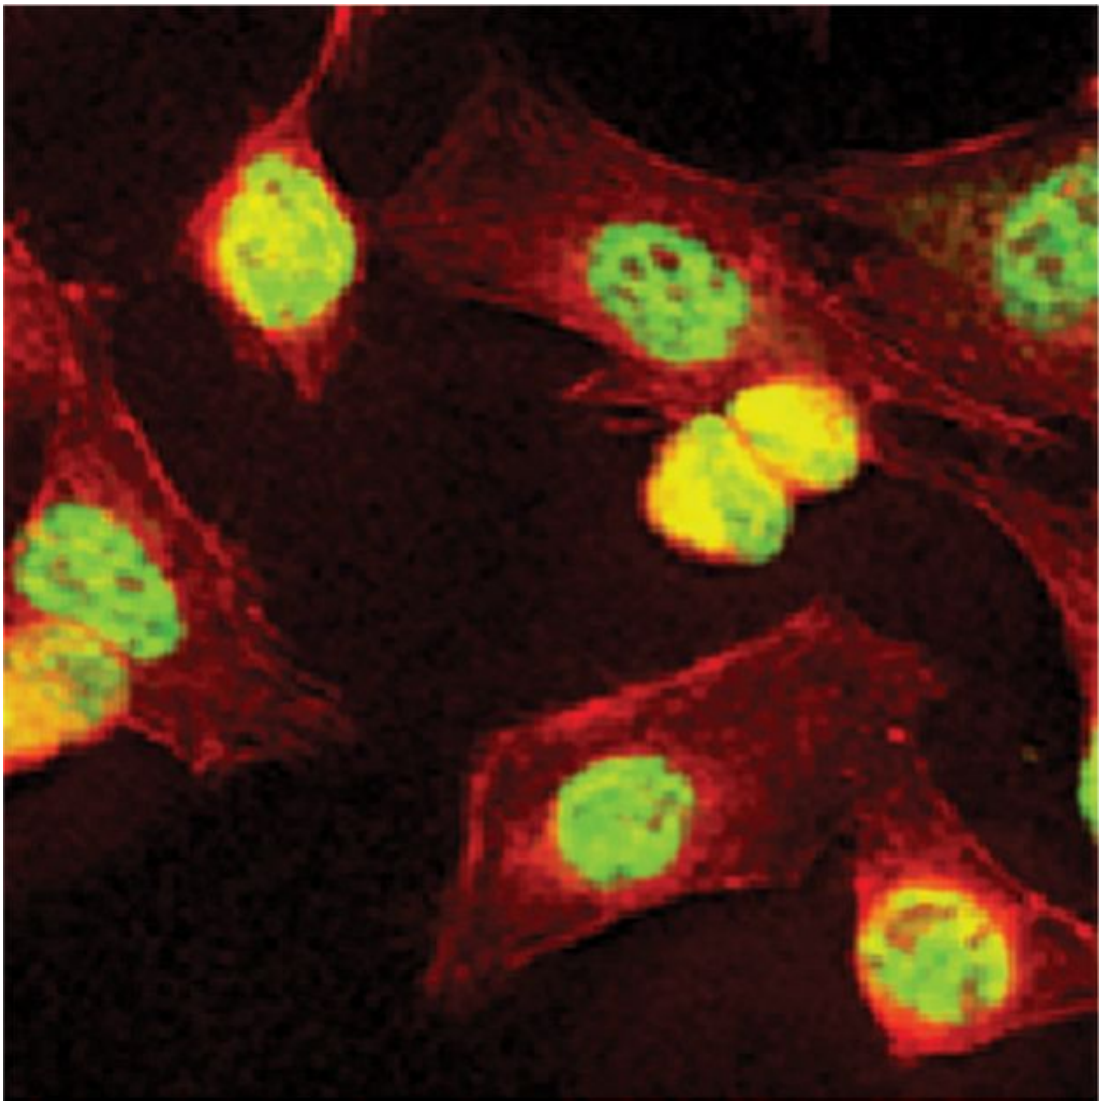
immortalization
: Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

OceanofPDF.com

3.6 Tumor virus genomes persist in virus-transformed cells by becoming part of host-cell DNA

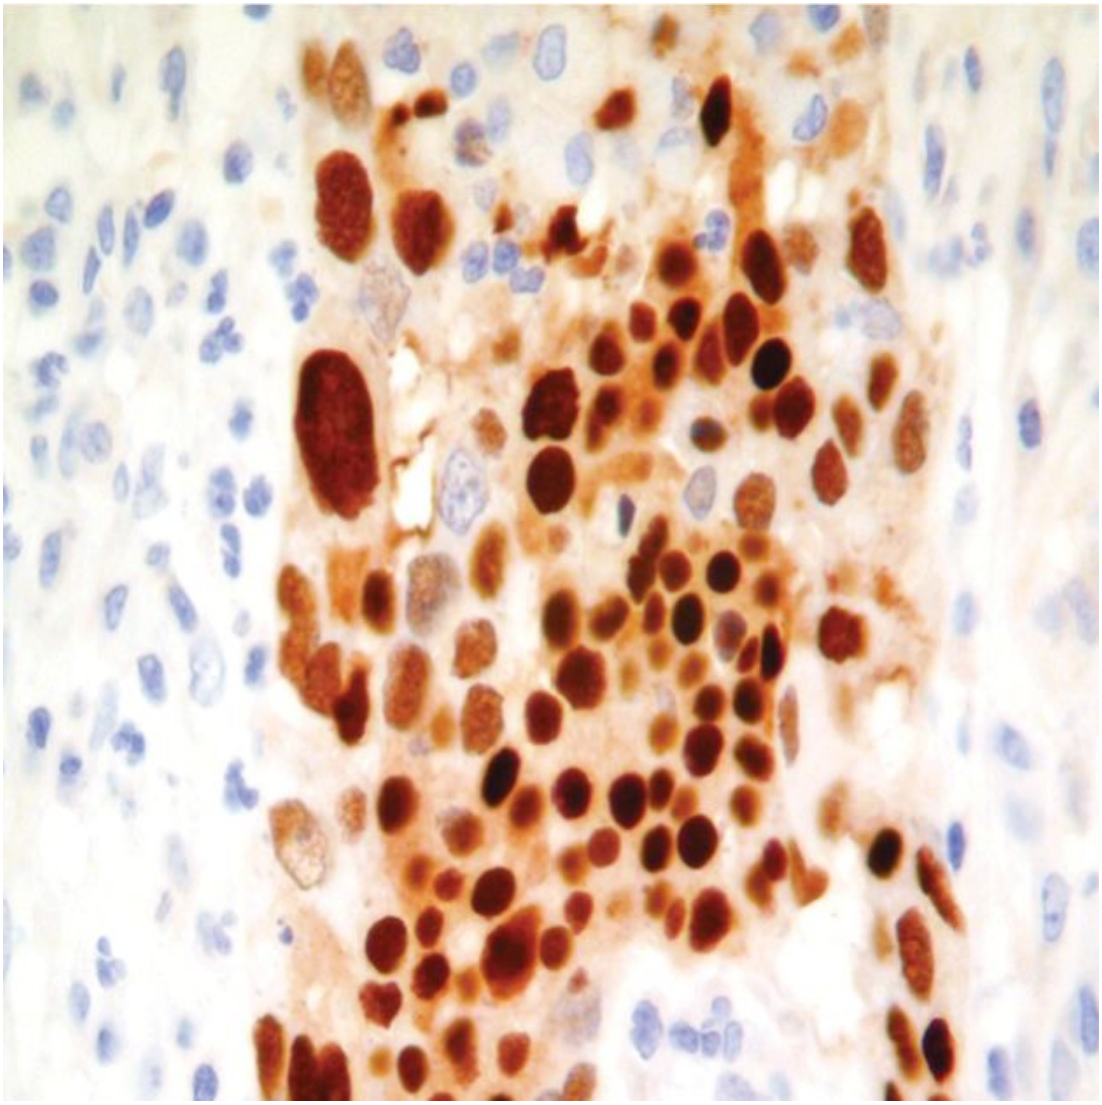
The Berkeley experiment (see Section 3.3) provided strong evidence that the continued actions of the RSV genome were required to maintain the transformed state of cells, including those that were many cell generations removed from an initially infected progenitor cell. This meant that some or all of the viral genetic information needed to be perpetuated in some form, being passed from a transformed mother cell to its two daughters and, further on, to descendant cells through many cycles of cell growth and division. Conversely, a failure to faithfully transmit these viral genes to descendant cells would result in the reversion of such cells to those showing normal growth behavior.

Paralleling the behavior of RSV, cell transformation achieved by two intensively studied DNA tumor viruses—SV40 and the murine polyomavirus—also seemed to depend on the continued presence of viral genomes in the descendants of an initially transformed cell. The evidence proving this came in a roundabout way, largely from the discovery of tumor-associated proteins (T antigens) that were found in cancers induced by these two viruses. For example, sera prepared from mice carrying an SV40-induced tumor showed strong reactivity with a nuclear protein that was present characteristically in tumors triggered by SV40 and absent in tumors induced by other carcinogenic agents. The implication was that the viral genome residing in tumor cells encoded a protein (in this case, the SV40 T antigen) that induced a strong immunological response in the tumor-bearing mouse or rat host (**Figure 3.10**).



A micrograph shows nine or so cells with irregular, angular shapes. Cytoplasm appears in red and has a faintly visible fibrous structure. Cell nuclei appear in brightly glowing yellow and pale green.

(A)



A micrograph shows cancer cells in bladder tissue. Their densely packed nuclei are varying shades of reddish brown. A few of these nuclei are grossly enlarged. The nuclei of the surrounding normal cells are pale blue and less densely packed.

(B)

Figure 3.10 Expression of the SV40 T antigen When SV40-transformed cells are introduced into a syngeneic host, they provoke a strong immune response against the SV40-encoded T antigen (tumor antigen), which is usually termed “large T” (LT). Anti-LT serum, together with appropriate immunofluorescent tags, can be used to stain virus-transformed cells. (A) In the light micrograph shown here, an anti-LT monoclonal antibody (rather than anti-tumor serum) has been used to stain mouse cells that have been transformed by SV40, revealing the nuclear

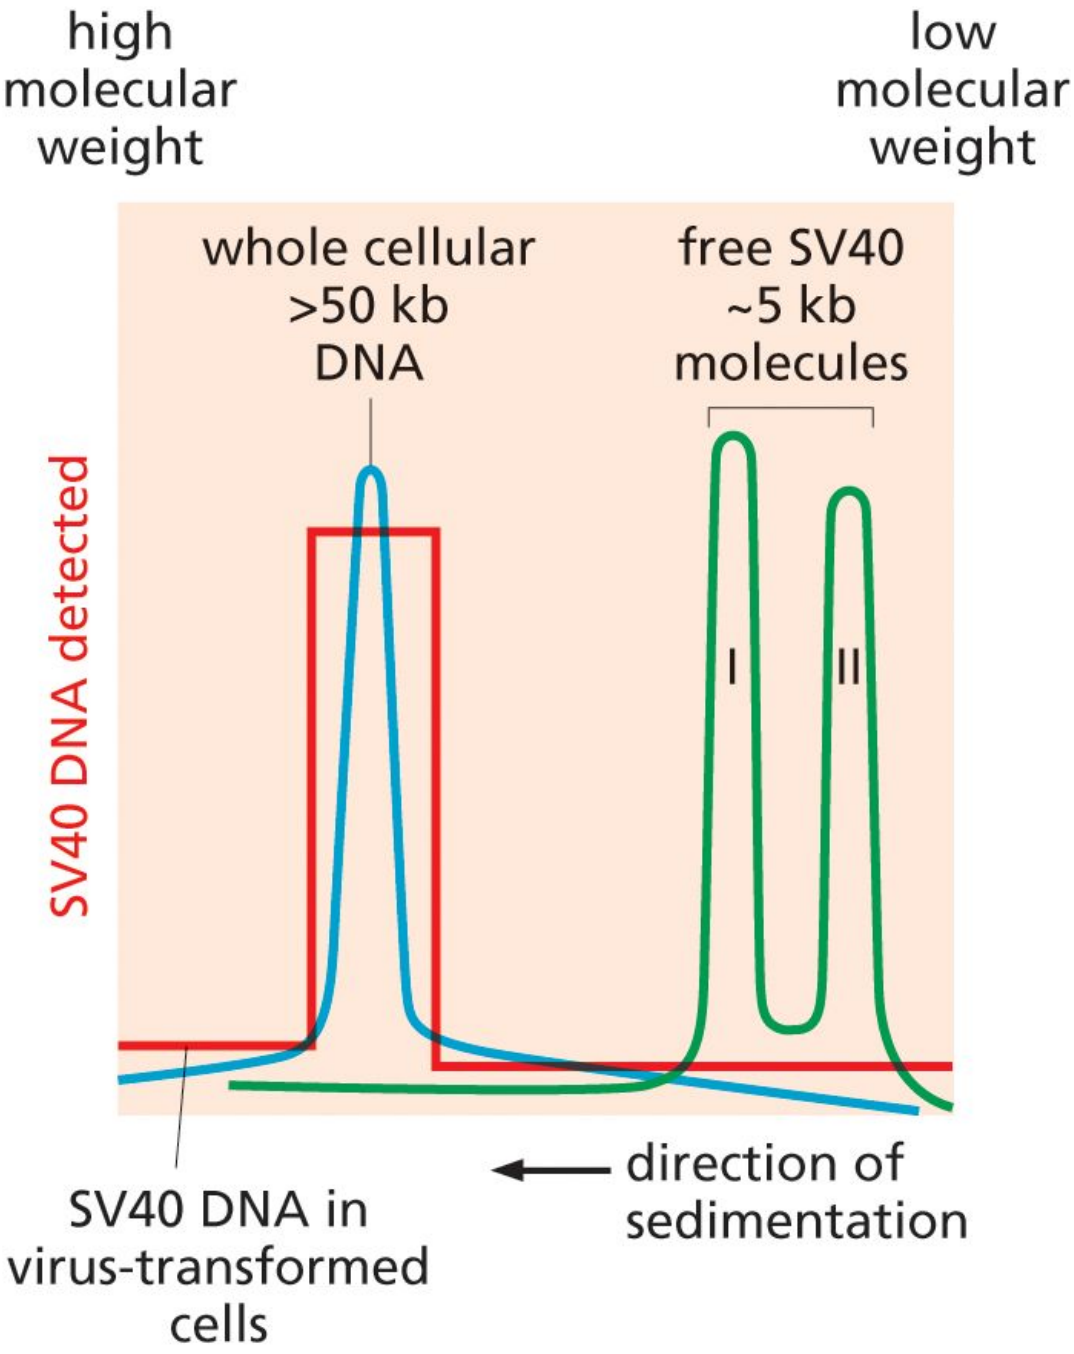
localization of LT (*green*); the cytoplasm of each cell has been stained with phalloidin (*red*), which reveals the F-actin fibers of the cytoskeleton. (B) While SV40 itself rarely if ever causes human tumors (see Section 3.4), immunosuppression can allow an otherwise latent close cousin of SV40, termed BK virus, to become active and occasionally oncogenic. Seen here is a urothelial (bladder) carcinoma arising in a kidney transplant patient. The tumor cells show strong staining for T antigen (*brown*), while the nearby normal urothelial cells are unstained. (The tumor cell nuclei show dramatic variations in size.) (A, courtesy of S.S. Tevethia. B, from I.S.D. Roberts et al., *Brit. J. Cancer* 99:1383–1386, 2008. With permission from Springer Nature.)

The display of the virus-induced T antigen correlated directly with the transformed state of these cells. Therefore, cells that lost the T antigen would also lose the transformation phenotype induced by the virus. This correlation suggested, but hardly proved, that the viral gene sequences responsible for transformation were associated with or closely linked to viral sequences encoding the T antigen.

The cell-to-cell transmission of viral genomes over many cell generations represented a major conceptual problem. Cellular genes were clearly transmitted with almost total fidelity from mother cells to daughter cells through the carefully programmed processes of chromosomal DNA replication and mitosis that occur during each cellular growth-and-division cycle. How could viral genomes succeed in being replicated and transmitted efficiently through an unlimited number of cell generations? This was especially puzzling, since viral genomes seemed to lack the genetic elements, specifically those forming centromeres, that were thought to be required for proper allocation of chromosomes to daughter cells during mitosis.

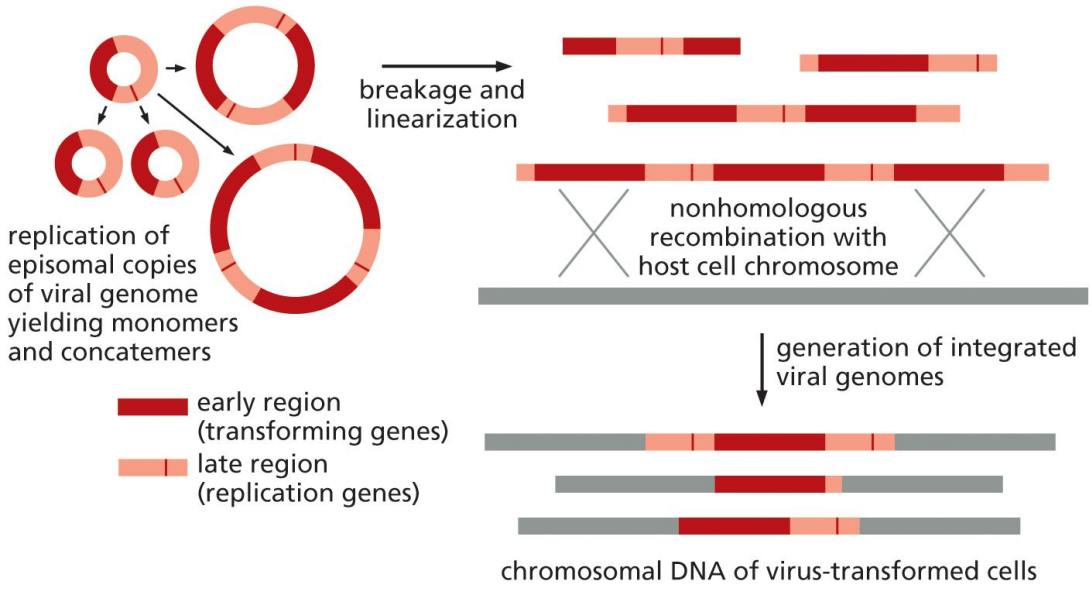
Adding to this problem was the fact that the DNA metabolism of papovaviruses, such as papillomaviruses and polyomaviruses, was very different from that of the host cells that they preyed upon. For example, when SV40 and the murine polyomavirus infected permissive host cells, the viral DNAs were replicated as autonomous, extrachromosomal molecules. Both viruses could form many tens of thousands of circular, double-stranded DNA genomes of about 5 kb in size, all derived from a single viral DNA genome initially introduced by an infecting virus particle (see Figure 3.8). While the viral DNA replication exploited a number of host-cell DNA replication enzymes (see Figure 3.2), it proceeded independently of the infected cells' chromosomal DNA replication. This nonchromosomal replication occurring during the lytic cycles of SV40 and the murine polyomavirus shed no light on how these viral genomes were perpetuated in populations of virus-transformed cells. The latter were, after all, nonpermissive hosts and therefore prevented these viruses from replicating their DNA, both in the initially infected cell and, presumably, in the descendants of this cell.

A solution to this puzzle came in 1968, when it was discovered that the viral DNA in SV40-transformed mouse cells was tightly associated with their chromosomal DNA. Using centrifugation techniques to gauge the molecular weights of DNA molecules, it became clear that the SV40 DNA in these cells no longer sedimented like a small (∼5 kb) viral DNA genome. Instead, the SV40 DNA sequences in virus-transformed cells co-sedimented with the high–molecular-weight (>50 kb) chromosomal DNA of the host cells (**Figure 3.11A**). In fact, the viral DNA in these transformed cells could not be separated from the cells' chromosomal DNA by even the most stringent methods of dissociation, including the harsh treatment of exposure to alkaline pH.



A graphic shows the results of separating D N A molecules in a centrifuge, with the lightest molecules on the right and the heaviest ones on the left. In the right half of the figure, two green peaks indicate the isolation of free S V 40 D N A, with roughly 5 kilobases per molecule. The peak for form 1 is to the left of the peak for form 2. In the left half of the figure, a single blue peak indicates the isolation of whole cellular D N A, with more than 50 kilobases

per molecule. This is where large amounts of S V 40 D N A from virus-transformed cells are detected.
(A)



A flowchart begins with the replication of episomal copies of a viral genome, yielding monomers and concatemers. The original genome and the copies are all ring-shaped and all contain a mix of so-called early regions, containing transforming genes, and late regions, containing replication genes. In the next step, breakage and linearization turn the rings into linear structures, which undergo nonhomologous recombination with a host cell chromosome. In the final step, generation of integrated viral genomes occurs, producing linear strings of chromosomal D N A of virus-transformed cells. The former early and late regions have been spliced into the middle of the host cell D N A segments.

(B)

Figure 3.11 Integration of SV40 DNA (A) DNA molecules from SV40-transformed cells were isolated and sedimented by centrifugation through an alkaline solution stabilized by a sucrose gradient (composed of more concentrated sucrose at the bottom and more dilute sucrose at the top and used to prevent mixing of different fluid strata within the centrifuge tube). Under these conditions, the high–molecular-weight cellular DNA (*blue*) sedimented a substantial distance down the sucrose gradient (*left side of graph*). In contrast, the SV40 DNA isolated from virus particles (*green*) sedimented more slowly, indicative of its lower molecular weight. Forms I and II viral DNA refer to the closed circular and nicked circular DNAs of SV40, respectively (see Figure 3.8). Use of an SV40-specific

radioactive probe revealed that the SV40 DNA sequences in SV40 virus–transformed cells co-sedimented with the high–molecular-weight chromosomal DNA of the virus-transformed cells. Because high pH conditions disrupt all noncovalent interactions, this co-sedimentation indicated the covalent association of the viral genomic DNA (*red*). with that of the host cell (*blue*). (B) When nonchromosomal (that is, episomal) SV40 genomes (*top leftmost circles*) replicate, they often generate large, tandemly repeated, circular genomes termed concatemers. Monomeric and concatemerized SV40 DNA genomes can undergo linearization and thereafter recombine at low efficiency with the host-cell chromosomal DNA (*gray*), doing so at random sites in the host genome; this leads to the covalent linkage of viral and cellular DNA sequences. Since the viral and host-cell genomes lack significant sequence identity, this type of recombination is termed nonhomologous or illegitimate recombination. Use of restriction enzyme cleavage-site mapping revealed the configurations of SV40 genomes integrated into the chromosomal DNA of virus-transformed cells. In some cells, only a portion of the viral genome was present; in others, full, multiple, head-to-tail tandem arrays were present. Cell transformation by SV40 requires only the genes in the "early region" of the viral genome (*dark red*). Consequently, all virus-transformed cells contained at least one uninterrupted copy of this early region but often lacked segments of the viral late region (*pink*), which is functionally unimportant for cell transformation. (A, adapted from J. Sambrook et al., *Proc. Natl. Acad. Sci. USA* 60:1288–1295, 1968. B, adapted from M. Botchan, W. Topp and J. Sambrook, *Cell* 9:269–287, 1976.)

These results indicated that SV40 DNA in virus-transformed cells had been inserted into the cells' chromosomes, becoming covalently linked to the chromosomal DNA. Such integration of the viral genome into a host-cell chromosome solved an important problem in viral transformation: transmission of viral DNA sequences from a mother cell to its offspring could be guaranteed, since the viral DNA would be co-replicated together with the cell's chromosomal DNA during the S (DNA synthesis) phase of each cell cycle. In effect, by integrating into the chromosome, the viral DNA sequences became as much a part of a cell's genome as the cell's own native genes (Figure 3.11B).

Some years later, this ability of the papillomavirus and polyomavirus genomes to integrate into host-cell genomes became highly relevant to the pathogenesis of one common form of human cancer—cervical carcinoma. Almost all (>99.7%) of these tumors have been found to carry fragments of human papillomavirus (HPV) genomes integrated into their chromosomal DNA. Provocatively, intact viral genomes are rarely discovered to be present in integrated form in cancer cell genomes. Instead, only the portion of the viral genome that contains oncogenic (cancer-causing) information has been found in the chromosomal DNA of these cancer cells, while the portion that

enables these viruses to replicate and construct progeny virus particles is almost always absent or present in only fragmentary form (see Figure 3.11B). Interestingly, among the HPV genes discarded or disrupted during the chromosomal integration process is the viral E2 gene, whose product serves to repress transcription of viral oncogenes (genes contributing to cell transformation); in the absence of E2, the viral E6 and E7 oncogenes present in the integrated viral genome segments (discussed in Chapters 8 and 9) are actively transcribed, thereby driving cervical epithelial cells toward a neoplastic phenotype. (An analogous situation is seen in SV40-transformed rodent cells in which the viral genes responsible for viral replication are also often absent.)

More recently, herpesviruses have been found to use at least two different molecular strategies to maintain intact viral genomes in infected cells over extended periods of time. Certain lymphotropic herpesviruses (which infect lymphocytes), specifically human herpesvirus 6 (HHV-6) and Marek's disease virus (MDV) of chickens, can integrate their genomes into the telomeric repeats (see Chapter 10) of the chromosomal DNA of their cellular hosts. This strategy enables these viruses to establish long-term latent infections, in which the viral genomes are maintained indefinitely while the viruses shut down active replication; after great delay, however, the viral genomes can excise themselves and launch active replication of the resulting non-chromosome-integrated (that is episomal) genomes.

More common, however, are molecular strategies that allow DNA tumor viruses, such as Kaposi's sarcoma herpesvirus (KSHV/HHV-8), to maintain their genomes continuously as episomes over many cell generations. Rather than covalently linking their genomes to cellular DNA, these viruses deploy viral proteins that serve as bridges between the episomal viral genomes and cellular chromatin. This allows the viral genomes to "hitchhike" with cellular chromosomes, ensuring nuclear localization during mitosis and proper allocation of viral genomes to daughter cells (**Supplementary Sidebar 3.5**).

Glossary

T antigen
: Tumor-associated antigen, such as that encoded by the genome of a transforming tumor virus such as SV40 and the genomes of the cells that it has transformed. *See* **tumor-associated antigen**.

centromere
: Region of a chromosome that holds the two chromatids together and that binds, via a kinetochore, with mitotic or meiotic spindle fibers.

integration
: Insertion of a fragment of foreign double-stranded DNA (e.g., the DNA genome of an infecting virus) into chromosomal DNA so that the foreign DNA becomes covalently linked to the chromosomal DNA segments flanking it on both sides and can be replicated together with the flanking DNA during subsequent rounds of cell growth and division.

oncogenic
: Referring to the ability to induce or cause cancer.

oncogene
: (1) A cancer-inducing gene. (2) A gene that can transform cells from a normal to a neoplastic state.

lymphotropic
: Capable of infecting lymphocytes.

episome
: (adj., **episomal**) A genetic element, implicitly formed of dsDNA, that exists in a cell, often over multiple cell generations, but is not physically linked via covalent bonds to the cell's chromosomal DNA.

episome
: (adj., **episomal**) A genetic element, implicitly formed of dsDNA, that exists in a cell, often over multiple cell generations, but is not physically linked via covalent bonds to the cell's chromosomal DNA.

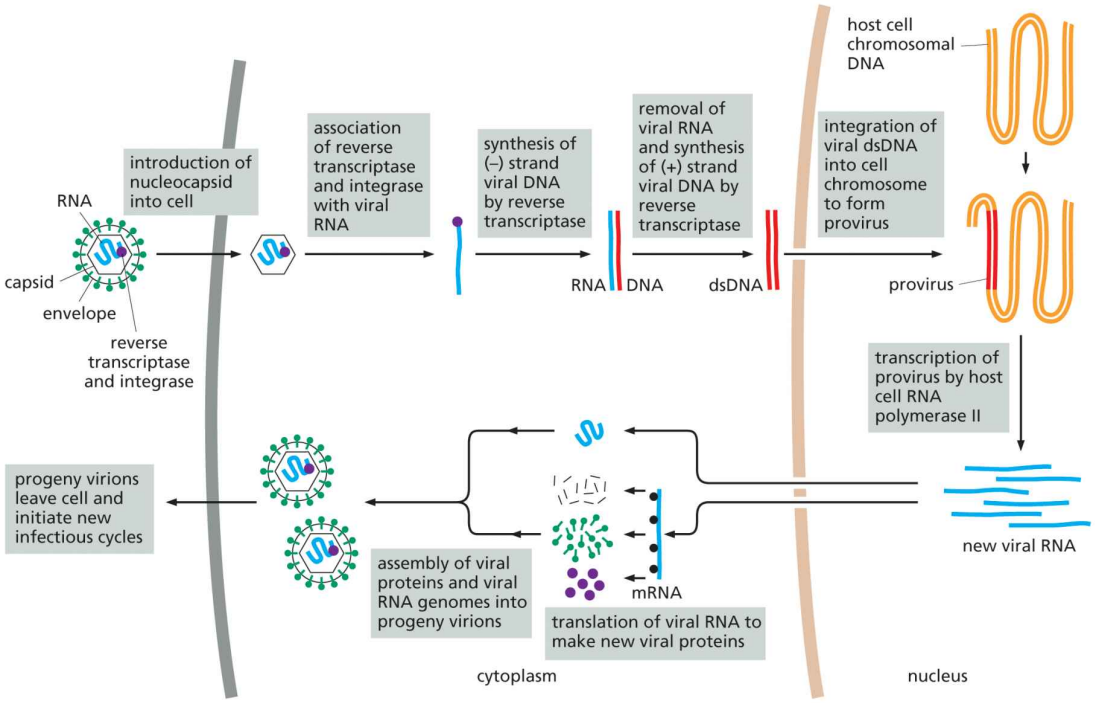
3.7 Retroviral genomes become integrated into the chromosomes of infected cells

The ability of SV40 and the other polyomaviruses to integrate copies of their genomes into host-cell chromosomal DNA solved one problem but created another that seemed much less solvable: how could RSV succeed in transmitting its genome through many generations within a cell lineage? The genome of RSV is made of single-stranded RNA, which clearly could not be integrated directly into the chromosomal DNA of an infected cell. Still, RSV succeeded in transmitting its genetic information through many successive cycles of cell growth and division.

This puzzle consumed Temin in the mid- and late 1960s and caused him to propose a solution so unorthodox that it was ridiculed by many, landing him in the scientific wilderness. Temin argued that after RSV particles (and those of related viruses) infected a cell, they made double-stranded DNA (dsDNA) copies of their RNA genomes. It was these dsDNA versions of the viral genome, he said, that became established in the chromosomal DNA of the host cell. Once established, the DNA version of the viral genome—which he called a provirus—then assumed the molecular configuration of a cellular gene and would be replicated each time the cell replicated its chromosomal DNA. In addition, the proviral DNA could then serve as a template for transcription by cellular RNA polymerase, thereby yielding RNA molecules that could be incorporated into progeny virus particles or, alternatively, could function as messenger RNA (mRNA) that was used for the synthesis of viral proteins (**Figure 3.12**). (The provirus concept was inspired, in part, by the 1952 discovery of prophages—latent forms of bacteriophages that reside in bacterial genomes.)



The life cycle of an R N A tumor virus like R S V. It begins when a virus sheds its envelope and the nucleocapsid within is introduced into the cytoplasm of a cell. This capsid contains an R N A chain that near one end has a clump of reverse transcriptase and integrase. Association of reverse transcriptase and integrase with viral R N A produces a single, straight genome strand with the reverse transcriptase and integrase clump at one end. Reverse transcriptase copies the R N A to produce a matching single minus strand of viral D N A. Removal of the viral R N A and synthesis of a plus strand of viral D N A results in double-stranded d s D N A. This then moves into the nucleus, where it is integrated into the cell chromosome to form a provirus. The host cell's R N A polymerase 2 transcribes the provirus to form new viral R N A. This is translated back out into the cytoplasm, where it makes new viral proteins of various forms. These viral proteins and the viral R N A genomes are assembled into progeny virions. The progeny particles leave the cell and initiate new infectious cycles.

Figure 3.12 The life cycle of an RNA tumor virus like RSV An infecting virion introduces its single-stranded (ss) RNA genome (*blue*) into the cytoplasm of a cell together with the reverse transcriptase enzyme (RT, *purple*). The RT makes a single-stranded DNA using the viral RNA as template complementary to the viral RNA (*red*), and then a second DNA strand (*red*). The reverse-transcribed dsDNA then moves into the nucleus, where it becomes integrated through the actions of the virus-encoded integrase into the cellular chromosomal DNA (*orange*). The resulting integrated provirus is then transcribed by host-cell RNA polymerase II into progeny viral RNA molecules (blue). The progeny RNA molecules are

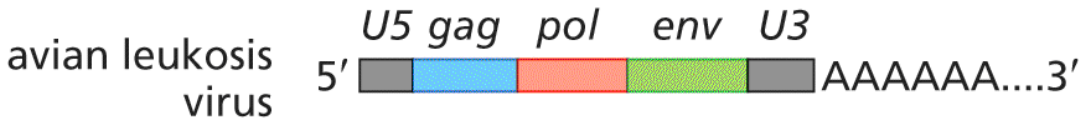
exported to the cytoplasm, where they either serve as mRNAs to make viral proteins or are packaged into progeny virus particles that leave the cell and initiate a new round of infection. (Not explained by this scheme is the mechanistic rationale for the incorporation of RT molecules within the virions. Thus, the indicated replication strategy could in principle be achieved if the RT were not carried within virions but instead was synthesized *de novo* on viral RNA templates only after the virions had entered the cell.) (Adapted from B. Alberts et al., Essential Cell Biology, 3rd ed. New York: Garland Science, 2010.)

The process of reverse transcription that Temin proposed—making DNA copies of RNA—was without precedent in the molecular biology of the time, which recognized information flow only in a single direction, specifically, DNA → RNA → proteins. But the idea prevailed, receiving strong support from Temin's and David Baltimore's simultaneous discoveries in 1970 that RSV and related virus particles carry the enzyme reverse transcriptase. As both research groups discovered, this enzyme has the capacity to execute the key copying step that Temin had predicted—the step required in order for RSV to transmit its genome through many cycles of cell growth and division.

It soon became apparent that RSV was only one of a large group of similarly constructed viruses (including HIV; **Supplementary Sidebar 3.6**), which together came to be called retroviruses to reflect the fact that their cycle of replication depends on information flowing "backward" from RNA to DNA. Within a year of the discovery of reverse transcriptase, the presence of proviral DNA was detected in the chromosomal DNA of RSV-infected cells. Hence, like SV40 and polyomavirus, retroviruses rely on integration of their genomes into the chromosome to ensure the stable retention and transmission of their genomes.

There is, however, an important distinction between the integration mechanisms used by retroviruses like RSV (see Figure 3.12) and the DNA tumor viruses such as SV40 and the murine polyomaviruses (see Figure 3.11B). Integration is a normal, essential part of the replication cycle of retroviruses. Indeed, retrovirus genomes carry the gene specifying an integrase. This enzyme is encoded by the viral *pol* gene (**Figure 3.13**) and is synthesized together with the reverse transcriptase as part of a larger polyprotein. Integrase is dedicated to mediating the process of chromosomal integration. Accordingly, during each cycle of infection and replication, the retroviral genome—its provirus—is integrated into the host chromosomal DNA through a precise, ordered process that ensures the presence of the entire viral genome and thus the retention of all viral genes. This contrasts with the behavior of DNA tumor viruses: chromosomal integration of their genomes is a very rare accident (<<1 per 1000 infections) that enables the perpetuation of viral genomes in the descendants of an initially infected cell; the rare SV40 genomes that do succeed in becoming established

in chromosomal DNA are found integrated in a haphazard fashion that often includes only fragments of the wild-type genome



The structure of the avian leukosis genome, with a 5 prime end on the left and a 3 prime end on the right. At the 5 prime end, from left to right, are a U 5 segment, a gag gene, a pol gene, an e n v gene, and a U 3 segment.

The structure of the Rous sarcoma virus genome, with a 5 prime end on the left and a 3 prime end on the right. At the 5 prime end, from left to right, are a U 5 segment, a gag gene, a pol gene, an e n v gene, a Sarc gene, and a U 3 segment.

(B)

Figure 3.13 Structure of the Rous sarcoma virus genome The RNA genome of RSV is closely related to that of a relatively common infectious agent of chickens, avian leukosis virus, or ALV (A). Both genomes include the *gag* gene, which encodes the proteins that, together with the viral RNA, form each virion's nucleoprotein core; the *pol* gene, which encodes the reverse transcriptase and integrase; and the *env* gene, which specifies the glycoprotein spikes of the virion (see **Supplementary Sidebar 3.6**). (B) The RSV genome carries, in addition, a gene (*src*, *brown*) that specifies the Src protein, which causes cell transformation. At both the left and right ends of these genomes are sequences—*U3* and *U5*—that are duplicated during the course of reverse transcription to generate the pair of identical long terminal repeats (LTRs, *gray*) at the ends of the provirus; the LTRs carry strong transcriptional promoters and sequences involved in chromosomal integration.

Glossary

provirus
: The dsDNA copy of a retroviral genome that is the product of reverse transcription; it can exist transiently, as an episomal (nonchromosomal) plasmid, or stably, following its integration into the chromosomal DNA of an infected host cell.

reverse transcription
: Enzymatic reaction whereby an enzyme, such as reverse transcriptase, copies an RNA template into a complementary DNA copy.

reverse transcriptase
: Enzyme capable of making a DNA complementary copy of an RNA molecule using the RNA molecule as template.

retrovirus
: A class of viruses that uses a reverse transcriptase enzyme to copy its genomic single-strand RNA into double-strand DNA that, after integration into a host cell chromosome, serves as template for transcription of viral mRNA and progeny viral genomes.

integrase
: An enzyme that is specialized to integrate an episomal DNA, such as a retroviral DNA genome, into host-cell chromosomal DNA. *See also* **integration, episome**.

polyprotein
: Initial product of translation that is cleaved subsequently into multiple smaller proteins, each of which may then exhibit its own distinct function.

OceanofPDF.com

3.8 A version of the *src* gene carried by RSV is also present in uninfected cells

Because the genomes of retroviruses, like those of the papillomavirus and polyomavirus, were found to be quite small (<10 kb), it seemed likely that the coding capacity of the retroviral genomes was limited to a small number of genes, probably far fewer than ten. Using this small repertoire of genes, retroviruses nevertheless succeeded in specifying some viral proteins needed for viral genome replication, others required for the construction and assembly of progeny virus particles, and yet other proteins used to transform infected cells.

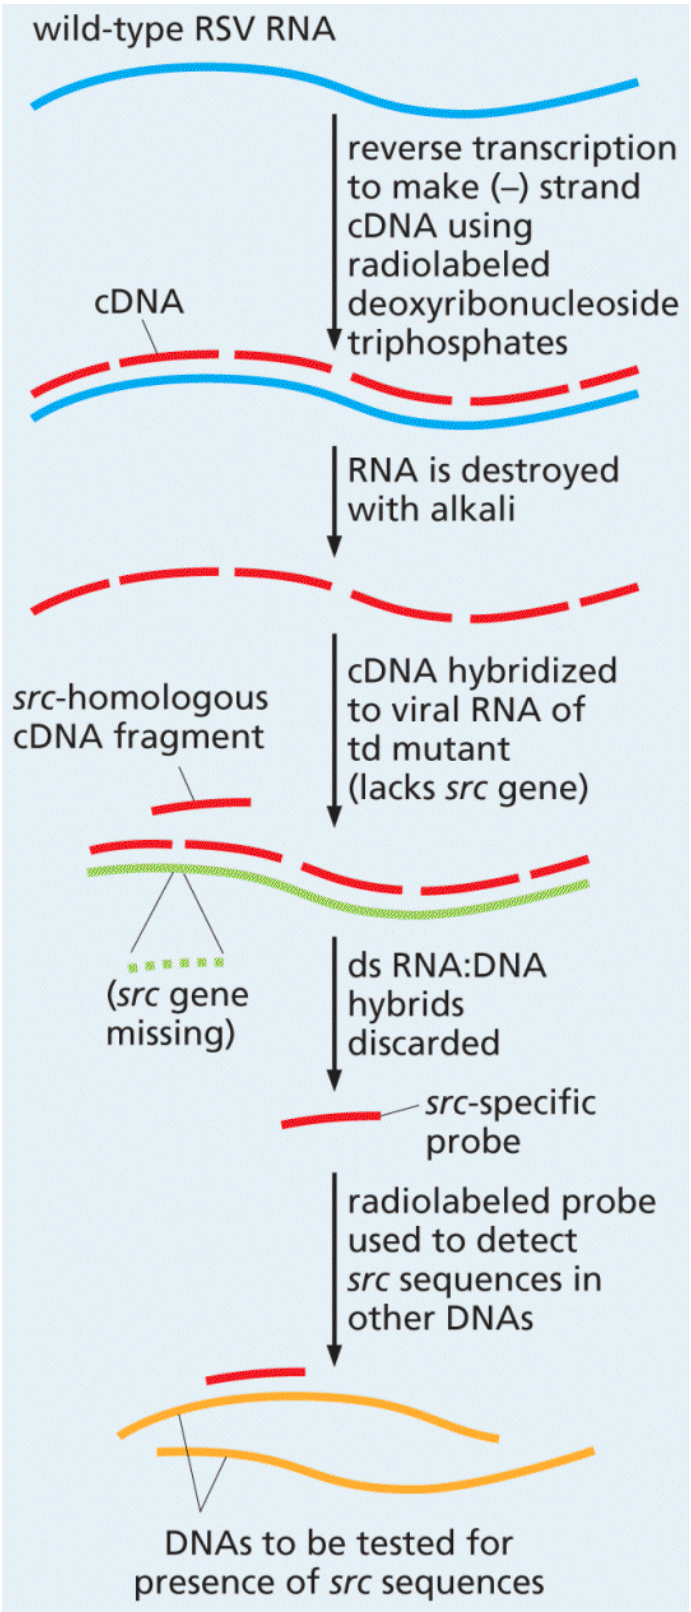
In the case of RSV, the use of mutant viruses revealed that the functions of viral replication (including reverse transcription and the construction of progeny virions) required one set of genes, while the function of viral transformation required another. Thus, some mutant versions of RSV could replicate perfectly well in infected cells, producing large numbers of progeny virus particles, yet such mutants lacked transforming function. Conversely, other mutant derivatives of RSV could transform cells but had lost the ability to replicate and make progeny virions in these transformed cells.

At least three retroviral genes were implicated in viral replication. Two of these encode structural proteins that are required for assembly of virus particles; a third specifies both the reverse transcriptase (RT) enzyme, which copies viral RNA into double-stranded DNA shortly after retrovirus particles enter into host cells, and the integrase enzyme, which is responsible for integrating the newly synthesized viral DNA into the host-cell genome (see Figures 3.12 and 3.13). A comparison of the RNA genome of RSV with the genomes of related retroviruses lacking transforming ability suggested that there was rather little information in the RSV genome devoted to encoding the remaining known viral function—transformation. Consequently, geneticists speculated that all of the viral transforming functions of RSV resided in a single gene, which they termed *src* (pronounced “sark”), to indicate its role in triggering the formation of sarcomas in infected chickens (see Figure 3.13B).

In 1974, the laboratory run jointly by J. Michael Bishop and Harold Varmus at the University of California, San Francisco, undertook to make a DNA probe that specifically recognized the transformation-associated (that is, *src*) sequences of the RSV genome in order to understand its origins and functions (**Sidebar 3.3**). This *src*-specific probe was then used to follow the fate of the *src* gene after cells were infected with RSV. The notion here was that uninfected chicken cells would carry no *src*-related DNA sequences in their genomes, which *src* sequences would become readily detectable in cells following RSV infection, having been introduced by the infecting viral genome.

Sidebar 3.3 The making of a *src*-specific DNA probe

In order to make a *src*-specific DNA probe, a researcher in Bishop and Varmus's laboratory exploited two types of RSV strains: a wild-type RSV genome that carried all of the sequences needed for viral replication and transformation, and a mutant RSV genome that was able to replicate but had lost, by deletion, the *src* sequences required for transformation (**Figure 3.14**). Using reverse transcriptase, he made a DNA copy of the wild-type sequences, yielding single-stranded DNA molecules complementary to the viral RNA genome. He fragmented the complementary DNA (often termed cDNA) and hybridized it to the RNA genome of the RSV deletion mutant that lacked *src* sequences, creating DNA–RNA hybrid molecules. The bulk of the cDNA fragments annealed to the RNA genome of the deletion mutant, with the exception of cDNA fragments derived from the region encoding the *src* sequences. He then retrieved the ssDNA molecules that failed to form DNA–RNA hybrids (discarding the hybrids). The result was ssDNA fragments that specifically recognized sequences contained within the deleted portion of the mutant RSV genome, that is, those lying within the *src* gene.



wild-type RSV RNA
reverse transcription to make (–) strand cDNA using radiolabeled deoxyribonucleoside triphosphates
cDNA
RNA is destroyed with alkali
cDNA hybridized to viral RNA of td mutant (lacks src gene)
src-homologous cDNA fragment
(src gene missing)
ds RNA:DNA hybrids discarded
src-specific probe
radiolabeled probe used to detect src sequences in other DNAs
DNAs to be tested for presence of src sequences

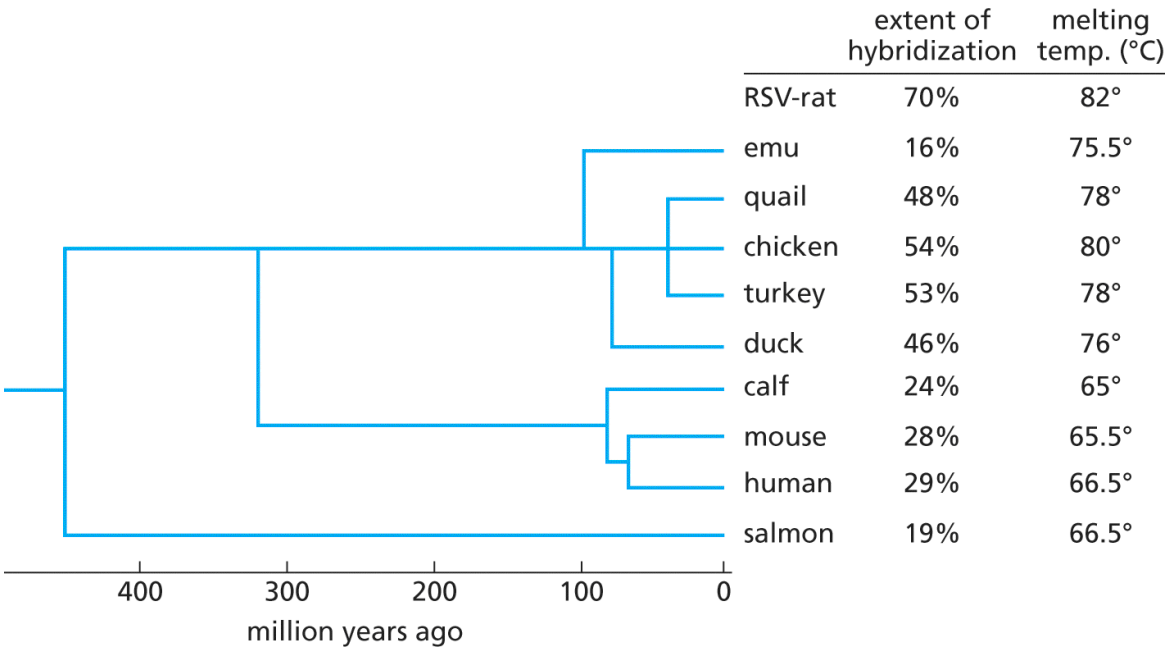
The construction of a Sarc-specific D N A probe. Wild-type R S V R N A is subjected to reverse transcription, using radiolabeled deoxyribonucleoside triphosphates, to make minus strand c D N A. After the R N A is destroyed with alkali, the c D N A is hybridized to viral R N A of t d mutant, which lacks the Sarc gene. This liberates a Sarc-homologous c D N A fragment, which remains after the R N A D N A hybrids are discarded. It is the radiolabeled Sarc-specific D N A probe. It can be used to detect Sarc sequences in other D N A that require testing to be for presence of Sarc sequences.

Figure 3.14 The construction of a *src*-specific DNA probe Wild-type (wt) RSV RNA (*blue*) was reverse-transcribed under conditions where only a single-stranded (ss) complementary DNA molecule (a cDNA; *red*) was synthesized. The wt single-stranded viral DNA was then annealed (hybridized) to viral RNA (green) of a transformation-defective (td) RSV mutant, which had lost its transforming function and apparently deleted its *src* gene. The resulting RNA:DNA hybrids were discarded, leaving behind the ssDNA fragment of the wtDNA that failed to hybridize to the RNA of the td mutant. This surviving DNA fragment, if radiolabeled, could then be used as a *src*-specific probe to detect *src*-related sequences in various cellular DNAs (*orange*) via DNA:DNA hybridization.

Because the initial reverse transcription of the wild-type RSV RNA was carried out in the presence of radiolabeled deoxyribonucleoside triphosphates, the *src*-specific DNA fragments (which constituted the *src* “probe”) were also labeled with radioisotope. This made it possible to discover whether DNAs of interest (such as the DNAs prepared from virus-infected or uninfected cells) also carried *src* sequences by determining whether or not the *src* probe (with its associated radioactivity) was able to hybridize to these cellular DNAs.

The actual outcome of this experiment was, however, totally different from expectation. In 1975, this research group, using their *src*-specific probe, found that *src* sequences were clearly present among the DNA sequences of uninfected chicken cells. These *src* sequences were present as single-copy cellular genes; that is, two copies of the *src*-related DNA sequences were present per diploid chicken cell genome—precisely the representation of the great majority of genes in the cellular genome.

The presence of *src* sequences in the chicken cell genome could not be dismissed as some artifact of the hybridization procedure used to detect them. Moreover, careful characterization of these *src* sequences made it unlikely that they had been inserted into the chicken genome by some retrovirus. For example, *src*-related DNA sequences were readily detectable in the genomes of several related bird species, and, more distantly on the evolutionary tree, in the DNAs of several mammals (**Figure 3.15**). The more distant the evolutionary relatedness of a species was to chickens, the weaker was the reactivity of the *src* probe with its DNA. This was precisely the behavior expected of a cellular gene that had been present in the genome of a common ancestral species and had acquired increasingly divergent DNA sequences as descendant species evolved progressively away from one another over the course of millions of years.



The Evolutionary tree of the Sarc gene, laid out horizontally with the present day on the right. The common ancestor of the chicken, the turkey, and the quail lived about 40 million years ago. The common ancestor of it and the duck lived about 80 million years ago. The common ancestor of it and the emu lived about 100 million years ago. The common ancestor of it and mammals such as the human, the mouse and the calf lived about 310 million years ago. The common ancestor of it and the salmon lived about 450 million years ago. To the right of the tree, a chart lists extent of hybridization and melting temperature in degrees Celsius for each species. RSV-rat, 70%, 82 degrees; emu 16%, 75.5 degrees; quail, 48%, 78 degrees; chicken, 54%, 80 degrees; turkey, 53%, 78 degrees; duck, 46%, 76 degrees; calf, 24%, 65

degrees; mouse, 28%, 65.5 degrees; human, 29%, 66.5 degrees; salmon, 19%, 66.5 degrees.

Figure 3.15 Evolutionary tree of the *src* gene The *src*-specific cDNA probe (see Figure 3.14) was annealed with the DNAs of a variety of vertebrate species—whose relatedness to the chicken is indicated on this evolutionary tree—as well as to a rat cell that had recently been infected and transformed by Rous sarcoma virus and by definition contained the entire sequence of RSV including its *src* gene (RSV-rat). The abscissa indicates the time when the last common ancestor shared by the chicken and each other vertebrate species lived. The best hybridization of the RSV *src* probe was with the DNA of an RSV-transformed rat cell (RSV-rat) carrying an RSV provirus (used as a positive control), as indicated by the percentage of the probe radioactivity that annealed to this cellular DNA and the higher melting temperature of the resulting hybrid. (Melting temperature refers to the temperature at which two nucleic acid strands separate from one another, that is, the temperature at which a double-helix is denatured. The higher the melting temperature, the greater the sequence complementarity and thus base-pairing between two annealing DNA strands; hence, genes borne by distantly related species, because of sequence divergence accumulated as they evolved, should hybridize only imperfectly with the chicken-derived *src* probe, and resulting hybrids should be disrupted at relatively low temperature.) The results for chicken DNA indicate that the sequence of the *src* gene of RSV deviates slightly from the related gene in the chicken genome. The *src* proto-oncogenes of species that were further removed evolutionarily from chickens showed lesser extents of hybridization. Subsequent work, not shown here, revealed the presence of *src* sequences in the DNA of organisms belonging to other metazoan phyla, such as arthropods (e.g., *Drosophila melanogaster*) and even a sponge, whose ancestors diverged from those of vertebrates and other metazoa ∼550 million years ago. The extensive evolutionary conservation of the *src* gene indicates that it played a vital role in the lives of all the organisms that carried it in their genomes. (Courtesy of H.E. Varmus and adapted from D.H. Spector, H.E. Varmus and J.M. Bishop, *Proc. Natl. Acad. Sci. USA* 75:4102–4106, 1978.)

The evidence converged on the idea that the *src* sequences present in the genome of an uninfected chicken cell possessed all the properties of a normal cellular gene, being present in a single copy per haploid genome, evolving slowly over tens of millions of years, and being present in species that were ancestral to all

modern vertebrates. This realization created a revolution in thinking about the origins of cancer.

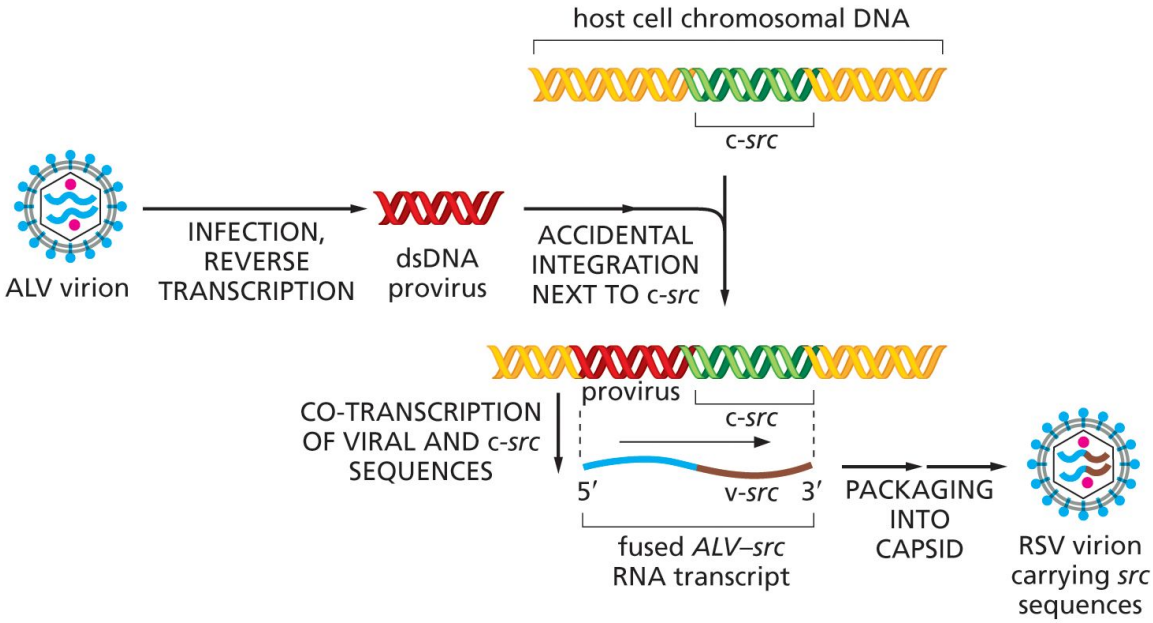
3.9 RSV exploits a kidnapped cellular gene to transform cells

The presence of a highly conserved *src* gene in the genome of a normal organism implied that this cellular version of *src*, sometimes termed c-*src* (that is, cellular *src*), played some role in the life of this organism (the chicken) and its cells. How could this role be reconciled with the presence of a powerful transforming *src* gene carried in the genome of RSV? This viral transforming gene (v-*src*) was closely related to the c-*src* gene of the chicken, yet the two genes had drastically different effects and apparent functions. When ensconced in the cellular genome, the actions of c-*src* were apparently compatible with normal cellular behavior and normal organismic development. In contrast, the very similar v-*src* gene borne by the RSV genome acted as a potent oncogene—a gene capable, following its introduction into a cell by an infecting virus particle, of transforming the previously normal cell into a tumor cell.

One solution to this puzzle came from considering the possibility that perhaps the *src* gene of RSV was not naturally present in the retrovirus ancestral to RSV. This hypothetical viral ancestor, while lacking *src* sequences, would be perfectly capable of replicating in chicken cells. In fact, such a *src*-negative retrovirus—avian leukosis virus (ALV)—was common in chickens and was capable of infectious spread from one chicken to another. This suggested that during the course of infecting a chicken cell, an ancestral virus, similar to this common chicken virus, somehow acquired sequences from the genome of a cell that it had infected (**Figure 3.16**), doing so through some genetic trick. The acquired cellular sequences (that is, the *src* sequences) were then incorporated into the viral genome, thereby adding a fourth gene to the existing three genes that this retrovirus used for its replication in infected cells (see Figure 3.13). Once present in the genome of RSV, the kidnapped *src* gene could then be altered and exploited by this virus to transform subsequently infected cells.



A diagram shows the process of the capture of Sarc by avian leukosis virus. Starting with an A L V virion, infection and reverse transcription produce a d s D N A provirus. This accidentally becomes integrated into host cell chromosomal D N A right beside a c-Sarc proto-oncogene. Co-transcription of the viral and c-Sarc sequences produces a fused A L V Sarc R N A transcript. Packaging into a capsid produces an R S V virion carrying Sarc sequences.

Figure 3.16 Capture of *src* by avian leukosis virus The precise mechanism by which an avian leukosis virus (ALV) captured a cellular *src* gene (c-*src*) is not known. According to the most plausible model, ALV proviral DNA (*red*) became integrated (by chance) next to a c-*src* proto-oncogene (*green*) residing in the chromosomal DNA of an infected chicken cell. The ALV provirus and adjacent c-*src* gene were then co-transcribed into a single hybrid RNA transcript (*blue and brown*). After splicing out c-*src* introns (not shown), this hybrid viral RNA was packaged into a virus particle that became the ancestor of Rous sarcoma virus (RSV). (Not shown is the acquisition during a subsequent infectious cycle of ALV sequences at the 3′ side of v-*src*, with the result that this viral oncogene became flanked on both sides by ALV sequences.)

This scheme attributed great cleverness to retroviruses by implying that they had the ability to pick up and exploit preexisting cellular genes for their own

purposes. Such behavior is most unusual for a virus, since virtually all other types of viruses carry genes that have little if any relatedness to DNA sequences native to the cells that they infect (**Supplementary Sidebar 3.7**).

But there was an even more important lesson to be learned here, this one concerning the c-*src* gene. This cellular gene, one among tens of thousands in the chicken cell genome, could be converted into a potent viral oncogene following some slight remodeling by a retrovirus such as RSV. Because it was a precursor to an active oncogene, c-*src* was called a proto-oncogene. The very concept of a proto-oncogene was revolutionary: it implied that the genomes of normal vertebrate cells carry a gene that has the potential, under certain circumstances, to induce cell transformation and thus cancer.

The structures of the c-*src* proto-oncogene and the v-*src* oncogene were worked out rapidly in the years that followed these discoveries in 1975 and 1976. Just as the viral geneticists had speculated, all of the viral transforming sequences resided in a single viral oncogene. Within the RSV RNA genome, the v-*src* gene was found at the downstream, 3′ end of the genome, added to the three preexisting retroviral genes that were involved in viral replication (see Figure 3.13). Amusingly, the c-*src* gene may have been acquired by ALV on only one occasion documented in the history of modern cancer research (see **Supplementary Sidebar 3.7**).

This scenario of acquisition and activation of c-*src* by a retrovirus led to three further ideas. First, if retroviruses could activate this proto-oncogene into a potent oncogene, perhaps other types of mutational mechanisms might reshape the normal c-*src* gene and yield a similar outcome. Maybe such mechanisms could activate a cellular proto-oncogene without removing the normal gene from its normal roosting site on the cellular chromosome. Maybe the information for inducing cancer was already present in the normal cell genome, waiting to be unmasked.

Second, it became clear that all of the transforming powers of RSV derived from the presence of a single gene—v-*src*—in its genome. This was of great importance, because it implied that a single oncogene could, as long suspected, elicit a large number of changes in the shape, metabolism, and growth behavior of a cell. More generally, this suggested that other cancer-causing genes could also act pleiotropically. Accordingly, if a transformed, tumorigenic cell differed from a normal cell in 20 or 30 distinct traits, perhaps these multiple changes were not dependent on the alteration of 20 or 30 different genes; instead, maybe a small

number of master control genes would suffice to transform a normal cell into a tumorigenic cell.

Third, RSV and its v-*src* oncogene might represent a model for the behavior of other types of retroviruses that were similarly capable of transforming infected cells *in vitro* and inducing tumors *in vivo*. Perhaps such retroviruses had acquired other cellular genes unrelated to *src*. While c-*src* was certainly the first cellular proto-oncogene to be discovered, maybe other cellular proto-oncogenes were hiding in the vertebrate cellular genome, waiting to be picked up and activated by some passing retrovirus.

3.10 The vertebrate genome carries a large group of proto-oncogenes

An accident of history—an encounter in 1909 between a Long Island chicken farmer and Peyton Rous—made RSV the first tumorigenic retrovirus to be isolated and characterized in detail. Consequently, RSV was favored initially with the most detailed molecular and genetic analysis. However, in the 1950s and 1960s, a group of other chicken and rodent tumor viruses were found that were subsequently realized to be members, like RSV, of the retrovirus class.

The diversity of these other transforming retroviruses and the diseases that they caused suggested that they, like RSV, might be carrying kidnapped cellular proto-oncogenes and might be using these acquired genes to transform infected cells. So, within a year of the discovery of v-*src* and c-*src*, the race began to find additional viruses that had traveled down a similar genetic path and picked up other, potentially interesting proto-oncogenes.

Another chicken retrovirus—the MC29 myelocytomatosis virus—which was known to be capable of inducing a malignancy of blood-forming cells in chickens, was one of this class. MC29 was also found to carry an acquired cellular gene in its genome, termed the v-*myc* oncogene, which this virus exploited to induce rapidly growing tumors in infected chickens. As was the case with v-*src*, the origin of the v-*myc* gene could be traced to a corresponding proto-oncogene residing in the normal chicken genome. Like *src*, *myc* underwent some remodeling after being incorporated into the retroviral genome. This remodeling imparted potent oncogenic powers to a gene that previously had played a normal physiologic, apparently essential role in the life of normal chicken cells.

Of additional interest was the discovery that MC29, like RSV, descended from avian leukosis virus (ALV). This reinforced the notion that retroviruses like ALV were adept at acquiring random pieces of a cell's genome. The biological powers of the resulting hybrid viruses would presumably depend on which particular cellular genes had been picked up. In the case of the large majority of randomly acquired cellular genes, hybrid viruses carrying such genes would show no obvious phenotypes such as tumor-inducing potential. Only on rare occasion, however, when a growth-promoting cellular gene—a proto-oncogene—happens to be acquired, the hybrid virus might exhibit a cancer-inducing phenotype that could lead to its discovery and eventual isolation by a virologist.

Mammals were also found to harbor retroviruses that are distantly related to ALV and, like ALV, are capable of acquiring cellular proto-oncogenes and converting them into potent oncogenes. Among these is the feline leukemia virus, which acquired the *fes* oncogene in its genome, yielding feline sarcoma virus, and a hybrid rat–mouse leukemia virus, which on separate occasions acquired two distinct proto-oncogenes: the resulting transforming retroviruses, Harvey and Kirsten sarcoma viruses, carry the H-*ras* and K-*ras* oncogenes, respectively, in their genomes. Within a decade, the repertoire of retrovirus-associated oncogenes had increased to more than two dozen, many named after the viruses in which they were originally discovered (**Table 3.3**). By now, more than fifty distinct vertebrate proto-oncogenes have been discovered through various experimental routes, thirty of which were initially identified through their association with a transforming retrovirus. [Many more genes can be classified as proto-oncogenes based on observations that their copy number is increased by gene amplification (see Section 4.2) in many human tumors.]

Table 3.3 Examples of acutely transforming retroviruses and the oncogenes that they have acquired[a]

Name of virus	Viral oncogene	Species	Major disease	Nature of oncoprotein
Hardy–Zuckerman feline sarcoma	*kit*	cat	sarcoma	steel factor RTK
Simian sarcoma	*sis*	woolly monkey	sarcoma	PDGF
AKT8	*akt*	mouse	lymphoma	ser/thr kinase
Avian virus S13	*sea*	chicken	erythroblastic leukemia[b]	RTK; unknown ligand
Myeloproliferative leukemia	*mpl*	mouse	myeloproliferation	TPO receptor
Regional Poultry Lab v. 30	*eyk*	chicken	sarcoma	RTK; unknown ligand
Avian sarcoma virus CT10	*crk*	chicken	sarcoma	SH2/SH3 adaptor
Avian sarcoma virus 17	*jun*	chicken	sarcoma	transcription factor

Name of virus	Viral oncogene	Species	Major disease	Nature of oncoprotein
Avian sarcoma virus 31	*qin*	chicken	sarcoma	transcription factor[c]
AS42 sarcoma virus	*maf*	chicken	sarcoma	transcription factor
Cas NS-1 virus	*cbl*	mouse	lymphoma	SH2-dependent ubiquitylation factor
ASV-16	*p3k*	chicken	hemangiosarcoma	lipid kinase
Abelson leukemia virus	*abl*	mouse	lymphosarcoma	tyr kinase

Abbreviations: PDGF, platelet-derived growth factor; RTK, receptor tyrosine kinase; ser/thr, serine/threonine; SH, *src*-homology segment; TK, tyrosine kinase; TPO, thrombopoietin.

In each case, a proto-oncogene found in the DNA of a mammalian or avian species was readily detectable in the genomes of all other vertebrates. There were, for example, chicken, mouse, and human versions of c-*myc*, and these genes seemed to function identically in their respective hosts. The same could be said of all the other proto-oncogenes that were uncovered. Soon it

became clear that this large repertoire of proto-oncogenes must have been present in the genome of the vertebrate that was the common ancestor of all mammals and birds, and that this group of genes, like most others in the vertebrate genome, was inherited by all of the modern descendant species.

Now, almost half a century later, we realize that these transforming retroviruses provided cancer researchers with a convenient window through which to view the cellular genome and its cohort of proto-oncogenes. Without these retroviruses, the discovery of many proto-oncogenes would have been exceedingly difficult. By fishing these genes out of the cellular genome and revealing their latent powers, these viruses catapulted cancer research forward by decades.

3.11 Slowly transforming retroviruses activate proto-oncogenes by inserting their genomes adjacent to these cellular genes

As described above, each of the various tumorigenic retroviruses arose when a nontransforming retrovirus, such as avian leukosis virus (ALV) or murine leukemia virus (MLV), acquired a proto-oncogene from the genome of an infected host cell. The result, in each case was an “acutely transforming” retrovirus whose transforming powers could usually be observed by its effects on monolayer cultures of infected cells (see Figure 3.4) and on virus-infected animal hosts, which developed tumors rapidly after infection. In fact, the “nontransforming” precursor viruses could also induce cancers, but they were able to do so only on a much more extended timetable; often months passed before these viruses succeeded in producing cancers. The oncogene-bearing acutely transforming retroviruses, in contrast, often induced tumors within days or weeks after they were injected into host animals.

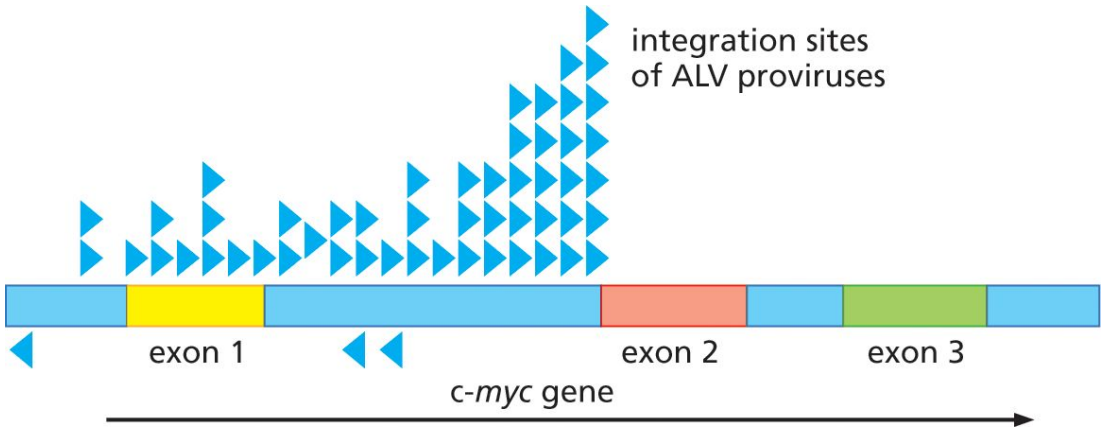
When the rapidly transforming retroviruses were used to infect cells in culture, the cells usually responded by undergoing changes in morphology and growth behavior that typify the behavior of cancer cells (see Table 3.2). In contrast, when the slowly tumorigenic, nontransforming viruses, such as ALV and MLV, infected cells, these cells released progeny virus particles but did not show any apparent changes in shape or growth behavior. This lack of change in cell phenotypes was consistent with the fact that these viruses appeared to lack oncogenes in their genomes.

These facts, when taken together, represented a major puzzle. How could viruses like MLV or ALV induce a malignancy if their genomes carried no oncogenes?

The solution came in 1981 from study of the leukemias that ALV induced in chickens, more specifically, from detailed analysis of the genomic DNAs of the leukemic cells. These cells invariably carried copies of the ALV provirus integrated into their genomes. By the time these experiments began, a decade after Temin and Baltimore’s discovery, it had become clear that the integration of retroviral proviruses occurs at myriad sites throughout the chromosomal DNA of infected host cells. Given the size of the chicken genome, there might be many millions of distinct chromosomal sites used

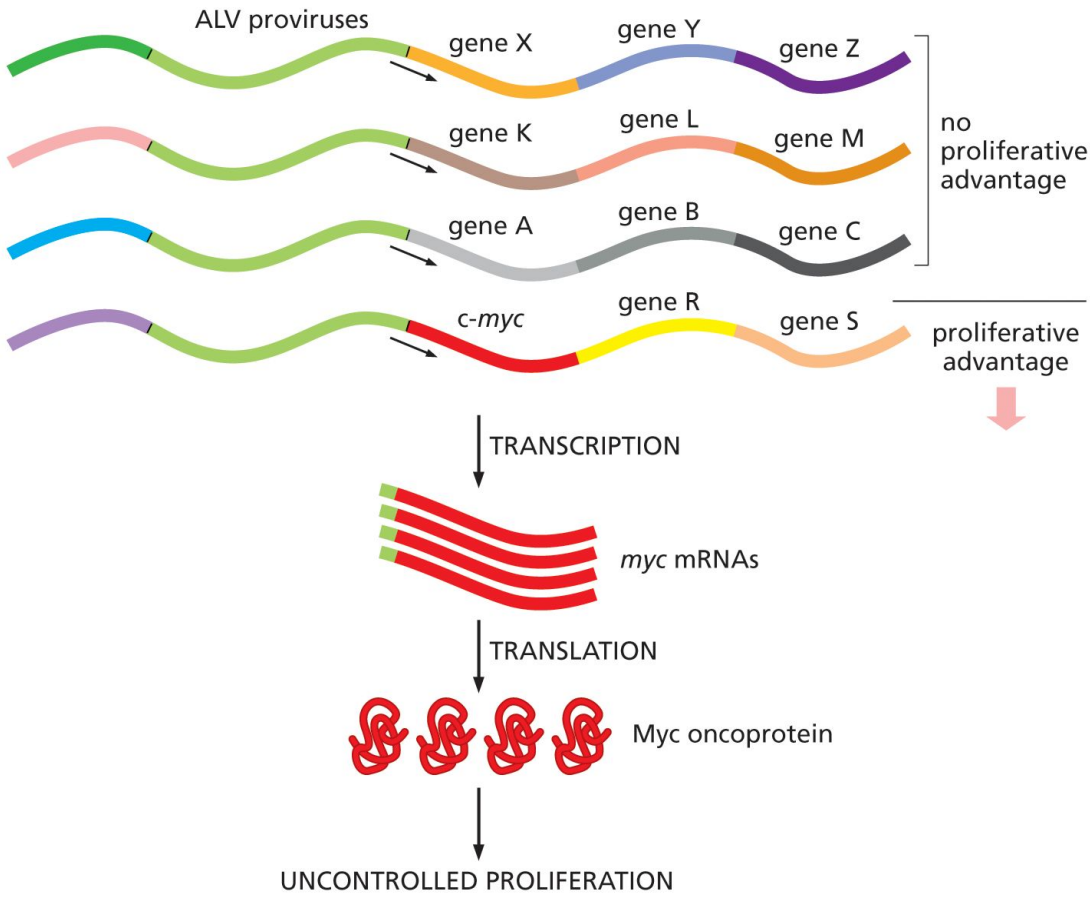
by ALV to integrate its provirus; moreover, each infected leukemia cell might carry one or several proviruses in its genome. Knowing all this, researchers nevertheless undertook to map the genomic sites in ALV-induced leukemias where ALV proviruses had integrated.

This molecular analysis of a series of ALV-induced leukemias, each arising independently in a separate chicken, revealed a picture very different from the expected collection of random integration sites. In a majority (>80%) of these leukemia cell genomes, the ALV provirus was found to be integrated into the chromosomal DNA immediately adjacent to or within the c-*myc* proto-oncogene (**Figure 3.17A**)! This observation, on its own, was difficult to reconcile with the notion that provirus integration occurs randomly at millions of sites throughout the genomes of infected cells.



A segment of chromosomal D N A carrying the c-m y c gene, with exons 1, 2 and 3 shown as colored subsegment spaced out, left to right, along the gene. Over 50 small triangles placed along the gene show the integration sites of A L V proviruses. A few of these are to the left of exon 1 or within it, but the large majority are between exons 1 and 2 and especially just to the left of exor 2. No integration sites are within or to the right of exon 2. Nearly all the triangles point rightward, but three point leftward.

(A)



Four different chromosome segments with an A L V provirus inserted. Three of them contain various collections of other genes that confer no proliferative advantage. The fourth contains the c-m y c gene immediately next to the A L V provirus. This combination has a proliferative advantage. Transcription produces many m y c m R N A, and then translation produces many M y c oncoproteins, in uncontrolled proliferation.

(B)

Figure 3.17 Insertional mutagenesis The oncogenic actions of viruses, such as avian leukosis virus (ALV), that lack acquired oncogenes could be explained by the integration of their proviral DNA adjacent to a cellular proto-oncogene. (A) Analysis of numerous B-cell lymphomas that were induced in chickens by ALV revealed that a large proportion of the ALV proviruses were integrated (*filled blue triangles*) into the chromosomal DNA segment carrying the c-*myc* proto-oncogene, usually in the same transcriptional orientation as that of the c-*myc* gene; the majority were integrated between the first noncoding exon of c-*myc* and the second exon, in which the *myc* reading frame begins. (B) ALV's oncogenic behavior could be rationalized as follows. In the course of ALV infection of

chicken lymphocytes, ALV proviruses (*green*) become integrated randomly at millions of different sites in the chromosomal DNA of these cells. (Chromosomal DNA maps of only four are illustrated schematically here.) On rare occasions, an ALV provirus becomes integrated (by chance) within the c-*myc* proto-oncogene (*red*). This may then cause transcription of the c-*myc* gene to be driven by the strong, constitutively acting ALV promoter, notably the one found at the 3′ (*right*) end of the provirus (see Figure 3.13). Because high levels of the Myc protein are potent in driving cell proliferation, the cell carrying this particular integrated provirus and activated c-*myc* gene will now multiply uncontrollably, eventually spawning a large host of descendants that will constitute a lymphoma. [A, adapted from J.R. Nevins and P.K. Vogt, “Cell Transformation by Viruses” in *Fields Virology*, Third Ed. (Lippincott-Raven, 1996). With permission from Wolters Kluwer.]

It soon became clear that the close physical association of an integrated proviral genome and the cellular *myc* proto-oncogene led to a functional link between these two genetic elements. The viral transcriptional promoter and enhancer (see Section 1.8), nested within the ALV provirus, overrode and disrupted the control mechanisms that normally govern expression of the c-*myc* gene (see Figure 3.17A). Now, instead of being regulated by its own native gene promoter, the cellular *myc* gene was placed directly under viral transcriptional control. As a consequence, rather than being regulated up and down by the finely tuned control circuitry of the cell, c-*myc* expression was taken over by a foreign usurper that drove its expression unceasingly and at a high rate. In essence, this hybrid viral–cellular gene residing in the chromosomes of leukemic cells now functioned much like the v-*myc* oncogene carried by avian myelocytomatosis virus.

Suddenly, all the clues needed to solve the puzzle of leukemogenesis (leukemia formation) by ALV fell into place. The solution went like this. During the course of infecting a chicken, ALV spread to thousands, then millions of cells in the hematopoietic system of this bird. Soon, the infection was so successful that the bird would become viremic, that is, its bloodstream carried high concentrations of virus particles. Each of the tens of millions of infections occurring within this bird resulted in the insertion of an ALV provirus at some random location in the genome of an infected cell. In the vast majority of cases, this provirus integration had no effect on the infected host cell, aside from forcing the host to produce large numbers of progeny virus particles. But on rare occasions, perhaps in 1 out of 10 million infections, a provirus became integrated by chance next to the c-*myc* gene (Figure 3.17B). This jackpot event led to an explosive outcome—conversion of the resident c-*myc* gene into a potent oncogene whose unceasing expression was now driven by the adjacently integrated provirus and its transcriptional promoter. The rare cell carrying this deregulated *myc* gene then initiated a program of uncontrolled proliferation, and within

weeks, some of the progeny cells evolved further into more aggressive cancer cells that constituted a leukemia. It was this neoplasia that alerted experimenters to the likelihood of an infection by a retrovirus.

This scenario explains the slow kinetics with which these leukemias arise after initial viral infection of a bird. Since activation of the c-*myc* gene through provirus integration is a low-probability event, many weeks and many millions of infectious events are required before these malignancies are triggered. This particular mechanism of proto-oncogene activation came to be called insertional mutagenesis; it explains, as well, the leukemogenic powers of other slowly acting retroviruses, such as MLV. By now, study of avian and murine retrovirus-induced infections has demonstrated integration events occurring next to more than 25 distinct cellular proto-oncogenes. Indeed, insertional mutagenesis can be used as a powerful strategy to find new proto-oncogenes (**Sidebar 3.4**; see Table 3.4). Moreover, insertional mutagenesis has had implications for the development of new approaches to curing disease using gene therapy (see **Supplementary Sidebar 3.8**).

Sidebar 3.4 Insertional mutagenesis uncovers novel proto-oncogenes

As described earlier (see Section 3.10), the analysis of the genomes of rapidly transforming retroviruses enabled investigators to identify a large cohort of proto-oncogenes. The phenomenon of insertional mutagenesis, first discovered through the insertion of an ALV genome adjacent to the c-*myc* proto-oncogene, offered an alternative strategy for discovering these cellular genes. Thus, a researcher could study a series of independently arising tumors, all of which had been induced by a retrovirus, such as ALV or MLV, that was known to lack its own oncogene. More specifically, this researcher could analyze the host-cell sequences that lay immediately adjacent to the integrated proviruses in the chromosomal DNA of the virus-infected, transformed cells. The hope was that the proviruses might be found to be integrated repeatedly next to a (possibly still-unknown) cellular gene whose activation was triggered by the transcriptional promoter of the provirus. The adjacent gene could be readily cloned, since it was effectively tagged by the closely linked proviral DNA.

The initial fruits of this strategy came from studying the breast cancers induced by mouse mammary tumor virus (MMTV), another retrovirus that lacked an oncogene in itsgenome. Researchers mapped the integration sites of MMTV proviruses in the genomes of mouse breast cancers that had been induced by this virus. Most of the proviruses were found to be integrated in one of three chromosomal locations, clustering next to cellular genes that were then called *int-1*, *int-2*, and *int-3* (**Table 3.4**). Each of these genes was later discovered to encode a protein involved in stimulating cell proliferation in one way or another. The deregulated expression of each of these genes, resulting from nearby MMTV provirus integration, seemed to be

responsible for triggering the cell proliferation that led to the appearance of mammary tumors.

The *int-1* gene, which was found to be homologous to the *wingless* gene of *Drosophila*, was renamed *Wnt-1*, and was the forerunner of a whole series of *Wnt* genes that have proven to be important vertebrate mitogens and morphogens, that is, factors controlling morphogenesis. This set of genes and the associated Wnt pathway is upregulated in many types of human cancer (see Chapters 5 and 6). More recently, this search strategy has uncovered a large group of other cellular genes, each of which, when activated by insertional mutagenesis mediated by MLV, triggers leukemias in mice (see Table 3.4).

Table 3.4 Examples of cellular genes found to be activated by insertional mutagenesis

Gene	Insertional mutagen	Tumor type	Species	Type of oncoprotein
Myc	ALV	B-cell lymphoma	chicken	transcription factor
Myc	ALV, FeLV	T-cell lymphoma	chicken, cat	transcription factor
Nov	ALV	nephroblastoma	chicken	growth factor
erbB	ALV	erythroblastosis	chicken	receptor TK
mos	IAP	plasmacytoma	mouse	ser/thr kinase
int-1[a]	MMTV	mammary carcinoma	mouse	growth factor
int-2[b]	MMTV	mammary carcinoma	mouse	growth factor

Gene	Insertional mutagen	Tumor type	Species	Type of oncoprotein
int-3	MMTV	mammary carcinoma	mouse	receptor[c]
int-H/int-5	MMTV	mammary carcinoma	mouse	enzyme[d]
pim-1	Mo-MLV	T-cell lymphoma	mouse	ser/thr kinase
pim-2	Mo-MLV	B-cell lymphoma	mouse	ser/thr kinase
bmi-1	Mo-MLV	T-cell lymphoma	mouse	transcription repressor
tpl-2	Mo-MLV	T-cell lymphoma	mouse	ser/thr kinase
lck	Mo-MLV	T-cell lymphoma	mouse	non-receptor TK
p53	Mo-MLV	T-cell lymphoma	mouse	transcription factor
GM-CSF	IAP	myelomonocytic leukemia	mouse	growth factor
IL2	GaLV	T-cell lymphoma	gibbon ape	cytokine[e]
IL3	IAP	T-cell lymphoma	mouse	cytokine

Gene	Insertional mutagen	Tumor type	Species	Type of oncoprotein
K-ras	F-MLV	T-cell lymphoma	mouse	small G protein
CycD1	F-MLV	T-cell lymphoma	mouse	G1 cyclin
CycD2	Mo-MLV	T-cell lymphoma	mouse	G1 cyclin

Abbreviations: ALV, avian leukosis virus; FeLV, feline leukemia virus; F-MLV, Friend murine leukemia virus; GaLV, gibbon ape leukemia virus; IAP, intracisternal A particle (a retrovirus-like genome that is endogenous to cells); Mo-MLV, Moloney murine leukemia virus; MMTV, mouse mammary tumor virus; ser/thr, serine/threonine; TK, tyrosine kinase.
Adapted in part from J. Butel, *Carcinogenesis* 21:405–426, 2000; and from N. Rosenberg and P. Jolicoeur, in J.M. Coffin, S.H. Hughes and H.E. Varmus (eds.), Retroviruses. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, 1997. Also in part from G.M. Cooper, Oncogenes, 2nd ed. Boston: Jones and Bartlett Publishers, 1995.

Unvoiced by those who uncovered insertional mutagenesis was another provocative idea: maybe it was possible that nonviral carcinogens could achieve the same end result as ALV did. Perhaps these other carcinogens, including X-rays and mutagenic chemicals, could alter cellular proto-oncogenes while these genes resided in their normal sites in cellular chromosomes. The result might be a disruption of cellular growth control that was just as destabilizing as the events that led to ALV-induced leukemias.

OceanofPDF.com

Glossary

leukemogenesis
: (adj., - **genic**) Process that creates a leukemia.

insertional mutagenesis
: Alteration of a gene and its function through the integration of a retroviral provirus or transposon into the gene itself or a closely linked chromosomal site.

morphogen
: Low–molecular-weight substance that induces cells to assemble and participate in the construction of a tissue of a certain shape and form.

viremia
: Presence of high concentrations of virus in the bloodstream.

3.12 Some retroviruses naturally carry oncogenes

The descriptions of retroviruses in this chapter indicate that they essentially fall into two classes. Some, such as ALV and MLV, carry no oncogenes but can induce tumors that erupt only after a long latent period (that is, many weeks) following the initial infection of a host animal. Other viruses, such as RSV, can induce cancer rapidly (that is, in days or several weeks), having acquired an oncogene from a cellular proto-oncogene precursor.

In reality, there is a third class of retroviruses that conforms to neither of these patterns. Most prominent among them is human T-lymphotropic leukemia virus type 1 (HTLV-I), which chronically infects about 1% of the inhabitants of Kyushu, the south island of Japan; in Japan as a whole about one thousand people die each year from HTLV-I–induced leukemias. An endemic infection is also present, albeit at a lower rate, in some islands of the Caribbean. Lifelong HTLV-I infection carries a 3–4% risk of developing adult T-cell leukemia, and the virus seems to be maintained in the population largely via milk-borne, mother-to-infant transmission.

There are no indications, in spite of extensive molecular surveys, that HTLV-I provirus integration sites are clustered in certain chromosomal regions. Accordingly, it appears highly unlikely that HTLV-I uses insertional mutagenesis to incite leukemias. Instead, its leukemogenic powers seem to be traceable to one or more viral proteins that are naturally encoded by the viral genome. The best understood of these is the viral Tax protein, whose product is responsible for activating transcription of proviral DNA sequences, thereby enabling production of progeny RNA genomes. At the same time, the *tax* gene product—the Tax oncoprotein—appears to activate two cellular signaling pathways involving NF-κB and PI3 kinase (Chapter 6). These pathways proceed to stimulate the proliferation of T lymphocytes (Chapter 15) and to suppress apoptosis (Chapter 9). While such induced proliferation, on its own, does not directly create a leukemia, it seems that populations of these HTLV-I–stimulated cells may progress at

a low but predictable frequency to spawn variants that are indeed neoplastic. In this instance, the expression of certain viral oncogenes, notably tax, appears to be an intrinsic and essential component of a retroviral replication cycle within host animals, rather than the consequence of rare genetic accidents that yield unusual hybrid genomes, such as the genome of RSV. Jaagsiekte sheep retrovirus represents a second example of an acutely transforming retrovirus that carries a viral oncogene exhibiting no apparent homology with a normal cellular gene; this poorly studied virus deploys the glycoprotein product of its *env* gene (see Figure 3.13) to transform infected cells, leading to contagious pulmonary carcinomas that spread through flocks of sheep.

OceanofPDF.com

Glossary

oncoprotein
: A protein specified by an oncogene that mediates its effects on cell physiology, often including neoplastic transformation.

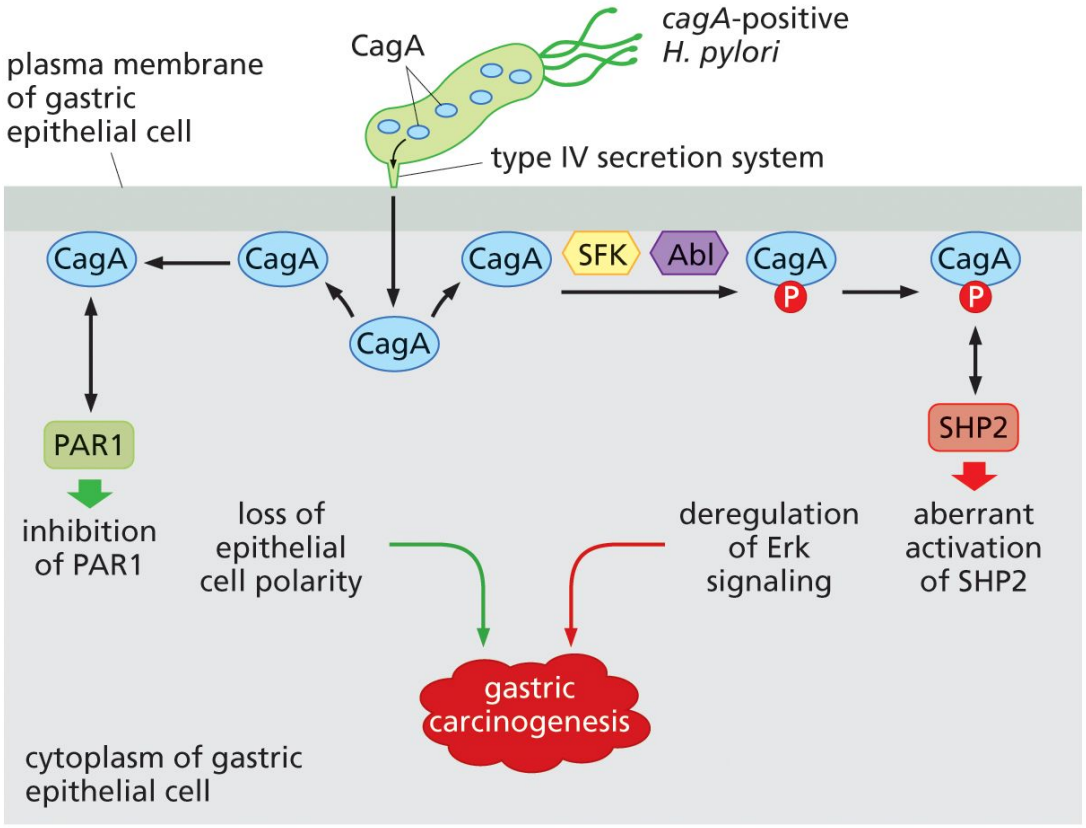
3.13 Bacterial cancers

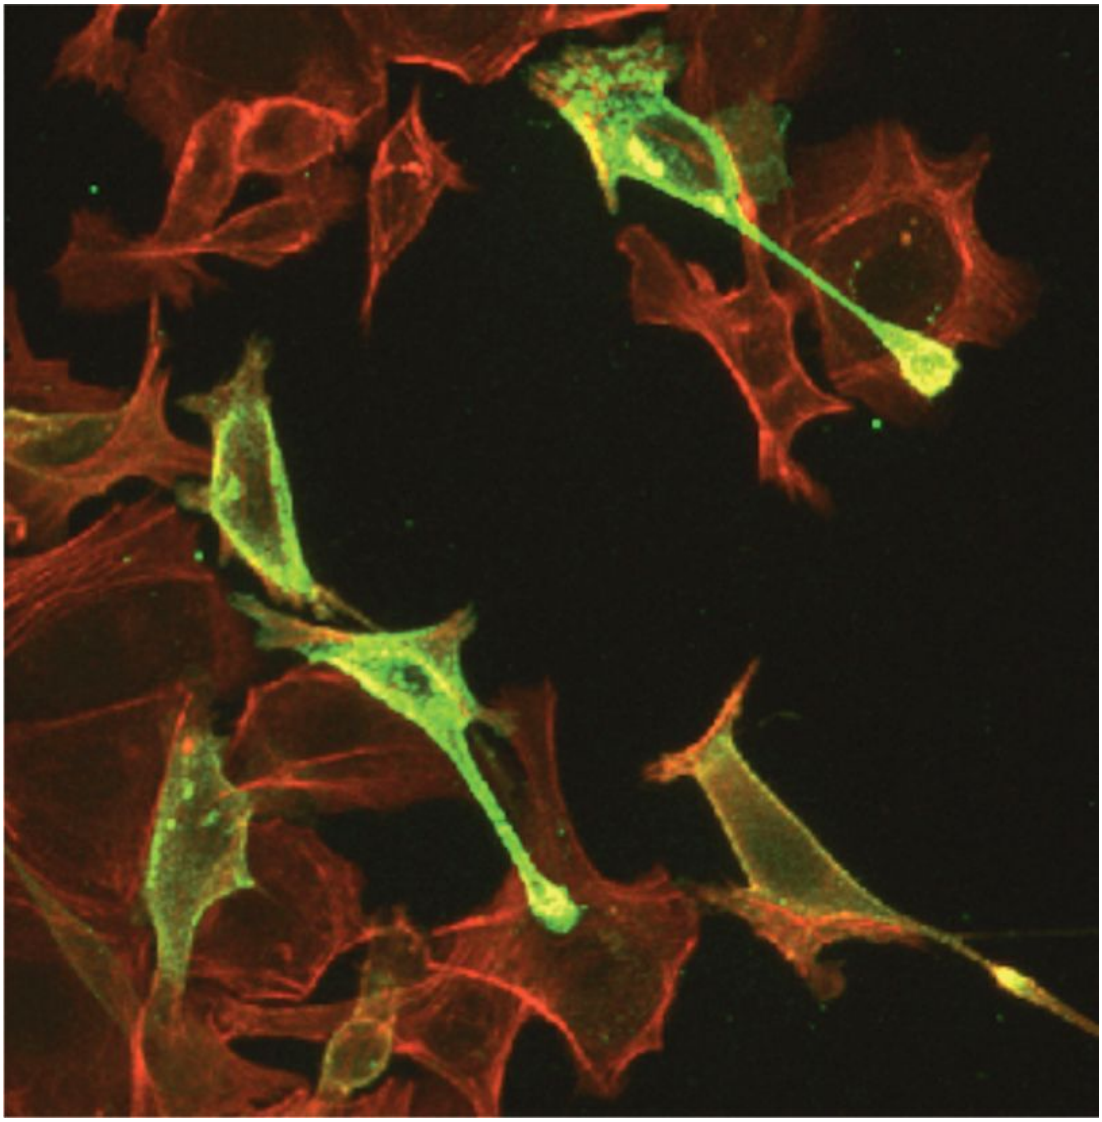
This chapter has focused on tumor viruses for two reasons: They opened the window on discovering the genes in our genomes that, in mutant form, can function to drive cancer cell proliferation. In addition, they are responsible for almost 20% of lethal cancers worldwide. [Most virus-induced cancers derive from infections by hepatitis B and C viruses (~600,000 deaths), which produce liver cancers after years of inducing chronic inflammation in this organ; as well as human papillomaviruses, whose genomes encode viral oncoproteins (~610,000 deaths.)] However, another class of infectious agents—bacteria—seem to drive the formation of a considerable proportion of a common cancer: gastric carcinomas. Worldwide, almost 1 million cases were diagnosed in 2012, three-quarters of which were likely to prove lethal. Indeed, while stomach carcinoma mortality rates are declining, these tumors still represent the third leading cause of cancer-associated death. It is estimated that at least 75% of these deaths are due to chronic infection by pathogenic strains of the common bacterium *Helicobacter pylori*. In Japan, 99% of cases of gastric carcinomas are associated with infection by some specific strains of *H. pylori*.

H. pylori actually causes gastric carcinomas through two mechanisms. Like hepatitis B and C viruses, it establishes chronic, long-term infections and associated inflammation; the latter condition serves to incubate and drive cancer formation, a topic discussed in more detail in Chapter 11. In addition, certain strains of *H. pylori* carry a 40-kb stretch of genes, termed the *Cag* pathogenicity island (PAI), which encodes ~30 protein products that enable the insertion of the CagA bacterial protein—also encoded by this PAI—into cells lining the stomach (**Figure 3.18**; **Supplementary Sidebar 3.9**). Once inside the cell cytoplasm, the introduced CagA protein participates in the deregulation of a series of cellular signals and thereby confers multiple cell-biological changes on these cells, including changes in cell shape, disruption of junctions formed between affected cells and their neighbors, invasiveness, enhanced proliferation, inhibition of apoptosis, and activation of gastric stem cells. Each of these changes in cellular phenotype will be addressed in later chapters of this book. For the moment, we note that these multiple changes in cell phenotype are, strikingly, precisely the ones that are associated with shifts occurring during the cell transformation orchestrated by well-characterized oncoproteins, such as those cited in this chapter. Hence, by these criteria, the bacterial CagA protein can be considered a bona fide pleiotropically acting oncoprotein.



A diagram shows how cag A-positive H. pylori triggers gastric carcinogenesis A cag A-positive H. pylori uses a Type 4 secretion system to inject cag A proteins through the plasma membrane of a gastric epithelial cell, into the cytoplasm. Some of these proteins cause inhibition of PAR 1, leading to loss of epithelial cell polarity. Other cag A proteins cause aberrant activation of S H P2, leading to deregulation of Erk signaling. Together, these two effects trigger gastric carcinogenesis.

(A)



A micrograph in which the cytoplasm of normal cells appears in red while a few altered cells glow bright yellow green. These cells have elongated portions that look like hummingbird beaks.

(B)

Figure 3.18 Perturbation of intracellular signaling pathways by *H. pylori*
CagA strains of *Helicobacter pylori* carry various versions of the *CagA* pathogenicity island (PAI) in their genomes; those with *CagA*-associated alleles that are especially virulent are associated with greatly increased incidence of gastric adenocarcinomas. (A) A bacterial micro-syringe functioning as a type IV secretion system (T4SS) forms a channel in the plasma membrane of host gastric epithelial cells through which it delivers the *H. pylori* CagA protein into the cytoplasm of these cells. PAR1 (partitioning-defective protein 1) is an important

regulator of the polarity of an epithelial cell. The inhibition of PAR1 leads to loss of epithelial cell polarity, whereas the activation of Erk signaling (see Section 6.5) stimulates cell proliferation. These *H. pylori*–induced changes, together with other factors, such as those of dietary origin, lead to gastritis (gastric epithelial inflammation) and, with some frequency, eventual formation of gastric adenocarcinomas. SHP2 is a phosphotyrosine phosphatase involved in regulating mitogenic signals downstream of growth factor receptors, as described in Chapter 6. (B) The biochemical changes elicited by CagA within cultured gastric carcinoma cells create the characteristic "hummingbird" morphological phenotype in these cells, in this case forced to express a virulent form of CagA (detected by immunofluorescence; *green*); F-actin cytoskeletal filaments are labeled with phalloidin (*red*). Indeed, this unique cell morphology is, on its own, a signature of the actions of the CagA protein. (A, courtesy of M. Hatakeyama. B, Republished with permission of American Society for Biochemistry & Molecular Biology, from Role of Partitioning defective 1/Microtubule Affinity-regulating Kinases in the Morphogenetic Activity of Helicobacterpylori CagA, Huaisheng Lu, Naoko Murata-Kamiya, Yasuhiro Saito, Masanori Hatakeyama, 2009 Aug 21; 284(34):23024-36. doi: 10.1074/jbc.M109.001008; permission conveyed through Copyright Clearance Center, Inc.)

Unanswered by these descriptions is the rationale of why certain *H. pylori* strains carry highly pathogenic versions of the *CagA* gene, that is, what proliferative advantage do these bacteria gain by inducing various changes in the cells lining the stomach? The answer seems to derive from the fact that CagA-activated gastric epithelium appears to offer a tissue microenvironment that is more hospitable to ongoing bacterial survival, shielding these cells from the contents of the hostile, highly acidic gastric lumen.

The incubation time of gastric adenocarcinomas is generally more than five decades, since infection generally occurs very early in life whereas tumors usually appear in individuals over the age of 50. While *H. pylori* infections are common worldwide, only those strains of the bacterium harboring the *Cag* PAI are thought to be highly effective in triggering gastric cancer. Of additional interest is the fact that CagA function, while being critical to the formation of many gastric carcinomas, is no longer required once these tumors erupt. Hence, it operates a "hit-and-run" oncoprotein, unlike Src, whose continued presence is required to maintain the transformed cell phenotype (see Section 3.3).

Finally, bacteria harboring the most virulent alleles of the *Cag* PAI are commonly present in East Asia while being relatively uncommon in the Western Hemisphere and Europe; these differences seem to explain the extraordinarily high rate of gastric cancer in certain parts of East Asia compared with the rest of the world. Importantly, the pathogenesis of most gastric cancers appears to depend on the collaborative effects

of *H. pylori* infection with certain co-factors, such as dietary components. The bacterium seems to be spread largely through vertical transmission (from parent to offspring). Of additional interest, a version of the *H. pylori*–associated CagA protein that was present in the Western Hemisphere prior to European colonization shows genetic affinity with CagA proteins of East Asia, suggesting a chain of transmission extending over the >12,000 years since the trans-Siberian migration of the ancestors of Amerindians.

3.14 Synopsis and prospects

By studying tumors in laboratory and domesticated animals, cancer biologists discovered a wide array of cancer-causing viruses during the twentieth century. Many of these viruses, having either DNA or RNA genomes, were found able to infect cultured cells and transform them into tumorigenic cells. These transforming powers pointed to the presence of powerful oncogenes in the genomes of the viruses, indeed, oncogenes that were potent enough to induce many of the phenotypes associated with cancer cells (see Table 3.2). Moreover, the ability of these viruses to create transformed cells in the culture dish shed light on the mechanisms by which such viruses could induce cancers in the tissues of infected host animals.

A major conceptual revolution came from the detailed study of RNA tumor viruses, specifically, Rous sarcoma virus (RSV). Its oncogene, termed v-*src*, was found to have originated in a normal cellular gene, c-*src*. This discovery revealed the ability of nontransforming, slowly tumorigenic retroviruses, such as ALV (avian leukosis virus), to acquire certain normal cellular genes and convert these captured genes into potently transforming oncogenes. The hybrid viruses that arose following these genetic acquisitions were now able to rapidly induce tumors in infected hosts.

Even more important were the implications of finding the c-*src* gene. Its presence in uninfected cells demonstrated that the normal cellular genome carries a proto-oncogene that can be converted into an oncogene by altering its sequences. (The details of these alterations will be described in the next several chapters.) Soon a number of retroviruses of both avian and mammalian origin were discovered to carry other oncogenes that had been acquired in similar fashion from the genomes of infected cells. While each of these proto-oncogenes was found initially in the genome of one or another vertebrate species, we now know that all of these genes are represented in the genomes of all mammals and likely all vertebrates. Consequently, the generic vertebrate genome carries dozens of such normal genes, each of which has the potential to become converted into an active oncogene.

Yet other proto-oncogenes were discovered by studying the integration sites of proviruses in the genomes of tumors that had been induced by nontransforming retroviruses, such as murine leukemia virus (MLV) and ALV. The random integration of these proviruses into chromosomal DNA occasionally yielded, through the process of insertional mutagenesis, the conversion of a proto-oncogene into an activated oncogene that could readily be isolated because of its close physical linkage in the cell genome to the provirus. On many occasions, insertional mutagenesis led to rediscovery of a proto-oncogene that was already known because of its presence in an acutely transforming retrovirus; *myc* and avian myelocytomatosis virus (AMV) exemplify this situation. On other occasions, entirely novel proto-oncogenes were discovered through study of provirus integration sites; the *int-1* gene activated by mouse mammary tumor virus (MMTV) provides a striking example of this route of discovery. This gene (the prototype of a class of genes now termed *Wnts*) is now known to encode a key component of a cellular signaling pathway frequently corrupted in human cancers. In fact, the process of insertional mutagenesis remained little more than a laboratory curiosity, of interest to only a small cadre of cancer biologists, until it was reported to lead to leukemias in several children being treated by gene therapy (**Supplementary Sidebar 3.9**).

The discoveries of proto-oncogenes and oncogenes, as profound as they were, provoked as many questions as they answered. It remained unclear how the retrovirus-encoded oncogene proteins (that is, oncoproteins) differed functionally from the closely related proteins encoded by corresponding proto-oncogenes. The biochemical mechanisms used by these oncoproteins to transform cells were also obscure.

The biochemical mechanisms used by DNA tumor viruses to transform infected cells were even more elusive, since these viruses seemed to specify oncoproteins that were very different from the proteins normally made by their host cells. Such differences suggested that these viral oncoproteins could not insinuate themselves into the cellular growth-regulating machinery in any easy, obvious way. Only in the mid-1980s, ten years after this research began, did their transforming mechanisms become apparent, as we will see in Chapters 8 and 9.

For many cancer researchers, and for the public that supported this research, there was a single overriding issue that had motivated much of this work in the first place: did any of these viruses and the proto-oncogenes that they activated play key roles in causing human cancers? In fact, about one-fifth of the human cancer burden worldwide is associated with infectious agents. Hepatitis B and C viruses (HBV, HCV), Epstein–Barr virus (EBV), human papillomaviruses (HPVs), and *H. pylori* play key roles in triggering commonly occurring cancers. Indeed, even infrequently occurring human tumors that seem to be familial have been traced in recent years to viral infections (see **Supplementary Sidebar 3.5**). So, this recognized role of viruses in cancer pathogenesis is substantial and growing. Still, these various infectious agents—now understood to cause many cancers throughout the world—do not include the retroviruses and the DNA tumor viruses, such as SV40, that were intensively studied in the 1970s. Hence, from the perspective of improving public health, was the research described in this chapter truly justified?

The response to this question is a resounding yes. Even if the tumor viruses described were not responsible for inciting a single case of human cancer, the contributions of this research to understanding the mechanisms of human cancer development were clear: this research opened the curtain on the genes in our genome that play central roles in all types of human cancer. It accelerated by decades our understanding of cancer pathogenesis at the level of genes and molecules. It catapulted cancer research from a descriptive science into one where complex phenomena could finally be understood and explained in precise, mechanistic terms.

OceanofPDF.com

Key concepts

- Decades after Peyton Rous's 1910 discovery that a virus could induce tumors in chickens, the transformation of cultured cells into tumor cells upon infection with Rous sarcoma virus (RSV) resurrected tumor virus research and led to the realization that cancer could be studied at the level of the cell.
- Transformed cells in culture have numerous unusual characteristics, including altered morphology, lack of contact inhibition, anchorage independence, proliferation in the absence of growth factors, immortalization, and tumorigenicity, the latter being the acid test for full cellular transformation.
- The transformation phenotype induced by RSV infection was found to be transmitted to progeny cells and to depend on the continued activity of an RSV gene product.
- In addition to RNA viruses like RSV, several classes of DNA viruses—including the papillomavirus, polyomavirus, human adenovirus, herpesvirus, and poxvirus—were found to induce cancers in laboratory animals or humans.
- While the genomes of RNA tumor viruses consist of single-stranded RNA, the genomes of DNA tumor viruses consist of double-stranded DNA (dsDNA).
- Since replication of viral DNA genomes normally occurs independently of the host cells' DNA and since viral genomes lack the DNA segments (centromeres) to properly segregate during mitosis, the transmission of DNA tumor virus genomes from one cell generation to the next posed a conceptual problem, until it was discovered that DNA tumor virus genomes integrate into host-cell chromosomal DNA.
- Since the genomes of RNA tumor viruses consist of single-stranded RNA that cannot be incorporated into host DNA, and since re-infection does not explain the persistence of the transformed state in descendant cells, Howard Temin postulated that RNA viruses make double-stranded DNA copies of their genomes—the process of reverse transcription—and that these DNA copies are integrated into the host's chromosomal DNA as a part of the normal viral replication cycle. This

represents a major distinction from most DNA tumor viruses, for which integration of their genomes into chromosomal DNA is a very rare, haphazard event and not an integral part of viral replication.

- Because their replication cycle depends on information flowing backward (that is, from RNA to DNA), RNA viruses came to be called retroviruses and the DNA version of their viral genomes was called a provirus.
- Working with RSV, researchers found that viral replication and cell transformation were specified by separate genes, with the transforming function residing in a single gene called *src*.
- Use of a DNA probe that specifically recognized the transformation-associated (that is, *src*) sequences of the RSV genome led to the unexpected discovery that *src*-related sequences were present in the DNA of uninfected chicken cells. Further research indicated that the *src* gene was a normal, highly conserved gene of all vertebrate species (as later proved true of many other such genes).
- The difference between the actions of the cellular version of *src* (c-*src*), which supports normal cell function, and the viral version (v-*src*), which acts as an oncogene, could be explained if v-*src* were an altered version of a c-*src* that had originally been kidnapped from a cellular genome by an ancestor of RSV and thereafter reshaped into an active oncogene.
- Because it can serve as a precursor to an oncogene, c-*src* was called a proto-oncogene, a term implying that normal vertebrate cells contain genes that have the intrinsic potential to become converted into oncogenes that can induce cancer.
- The actions of v-*src* indicated that a single oncogene could act pleiotropically to evoke a multiplicity of changes in cellular traits. In addition, the discovery of c-*src* in the normal cellular genome suggested the possibility that other mutational mechanisms, notably those not involving viruses, might activate proto-oncogenes that continued to reside in their normal sites in cellular chromosomes.
- In contrast to RSV, nontransforming, slowly tumorigenic retroviruses lack their own oncogenes and occasionally cause tumors by integrating their genomes adjacent to proto-oncogenes in the chromosomal DNA of infected host cells, a process called insertional mutagenesis. This chance occurrence places the proto-oncogene under the control of the

viral transcriptional promoter, which deregulates the gene's expression and leads to uncontrolled cell proliferation. Insertional mutagenesis can also be exploited to find new proto-oncogenes.

- The formation of most oncogene-bearing, rapidly transforming retroviruses involves the replacement of viral replicative genes by acquired cellular oncogenic sequences. This results in the formation of a potently transforming virus that cannot proliferate on its own due to the loss of viral genes that are essential for replication.
- In addition to the nontransforming retroviruses (which work via insertional mutagenesis) and the acutely transforming ones (which work via acquired oncogenes), retroviruses exist whose carcinogenic powers are traceable to their own viral gene products. Needed for viral replication, these viral proteins have the side effect of also activating the expression of cellular genes involved in cell growth and proliferation.
- Stomach cancer, which is responsible for almost a million deaths internationally each year, is often provoked by strains of *H. pylori* that inhabit the gastric mucosa and inject the CagA bacterial protein into the cytoplasm of gastric epithelial cells, evoking a series of transformation-related phenotypes in these cells that set the stage for the formation of full-blown stomach cancers.

OceanofPDF.com

Thought questions

1. What observations favor or argue against the notion that cancer is an infectious disease?
2. How can one prove that tumor virus genomes must be present in order to maintain the transformed state of a virus-induced tumor? What genetic mechanisms, do you imagine, might enable this process to become “hit-and-run,” in which the continued presence of a tumor virus is not required to maintain the tumorigenic phenotype after a certain time?
3. Why are oncogene-bearing viruses like Rous sarcoma virus so rarely encountered in wild populations of chickens?
4. What evidence suggests that the phenotypes of cells transformed by tumor viruses *in vitro* reflect comparable phenotypes of tumor cells *in vivo*?
5. What logic suggests that the chromosomal integration of tumor virus genomes is an intrinsic, obligatory part of the replication cycle of RNA tumor viruses but an inadvertent side product of DNA tumor virus replication?
6. What evidence suggests that a proto-oncogene like c-*src* is actually a normal cellular gene rather than a gene that has been inserted into the germ line by an infecting retrovirus?
7. How do you imagine that DNA tumor viruses and retroviruses like avian leukosis virus arose in the distant evolutionary past?
8. Why do retroviruses like avian leukosis virus take so long to induce cancer?

Supplementary Sidebars

Supplementary Sidebar 3.1 Peyton Rous and the discovery of Rous sarcoma virus

[Francis] Peyton Rous began his study of tumor viruses in the years 1909–1910 (**Figure S3.1**). His work followed a report by two Danish virologists—Vilhelm Ellermann and Oluf Bang—demonstrating that a transmissible agent caused a chicken erythroblastosis (a leukemia of the red cell lineage). Direct evidence of the existence of infectious agents that could trigger tumor formation was lacking until the research of

(A)

(B)

Figure S3.1 Peyton Rous and a hen that helped to launch modern cancer research (A) Francis Peyton Rous (shown as a young researcher, *left*) began his work in 1909 that led to the discovery of Rous sarcoma virus (RSV). In 1966, more than 50 years later, Rous (seen in a photo of that time, *right*) received the Nobel Prize in Physiology or Medicine for this seminal work—a tribute to both his persistence in science and his longevity. (B) His good fortune began when a Long Island, N.Y., chicken farmer brought Rous, then working at the Rockefeller Institute in New York, a prized barred Plymouth Rock hen. The farmer wanted Rous to treat the large tumor growing in its chest muscle; Rous, the famed chicken doctor, saw an experimental opportunity instead and dispatched the hen, extracting the tumor. The arthritic hands carrying a sarcoma-bearing chicken may or may not be those of the chicken farmer. (A, courtesy of the Rockefeller Archives Center. B, from P. Rous, *J. Exp. Med.* 12:696–705, 1910.)

Ellermann, Bang, and Rous. Unlike Ellermann and Bang, Rous continued to follow up the characterization of the virus that he had isolated, which came to be called Rous sarcoma virus (RSV). While a number of other diseases had been associated over the previous decade with infectious agents—both bacteria and viruses—the development of tumors had no obvious connection with such agents until their work, which represented a milestone in twentieth century cancer research.

Supplementary Sidebar 3.2 Tissue Culture

Over the past half century a variety of procedures have been developed that enable the propagation of cells *ex vivo* (outside of living tissues) and thus *in vitro* (in culture vessels). Sometimes this procedure begins by dissociating living cells from a tissue using proteases to break down the extracellular matrix, yielding single-cell suspensions that can be introduced into culture vessels, almost always Petri dishes that contain a liquid medium that enables the survival and proliferation of the introduced cells. Subsequently, cells are passaged from an initially seeded Petri dish to another, being released from their anchorage to the bottom of the first Petri dish by the use of trypsin protease and then, as single-cell suspensions, introduced into fresh medium that is placed, in turn, into the second Petri dish.

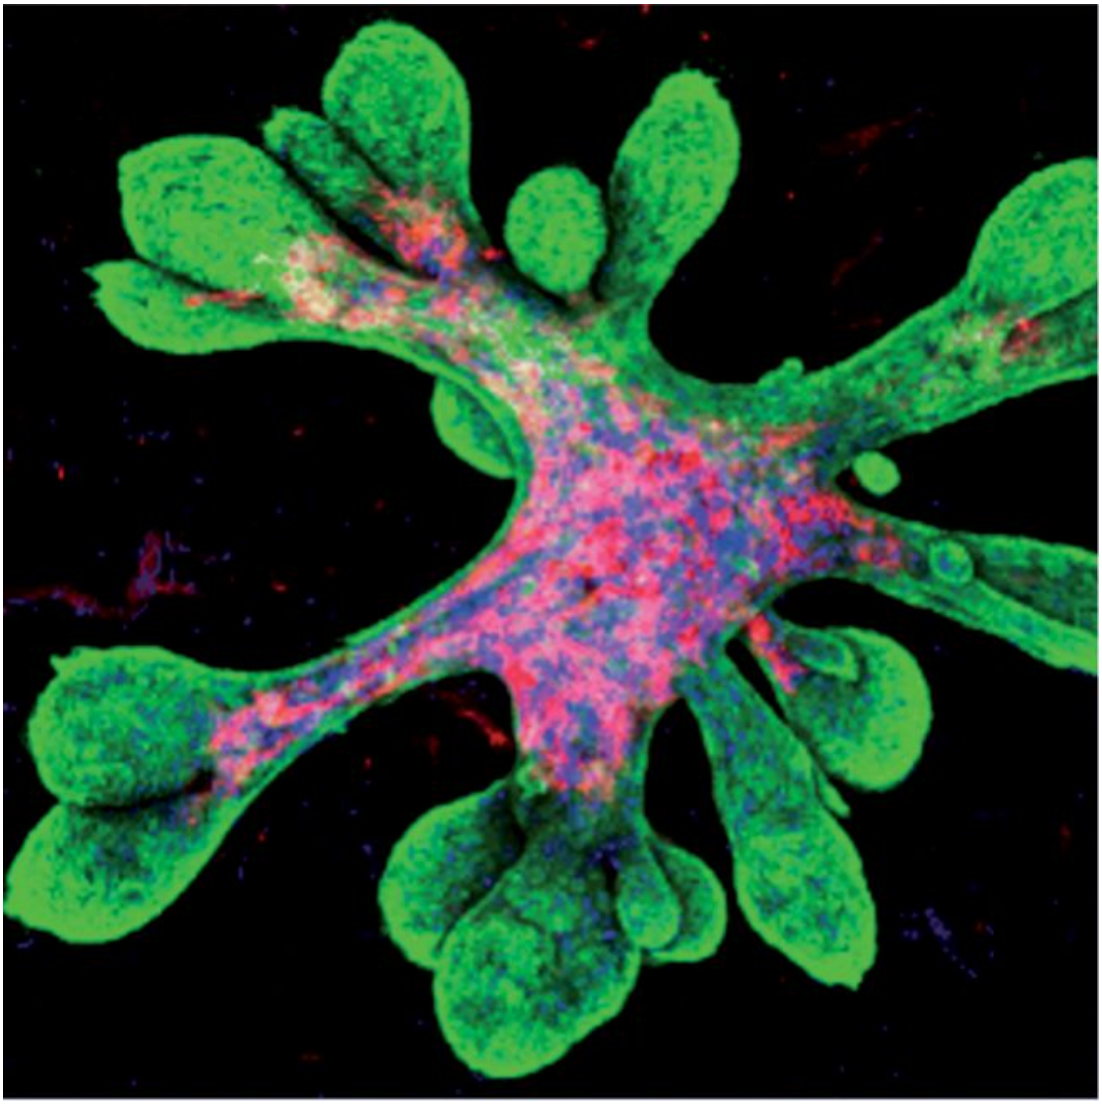
The medium itself is usually composed of nutrients such as glucose, essential amino acids, and vitamins that the cells cannot make for themselves plus various salts. In addition to these ingredients, the medium invariably contains admixed serum, usually of bovine origin, that provides various growth factors that stimulate the cells to survive and proliferate. Without the admixed serum, cells may survive for an extended period of time in the culture vessel but will rarely if ever proliferate (see Section 5.1). This general procedure for propagating cells *in vitro* was first devised in the mid-1950s and slight variants of it have remained as standard operating procedure since that time. Changes have been made in the composition of certain ingredients, specifically, chemically defined compounds. Most cells that are propagated *in vitro* will secrete extracellular matrix (ECM) components that adhere to the bottom surface of the Petri dish. Thereafter, the cells will attach to the resulting ECM via a series of cell-surface integrins that they employ to directly tether themselves to the various glycoprotein components of the ECM (see Section 5.9). Accordingly, the protease—usually trypsin—employed to liberate the cells from attachment to the dish works by degrading both ECM components and integrins.

By necessity, these *in vivo* culture conditions deviate significantly from those that cells experience in living tissues. Cells usually experience relatively low oxygen tensions within living tissues, often as low as 2 to 3%, whereas tissue culture is usually practiced in incubators that use ambient air where oxygen tensions are ~21%. In addition, cells within incubators are routinely exposed to a mixture of ambient air (~95%) and carbon dioxide (~5%), in order to maintain the proper pH of the culture medium. Incubators are maintained at ~37°C in order to approximate the temperature inside the human body.

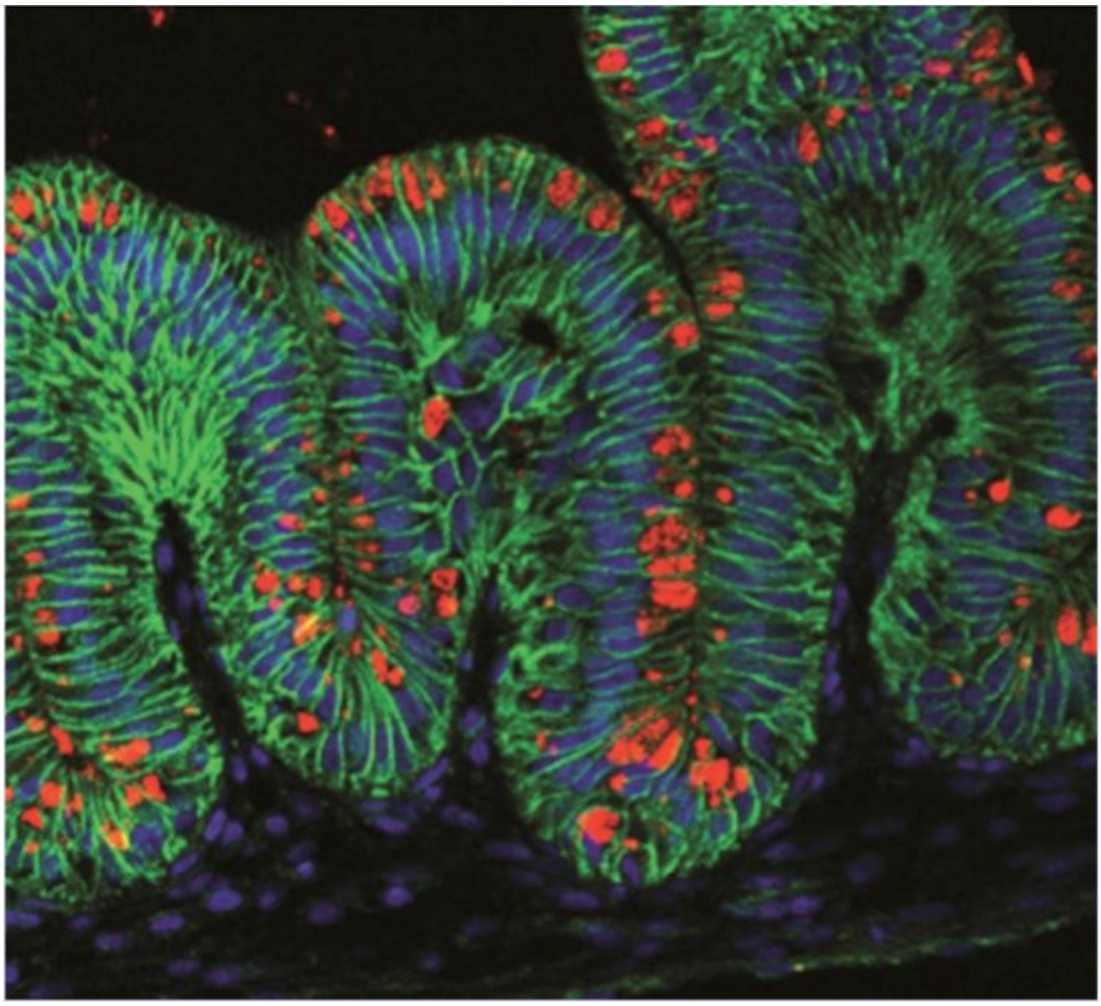
These various conditions nevertheless fail to closely replicate conditions that cells experience within living tissues. This explains why many cell types explanted from living tissue do not thrive *ex vivo* and soon senesce or die. Others can be propagated for an extended period *in vitro* before they eventually develop variants that are well

adapted to multiplying in tissue culture and begin to proliferate robustly; these adapted cells may deviate in significant ways from their progenitors that were initially prepared from living tissues. Traditional culture conditions using admixed serum in the medium favor the outgrowth of mesenchymal cells, such as fibroblasts and cancer cells, both of which often require minimal adaptation to these culture conditions. Generally, epithelial cells, including both normal and neoplastic cells, are more difficult to propagate under these conditions, which has resulted in the formulation of *serum-free* media that permit many explanted cells to proliferate with minimal adaptation. Nonetheless, many cell populations, even after being ostensibly adapted to proliferate in culture, will eventually halt proliferation, exhibiting the phenomenon of cell senescence that is described in detail in Chapter 10. (It remains unclear whether the senescence exhibited by many cell types in culture, which involves a halting of proliferation but extended continued survival in a viable state, represents an intrinsic limitation of the cells or the consequences of sub-optimal conditions of culture.) Cancer cells usually do not enter senescence *in vitro* and are thus considered to be immortalized (see Chapter 10).

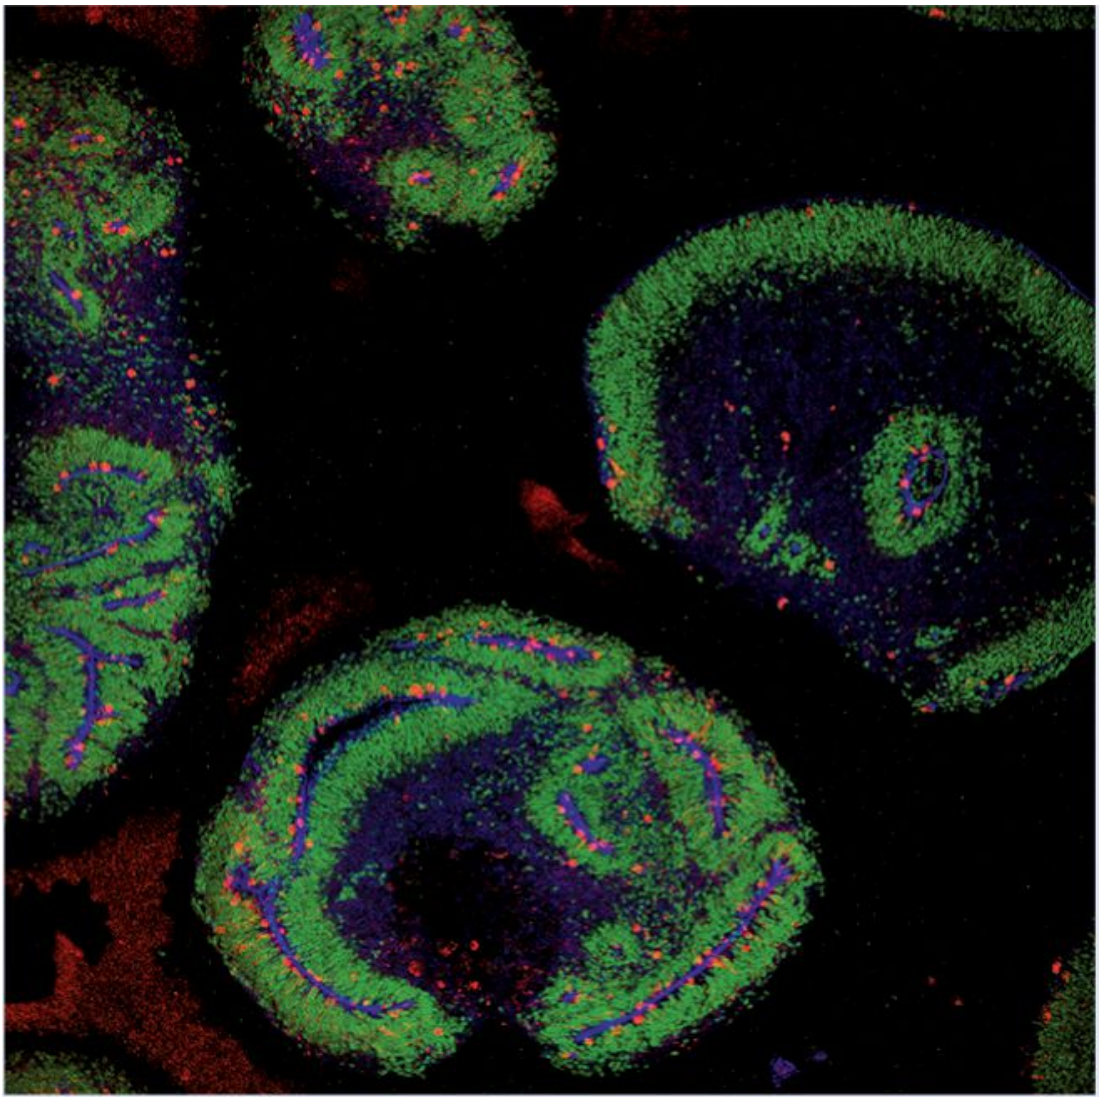
A final variable of propagation *ex vivo* involves the dimensionality of cells in culture. Thus, propagation in Petri dishes involves cell growth and proliferation in two dimensions (2D), that is, across the bottom surface of the dish, whereas growth of cells *in vivo* involves growth in a three-dimensional environment (3D). This realization has prompted the development of a diverse array of procedures for propagating cells in 3D in a variety of gels and matrices, either entirely artificial (for example, agarose) or derived from a natural ECM (for example, Matrigel). In both cases, cells are presumed to condition their surroundings by secreting ECM molecules to which they can attach, in addition to those that may have already been provided by the gel matrix (in the case of Matrigel). Such cells can in turn generate multicellular structures that more closely approximate those generated during normal tissue morphogenesis, indeed generating structures, termed organoids, that approximate in morphology and function the corresponding structures within living tissues (**Figure S3.2**).



(A)



(B)



(C)

Figure S3.2 Organoids The practice of propagating cells in two-dimensional (2D) culture—usually on the bottom surfaces of Petri dishes—by necessity dictates a topological state that deviates from the three-dimensional environment that cells experience within living tissues. In recent years, a series of procedures have been developed to allow cells and fragments of tissues to be propagated in a three-dimensional (3D) matrix that is supplemented by a variety of growth factors, nutrients, and extracellular matrix constituents and permit implanted cells to form mini-organs that closely resemble in their histopathology the corresponding normal tissues they are intended to model. (A) When placed into organoid culture, mammary epithelial cells self-organize into the bilayered lobular structures seen in the mammary gland, including luminal cells stained with antibodies against cytokeratins 8 and 18 (*green*) and basal/myoepithelial cells stained with antibody

against cytokeratin 14 (*pink*; nuclei/DNA, *blue*). Supplementary Sidebar 3.3 Howard Temin and the retrovirus theory

Temin received his Ph.D. training at the California Institute of Technology in Pasadena, under the aegis of Prof. Renato Dulbecco and post-doctoral fellow Harry Rubin. He continued his research on Rous sarcoma virus at the University of Wisconsin at Madison (**Figure S3.3**). As early as 1963, Temin reported that the synthesis of the virion RNA of RSV could be blocked by the drug actinomycin D, known at the time to inhibit DNA-dependent RNA synthesis. His findings caused him to propose that the transmission of an RSV genome from one cell generation to the next depended on the formation of a DNA provirus that was integrated into the host-cell chromosomal DNA and transcribed thereafter into viral RNA; his thinking was inspired in no small part by the discovery of one form of a bacteriophage genome that became integrated into the chromosomal DNA of a latently infected bacterial cell. Because this mechanism ran counter to the then-widely accepted canonical model of information transfer in cells, that is, DNA → RNA → proteins, he was ridiculed for years and his research was ignored by most virologists until the simultaneous, independent discoveries of the reverse transcriptase enzyme by his research group and that of David Baltimore, then at MIT, in 1970 (Baltimore had also studied with Dulbecco). While this enzyme, on its own, represented only one component needed to validate the overall scheme that he had initially proposed, the scheme as a whole was immediately accepted by many as firmly established. Indeed, because reverse transcriptase activity was thought to be absent in normal mammalian cells, this discovery led to the search by others for such enzymatic activity in various human tumors as a means of associating their formation with retrovirus infections.

Figure S3.3 Howard Temin. Temin, pictured here in 1964, began his work by demonstrating the ability of Rous sarcoma virus to transform cells *in vitro* and later showed the persistence of the virus in the infected, transformed cells. He postulated the existence of a DNA provirus and subsequently shared the 1975 Nobel Prize in Physiology or Medicine with David Baltimore for their

simultaneous discoveries of the enzyme reverse transcriptase. (Courtesy of *The Capital Times*.)

Temin passed away at the relatively early age of 59 in 1994 and did not live to see the full ramifications of his 1970 discovery that continued to play out into the 21st century. His post-doctoral mentor, Harry Rubin, born eight years earlier, moved to the University of California, where he continued research on the cell biology of neoplastic transformation; he died in 2020 at the age of 93, more than a quarter century after his former colleague Temin. Temin, Baltimore, and Dulbecco shared the Nobel Prize for their research on RSV in 1975. In fact, their paths had crossed on multiple occasions earlier in their lives. As high school students, the two attended together a summer school held in 1952 at the Jackson Laboratory in Bar Harbor, Maine, and as undergraduates, they both attended, at different times, Swarthmore College in Pennsylvania; while there, Baltimore's roommate was Peter Temin, Howard Temin's younger brother.

Supplementary Sidebar 3.4 Is SV40 responsible for the mesothelioma plague?

The mesothelium is the membranous outer lining of many internal organs and derives directly from the embryonic mesoderm. Mesotheliomas—tumors of various mesothelial surfaces, notably the pleural membranes of the chest—were virtually unknown in the United States in the first half of the twentieth century. Beginning in about 1960, however, their incidence began to climb steeply. By the end of the century, the annual incidence in the United States approached 2500, and over the following decade, the annual incidence increased to 3200 cases. The tumors were attributed mostly to asbestos exposure, specifically to a subtype termed crocidolite. The disease is seen frequently among those who have worked with asbestos, which was used as a heat-resistant insulating material until being banned in the United States in the 1980s. However, 20% of mesothelioma patients have no documented exposure to asbestos, a fact that has provoked a search for other etiologic (causative) agents.

SV40 was suggested as a plausible etiologic agent of mesothelioma. By 2003, forty-one laboratories across the world had reported SV40 DNA, RNA, or protein in mesothelioma cells. Traces of the virus are otherwise rarely found in human tumors, with the exception of certain types of brain tumors. Cultured human mesothelial cells are readily infected by SV40, and this infection leads rapidly to their immortalization , that is, to the ability of these cells, which usually have limited proliferative potential in culture, to multiply indefinitely.

The presence of SV40 contamination in certain initially used poliovirus vaccine stocks has raised concerns that mesothelioma may have been induced in many individuals as

an unintended side effect of poliovirus vaccination. However, there are many individuals with mesotheliomas who are highly unlikely to have been exposed to these vaccines. Moreover, the viral T-antigen protein, whose presence is invariably observed in SV40-transformed cells (see Section 3.6), is rarely detected in mesothelioma tumor cells. Also, attempts at demonstrating viral DNA have usually yielded DNA segments that are indicative of laboratory artifacts, for example, contamination of mesothelioma tumor samples by laboratory stocks of SV40 or by recombinant DNA plasmids engineered to include segments of the viral genome. The discoveries of such contaminations provide increasing ammunition for those who are skeptical of SV40's role in mesothelioma pathogenesis.

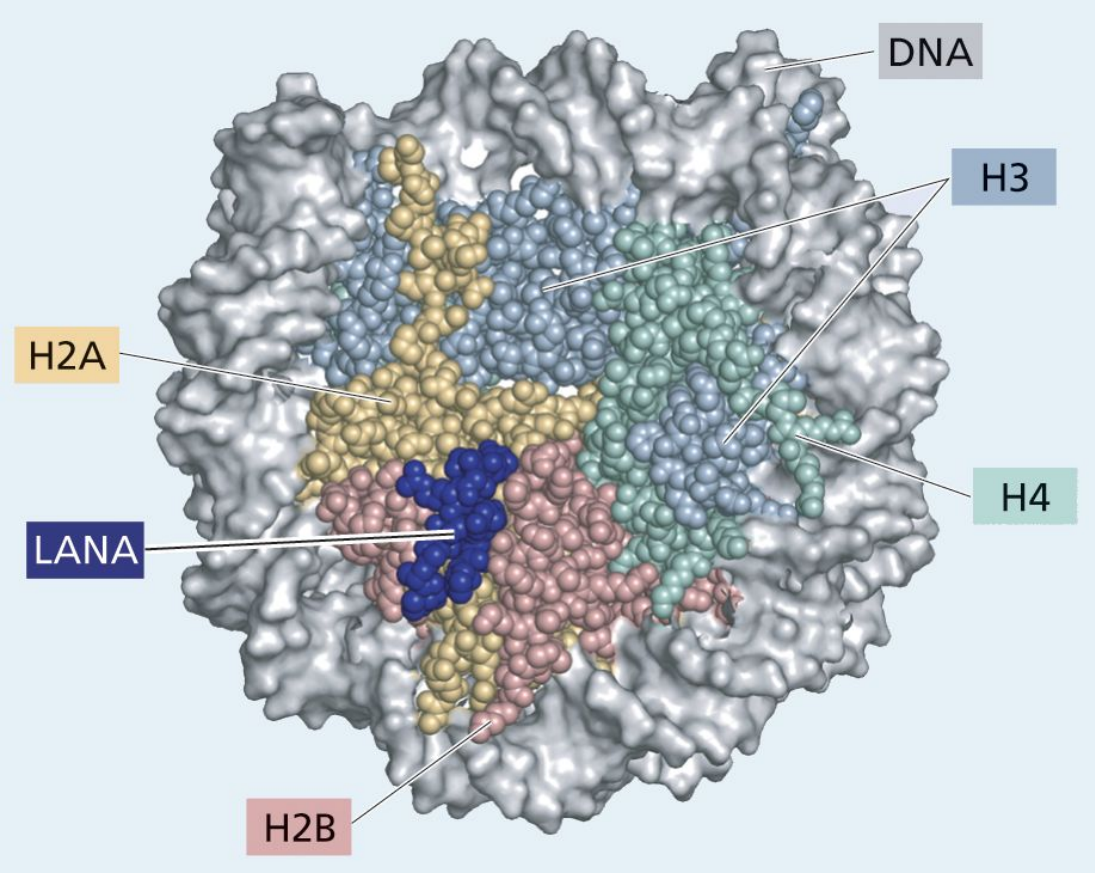
As many as 85% of humans are known to be infected with two viruses that are closely related to SV40—JC and BK—and antisera that recognize the capsids of these viruses cross-react with the capsid of SV40, explaining many of the claims that SV40 is often present in human tissues. In immunosuppressed individuals, notably AIDS patients, JC virus can cause a fatal brain degeneration—progressive multifocal leukoencephalopathy (PML). And in patients who are immunosuppressed because they are organ transplant recipients, BK virus has been implicated in the causation of certain carcinomas (see, for example, Figure 3.10B).

Supplementary Sidebar 3.5 Maintenance of KSHV and HPV genomes in episomal and chromosomal form

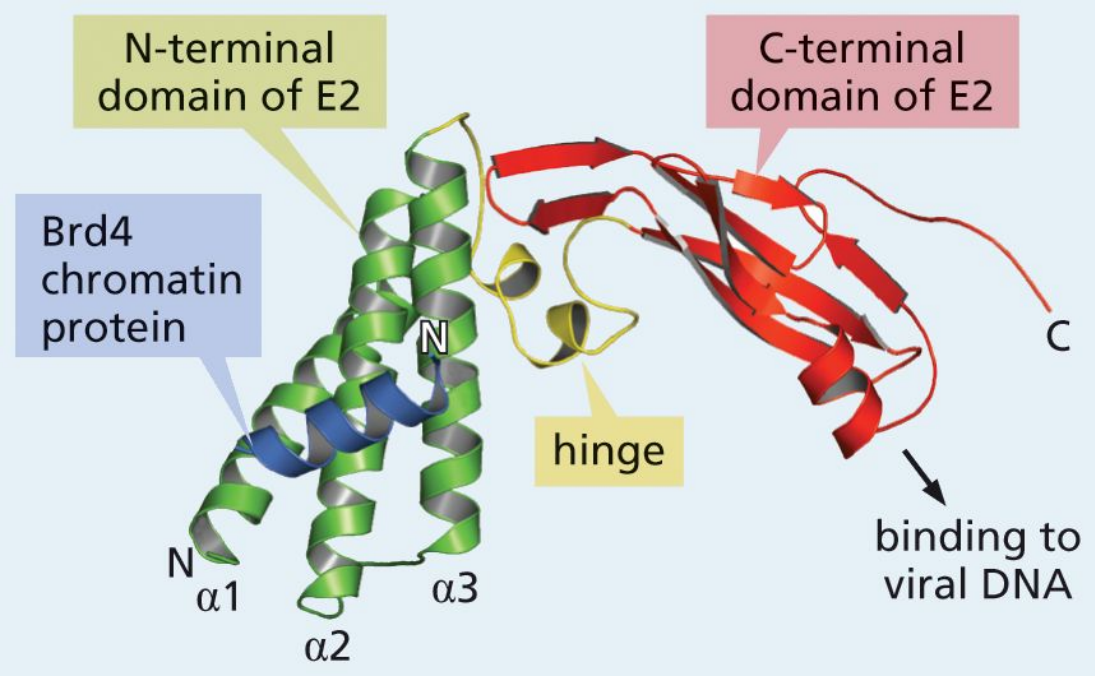
Kaposi's sarcoma (KS) was recognized as a distinct disease entity in 1872. Over the following century it was found to occur on rare occasion, mostly in men of Mediterranean or Near Eastern ancestry. On the basis of this association, the disease was presumed to represent a hereditary condition transmitted through the human germ line by unknown alleles. However, this otherwise-rare tumor became commonplace with the eruption of the AIDS epidemic in the early 1980s, which made it clear that KS is caused by an infectious agent that is normally kept under control by a functional immune system. Finally, in 1996, the responsible agent was identified as a new virus of the herpesvirus class and named human herpesvirus-8 (HHV-8) or Kaposi's sarcoma herpesvirus (KSHV). Its discovery provoked interest in how the viral genome is maintained in infected cell populations over multiple cell generations.

In fact, herpesvirus genomes, like those of papillomaviruses, are able to persist for years in a virus-infected tissue in an episomal form, that is, as molecules that are not integrated covalently into the host-cell chromosomal DNA. In the case of KSHV/HHV-8, this is achieved through the actions of its LANA protein (**Figure S3.4A**), which binds to terminally repeated sequences in the viral genome and, at the same time, to the histone molecules forming the core nucleosome (see Figure 1.16).

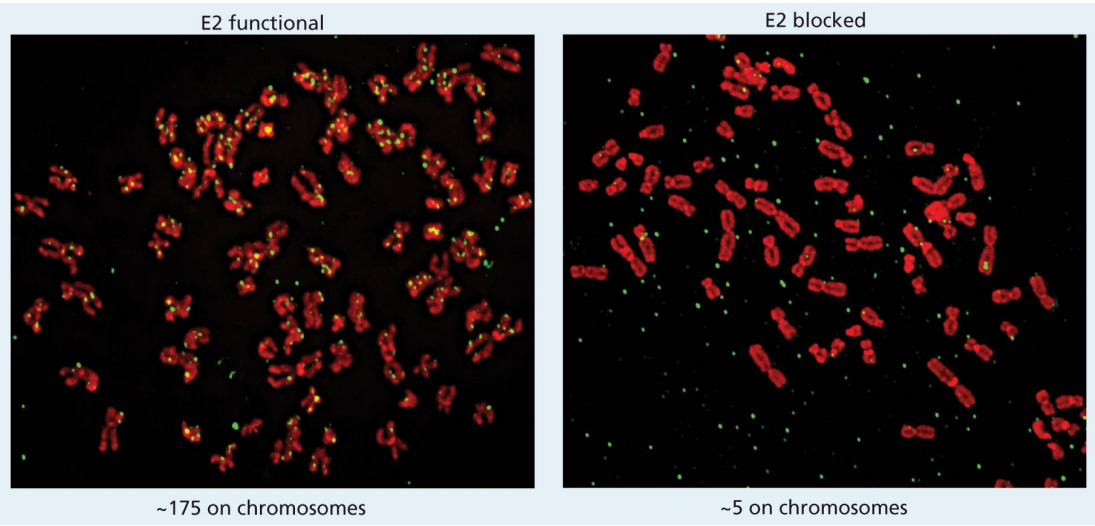
This enables maintenance of the viral genome even though direct covalent linkage between viral and host DNAs is absent.



(A)



(B)



(C)

Figure S3.4 Tethering of episomal viral genomes to host-cell chromatin
Certain DNA viruses maintain chronic infections through their ability to maintain their genomes stably but in an unintegrated (episomal) configuration over many successive cell generations. They do so by synthesizing viral proteins that are able to physically link the viral nucleoprotein to the chromatin of the infected host cell when that cell passes through mitosis, ensuring transmission of the viral episomal genomes to both daughter cells. (A) In the case of KSHV/HHV-8, the agent of

Kaposi's sarcoma, the virus makes a protein termed LANA (latency-associated nuclear antigen; *blue*) that is able, on the one hand, to associate with a nucleosome at the interface between its H2A and H2B histones (see Figure 1.16) and, on the other, to bind terminal repeat sequences in the viral DNA genome. (B) Human papillomavirus type 16 (HPV-16) uses the N-terminal domain of its E2 protein (*light green*) to tether the episomal viral DNA genome to the Brd4 chromatin-remodeling protein (*blue*), which is bound, in turn, to cellular chromatin during mitosis, enabling the viral genome (tethered to the C-terminal domain of E2) to "hitchhike" with the cellular chromosomes during mitosis. (C) The association of HPV-16 genomes with metaphase chromosomes can be gauged using HPV-16–specific DNA probes in FISH (fluorescence *in situ* hybridization) analyses. The chromosomes are stained here in *red*, while the viral genomes are detected as *yellow* dots if they are located above the metaphase chromosomes and as *green* dots if they are not located above the chromosomes. In the left panel, the E2 protein is functioning normally in chromosomal tethering, whereas in the right panel, its ability to bind to the Brd4 chromatin-associated protein has been blocked. As indicated, enumeration of the viral genomes above chromosomes reveals a drastic decrease in the metaphase chromosome-associated viral genomes when E2 tethering function is blocked. (A, from A.J. Barbera et al., *Science* 311:856–861, 2006. With permission from AAAS. B and C, from E.A. Abbate, C. Voitenleitner and M.R. Botchan, *Mol. Cell* 24:877–889, 2006. With permission from Elsevier.)

A similar dynamic operates in human papillomavirus (HPV)–infected tissues. Following initial infection, HPV-infected cells and viral genomes in general are cleared from the infected tissue within a period of weeks or months by the immune system. However, in a minority of infected individuals, the HPVs persist, establishing chronic infections in epithelial tissues and maintaining their genomes, once again, in an episomal state, apparently for years, if not decades. These viral infections sometimes trigger low- and then high-grade squamous intraepithelial lesions (LSILs, HSILs) of the cervix; the number of episomal HPV genomes per cell generally increases during this progression and, depending on the subtype of HPV virus, may reach more than several hundred copies per infected cell.

On rare occasion, these chronic infections may trigger the onset of frank malignancies —cervical carcinomas; squamous cell carcinomas triggered by HPV can also arise in the oropharynx. In the genomes of the cervical carcinoma cells, oncogenic fragments of the HPV genomes are invariably found in an integrated state, while the episomal HPV genomes are generally no longer detectable. This integration is achieved by mechanisms similar to those used by SV40 to establish its genome in cells that it has transformed (see Figure 3.11) and involves nonhomologous or illegitimate recombination between viral genomes and host-cell chromosomal sequences. Such

chromosomal integration, as was the case with SV40, ensures the perpetuation of the HPV genome fragments in descendant cells. In fact, the HPV genomes seem to be integrated preferentially in chromosomal "common fragile sites"—chromosomal regions (numbering more than 100) that are scattered throughout normal genomes and exhibit relatively high genetic instability, including susceptibility to dsDNA breakage.

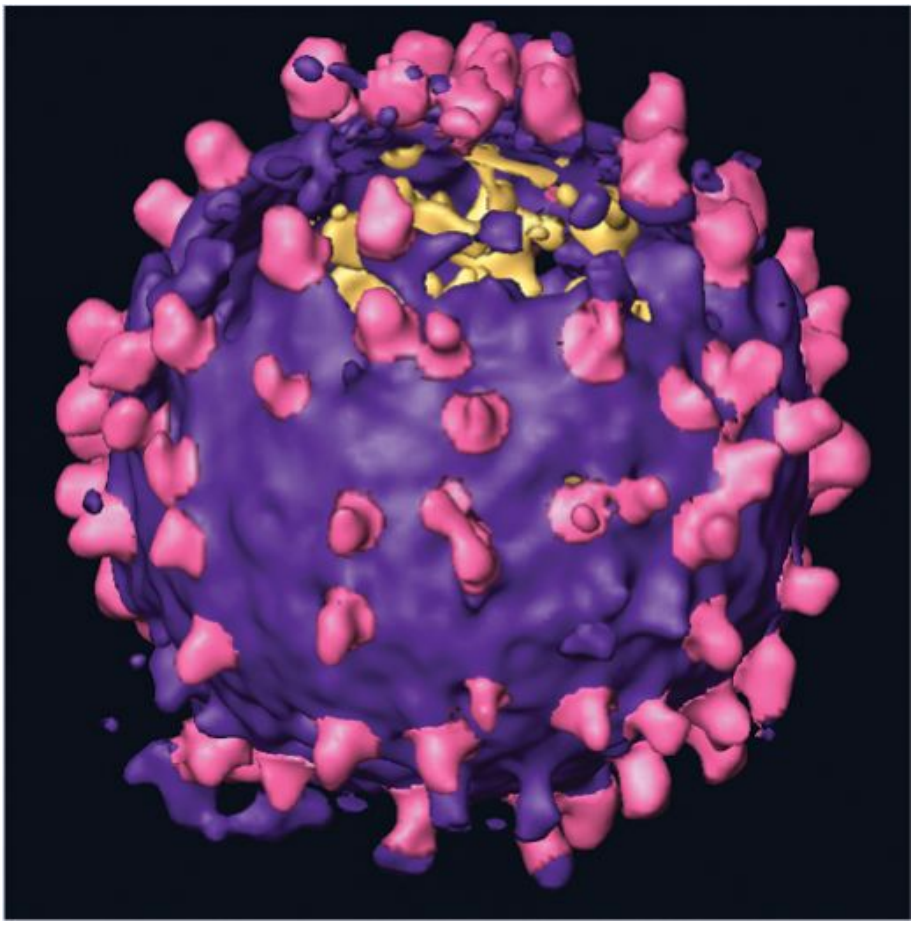
The integration of HPV genomes has a second functional consequence: the molecular steps that lead to integration usually result in the deletion or inactivation of certain viral genes that are needed for replication of episomal viral DNA, and of other viral genes whose products operate to repress expression of the mRNAs encoding the virus-encoded oncoproteins (the latter described in Chapters 7 and 8). Once freed of this transcriptional repression, the viral mRNAs and, as a consequence, viral oncoproteins are expressed by the integrated viral genomes at far higher levels, thereby driving the progression of pre-neoplastic virus-infected cells into carcinoma cells.

The transcriptional repression of HPV mRNAs that serve as templates for viral oncoprotein expression is the task of the viral E2 protein, which has a second, ostensibly related function: it acts to link the unintegrated viral genome to a cellular protein that is bound to chromatin during mitosis (as an example, see Figure S3.4B). This ensures the tethering of the viral genome to chromosomes during mitosis (Figure S3.4C). When this tethering is blocked experimentally, the viral genomes are unable to "hitchhike" with the host-cell chromosomes during mitosis and consequently are largely left in the cytoplasmic compartment of the mitotic cells, which leads to their rapid loss following multiple successive cellular growth-and-division cycles.

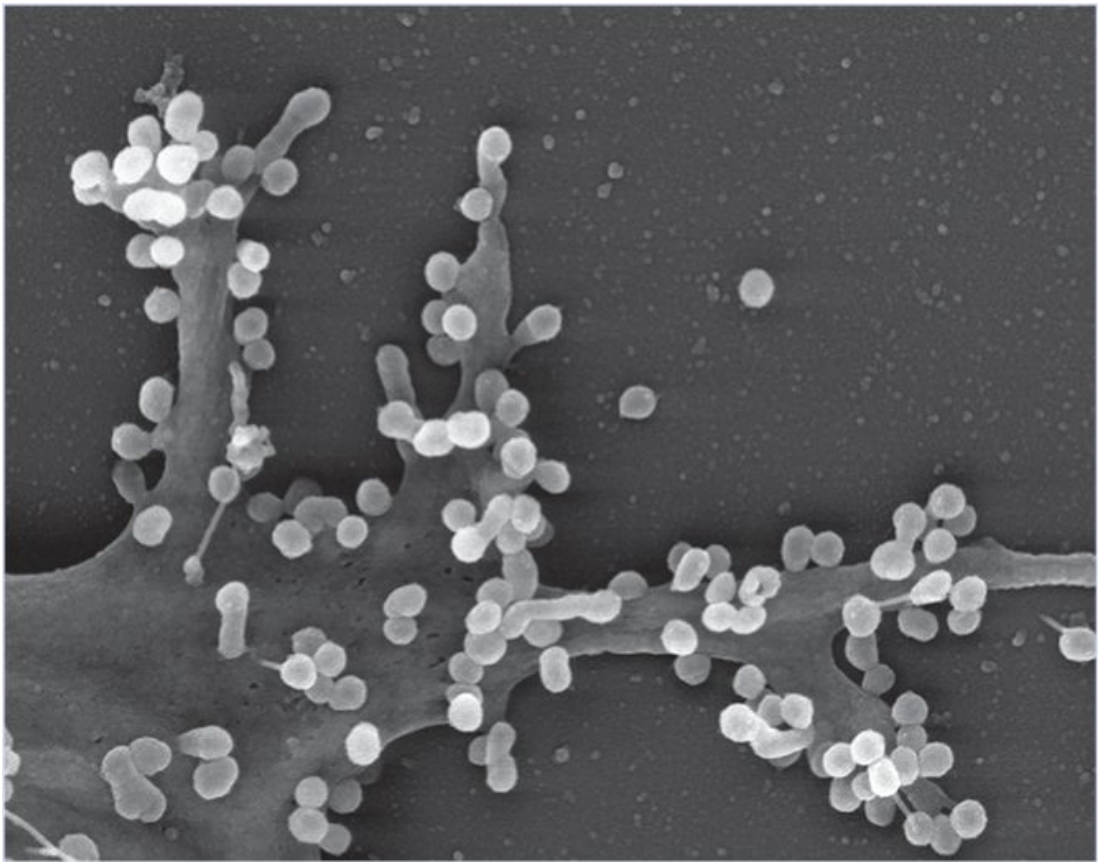
Supplementary Sidebar 3.6 Retroviruses and HIV

The discovery of the reverse transcriptase enzyme by Howard Temin and David Baltimore in 1970 (see **Supplementary Sidebar 3.3**) led to the explosion of research into this class of viruses, which led to the discovery of the origins of the *src* oncogene borne by Rous sarcoma virus and, subsequently, a large number of acutely transforming retroviruses, each of which was found to have acquired and activated a cellular proto-oncogene (see Table 3.3). In 1981 a new disease condition was discovered in homosexual men and drug users, primarily in San Francisco and New York, which soon was termed acquired immunodeficiency syndrome (AIDS) to contrast it with inborn immunodeficiency syndromes. Within two years, the origins of this apparently transmissible disease had been traced to a virus that, like ALV, RSV, and MLV, carried a reverse transcriptase in its virion (**Figure S3.5**). Human immunodeficiency virus (HIV), as it was soon called, is a true retrovirus distantly related to the avian and murine retroviruses discussed in Section 3.7. The extraordinarily rapid association of a newly discovered clinical condition (AIDS) with a specific causative agent (HIV) was directly due to the large body of information on

retroviruses that had been accumulated over the preceding decade in research focused on retroviruses associated with cancer. Hence, as is often the case, basic curiosity-driven research yielded benefits that could not have been anticipated when such research began a decade earlier.



(A)



(B)

Figure S3.5 Retroviruses (A) Cryoelectron microscopy and complex image-processing algorithms have produced the first high-resolution reconstructed image of a murine leukemia virus (MLV) virion; MLV is related to RSV, and its virion has a structure similar to that of RSV. The glycoprotein spikes are seen here in *magenta*, while the lipid bilayer of the virion is shown in *purple*; parts of the underlying nucleocapsid, revealed at lower resolution, are shown in *yellow*. (B) Scanning electron micrograph of human immunodeficiency virus (HIV) nucleocapsid cores budding from the surface of baby hamster kidney (BHK) cells; HIV-infected lymphocytes generate similar images. HIV is a member of the same family of viruses as RSV and MLV. (A, from F. Förster et al., *Proc. Natl. Acad. Sci. USA* 102:4729–4734, 2005. With permission from National Academy of Sciences. B, courtesy of P. Roingeard.)

Supplementary Sidebar 3.7 Where do viruses and their genes originate?

The discovery by Varmus and Bishop's laboratory of the cellular origins of the RSV *src* gene provoked the question of where most viral genes come from and how viruses

originate. Viral genome replication—in both DNA and RNA virus replication cycles—is executed with far less fidelity than is the replication of cellular DNA. The consequence is that viral genome sequences evolve far more rapidly than the genomic sequences of metazoan cells. Hence, most traces of precursor gene sequences that may have been present in ancestral viruses or in host cells were erased by this rapid evolution hundreds of millions of years ago.

We will probably never know where and how most viral genomes originated. Presumably, viruses have been around since the cells that they parasitize first appeared. Some types of viruses may have begun as renegade genes that broke away from cellular genomes and struck out on their own. RNA viruses may bear vestiges of early cellular life forms that used RNA molecules as genomes and, in the case of retroviruses, of a later stage of cellular evolution when a reverse transcriptase-like cellular enzyme enabled the transition from cellular RNA to cellular DNA genomes.

Whatever their origins, the great majority of viral genes have no obvious relatedness with the genes of their hosts. This highlights the uniqueness of the Varmus and Bishop finding that retroviruses can apparently acquire and transduce (carry in their genomes) cellular genes, seemingly promiscuously. This flexibility of their genomes suggested a novel application of retroviruses, which began to flourish in the mid-1980s: a variety of interesting genes were introduced into retroviral genomes using recombinant DNA techniques. The resulting viral genomes were then used as vectors to transduce these genes into cultured cells *in vitro* and into living tissues *in vivo* (the latter application often being referred to as “gene therapy”; see **Supplementary Sidebar 3.8**).

Supplementary Sidebar 3.8 Gene therapy can occasionally have tragic consequences

Gene therapy has been found to be most applicable to diseases of the hematopoietic system. Thus, children who are born with a severe immunodeficiency due to a germ-line–specified defect in one or another critical component of the immune system can, in principle, be cured if the missing gene is transduced into their bone marrow stem cells using retrovirus vectors. In more detail, retrovirus genomes can be reconstructed by deleting genes required for viral replication and inserting a gene or genes of interest in their place. In this case, the virus is being used to convey genes of interest into infected cells, and the retrovirus itself is therefore termed a vector. Cells infected by hybrid viruses carrying genes-of-interest will therefore be infected stably and produce the product of the vector-borne gene stably and possibly indefinitely. (Because a gene or genes essential for replication must be deleted from the viral genome in order to accommodate an inserted gene-of-interest, the cells used to produce large amounts of such hybrid viruses must also be supplied with genes encoding the missing replicative genes of the retrovirus.) In one version of retroviral gene therapy, hematopoietic stem

cells are infected *in vitro* by a gene-transducing retroviral vector; these stem cells are then introduced into afflicted children, in whose bone marrow these cells become stably engrafted. The differentiated progeny of these engrafted, genetically altered stem cells are then able to supply missing immune functions, thereby reversing the congenital immunodeficiency. (Clearly, one of the challenges of this particular gene therapy strategy is the difficulty of transducing a gene, using the viral vector, into a high enough proportion of cells within the marrow of the patient to ensure a major shift in systemic function.)

Just such a therapeutic approach was launched in France. Bone marrow stem cells from ten children suffering from a congenital severe combined immunodeficiency (SCID), which involves the absence of T cells and NK cells (to be described in Chapter 16), were infected with a Moloney murine leukemia virus (Mo-MLV)–derived retroviral vector; the vector transduced a gene specifying the gene product that the children lacked—the γc protein, a component of the interleukin receptors that allow proper development and regulation of the immune system. Nine of these children responded by showing a dramatic reconstitution of their immunological function. However, in the years after the inception of this trial, four of the children developed T-cell acute lymphoblastic leukemia.

In three of the four cases, analyses of the DNA of leukemic cells revealed proviruses derived from the viral vector that had become integrated within several kilobase pairs of the first exon of the *LMO2* gene, a proto-oncogene known to be activated in human T-cell leukemias. DNA of cells from the fourth patient showed a provirus integration near another proto-oncogene, *Bmi-1*. Three of these four leukemic children were eventually cured, and the nine surviving children showed restitution of their immune functions for periods as long as a decade following original treatment.

Given the known roles of the *LMO2* and *Bmi-1* oncogenes in leukemogenesis, the inserted proviruses were almost certainly responsible for triggering the four leukemias. Hence, insertional mutagenesis leading to oncogenesis, which had long been feared as a possible but remote risk incurred by such a gene therapy strategy, became a grim reality. In response to these findings, researchers have begun to develop new types of viral vectors that are less likely to activate proto-oncogenes via insertional mutagenesis, giving hope to those who are interested in correcting certain inborn defects through gene therapy.

Supplementary Sidebar 3.9 A bacterial agent of cancer pathogenesis

Helicobacter pylori was first identified in 1983 as a “curved bacterium” associated with chronic gastric inflammation. Over the ensuing decades it became increasingly associated with the pathogenesis of gastric adenocarcinomas. In certain parts of the

world, such as Japan, it is associated with essentially all cases of this disease, which is ten times more common in Japan than in the West. Its properties, in part revealed in Figure 3.18, enable it to create chronic inflammation in the stomach, often with loss of the acid-producing cells lining the stomach and resulting increases in the pH of stomach fluids. *H. pylori* bacteria become physically tethered to the epithelial cells lining the stomach wall, which results in turn in the injection of at least one protein, termed CagA, into the cytoplasm of the epithelial cells via a *CagA* pathogenicity island (PAI), a ~40 kb stretch of the *H. pylori* genome that encodes at least 30 distinct proteins. This injection is achieved by a series of *CagA*-encoded proteins that function essentially as a microsyringe. Various allelic versions of the *CagA* PAI are correlated with various degrees of risk of stomach cancer development. As might be surmised, the more virulent allelic versions of the *CagA* PAI are found in East Asian countries, where stomach cancer is often the leading cause of cancer-associated mortality. *H. pylori* appears to gain several advantages from its effects on the gastric mucosa. Its ability to increase the gastric pH creates a more hospitable tissue environment for its multiplication. In addition, it may gain vital nutrients, such as iron, from the gastric cells that it affects.

OceanofPDF.com

Glossary

ex vivo
: Occurring outside of a living body or organism. *Compare in vitro, in vivo*.

in vitro
: (1) Referring to biochemical processes, notably reactions, that occur outside of living cells, including in cell lysates or under conditions involving purified reactants. (2) Referring to the propagation of living cells in a vessel (e.g., a Petri dish) rather than in living tissues. *Compare* ***in vivo, ex vivo***.

medium
: The fluid in which cells are propagated *in vitro. See also* **tissue culture**.

passaging
: (1) Practice of transferring cells from one culture vessel to another, often performed because the cell population has filled up the first vessel. (2) Similarly, the transfer of tumor cells or infectious agents, notably viruses, from one host cell or organism to another. *See also* **serial passaging**.

integrin
: A heterodimeric cell surface receptor that binds components of the extracellular matrix and transmits information about this binding to the cell interior; the cytoplasmic domain of an integrin may also be coupled with components of the cytoskeleton, thereby linking the extracellular matrix to the cytoskeleton.

senescence
: A nongrowing state of cells in which they exhibit distinctive cell phenotypes and remain viable for extended periods of time but are generally unable to proliferate again; senescence often arises after extended passaging of cells *in vitro*, notably under suboptimal conditions of culture. *See* **replicative senescence**.

immortalization
: Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

organoid

An experimentally created model of a normal adult tissue, usually generated through incubation of organ-specific stemlike cells suspended in a three-dimensional gelatinous matrix containing a cocktail of factors designed to induce a tissue-specific differentiation program in the organoid.

immortalization

Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

oropharynx

adj., **oropharyngeal**) The cavity extending from the back of the mouth down the respiratory tract to the larynx (voice box).

nonhomologous recombination

Process of recombination between two DNA molecules in which the two participating molecules do not share significant sequence identity. *Also called* **illegitimate recombination**.

fragile site

A site along a chromosome that is intrinsically unstable and thus especially susceptible to breakage, the existence of which is often revealed when DNA replication forks proceeding through the site are stalled.

transduction

(1) Process whereby a signaling element, such as a protein, receives a signal and, in response, processes the signal and emits another signal. (2) Process by which a gene is introduced into a cell, usually by a vector such as a viral vector.

vector

(1) Agent, often a virus, that is able to carry (transduce) a gene from one cell to another. (2) An infected organism that serves to transmit and distribute an infectious agent to other organisms.

vector

(1) Agent, often a virus, that is able to carry (transduce) a gene from one cell to another. (2) An infected organism that serves to transmit and distribute an infectious agent to other organisms.

insertional mutagenesis

Alteration of a gene and its function through the integration of a retroviral provirus or transposon into the gene itself or a closely linked chromosomal site.

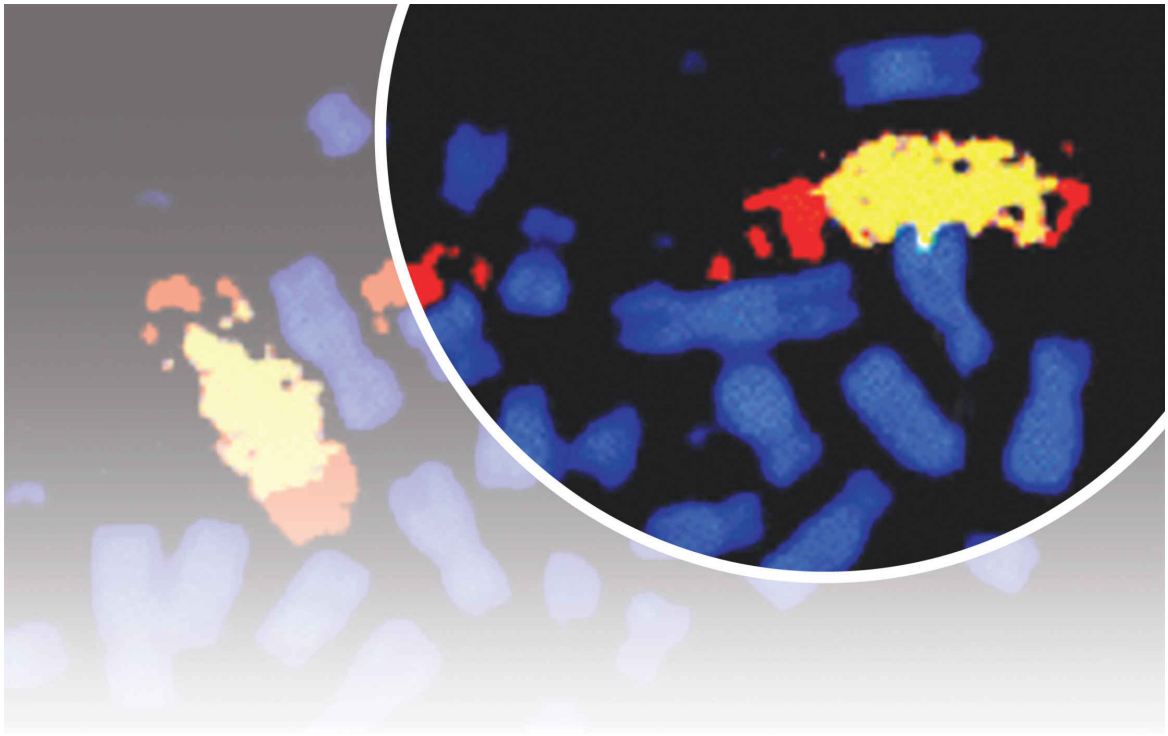
Chapter 4
Cellular Oncogenes



A fluorescence microscopy image with dark blue and bright red and yellow staining. The dark blue objects are chromosomes.

> The viral origin of the majority of all malignant tumors ... has now been documented beyond any reasonable doubt. It ... would be rather difficult to assume a fundamentally different etiology for human tumors.
>
> Ludwik Gross, tumor virologist, 1970

The DNA and RNA tumor viruses characterized in the 1970s provided cancer biologists with a simple and powerful theory of how human tumors could arise. Viruses that occurred commonly in the human population might, with some frequency, infect susceptible tissues and cause the transformation of infected cells. These cells, in turn, would begin to multiply and, sooner or later, form the large cell masses that were encountered frequently in the oncology clinic. Since

tumor viruses succeeded in transforming normal rodent and chicken cells into tumor cells with only a small number of introduced genes, these viruses might have similar powers in transforming human cells as well.

With the passage of time, this scenario, attractive as it was, became increasingly difficult to reconcile with the biology and epidemiology of human cancer. Most types of human cancer clearly did not spread from one individual to another as an infectious disease. Significant clusters of cancer cases—mini-epidemics of disease—were hard to find. Even more important, attempts undertaken during the 1970s to isolate viruses from most types of human tumors were unsuccessful. Of the hundred and more tumor types encountered in the oncology clinic, only two commonly occurring tumor types in the Western world—hepatomas (liver carcinomas) and cervical carcinomas—were known or suspected to be tied to specific viral causative agents.

These realizations evoked two responses. Those who hung tenaciously to tumor viruses as causative agents of all human cancers argued that chemical and physical carcinogens interacted with viruses that normally hid within the body's cells, activating their latent cancer-causing powers. Other researchers responded by jettisoning viruses entirely and began looking at another potential source of the genes responsible for human cancers—the cellular genome with its tens of thousands of genes. This second tack eventually triumphed, and by the late 1980s, the normal human genome was recognized to be a rich source of the genes that drive human cancer cell proliferation.

So, tumor viruses, once viewed as the key agents triggering all human cancers, failed to live up to these high expectations. Ironically, however, tumor virus research proved to be critical in uncovering many of the cellular genes that are indeed responsible for the neoplastic cell phenotype. The large catalog of cellular cancer-causing genes assembled over the ensuing decades—oncogenes and tumor suppressor genes—derives directly from these early efforts to find infectious cancer-causing agents in human populations.

4.1 Transfection of DNA provides a strategy for detecting nonviral oncogenes

In the 1970s some researchers attempted to connect chemical carcinogenesis of the type that Yamagiwa first developed (Section 2.8) with viral carcinogenesis. In particular, they sought an explanation that came from the fact that latent retroviral genomes could be found in abundance in the germ lines of various mammalian species. Such endogenous retroviral genomes, they argued, while normally transcriptionally silent, could be activated by various carcinogens, provoking virus production, viremia, and eventually cancer induction (**Supplementary Sidebar 4.1**). As attractive as this mechanism was, it failed to attract experimental support.

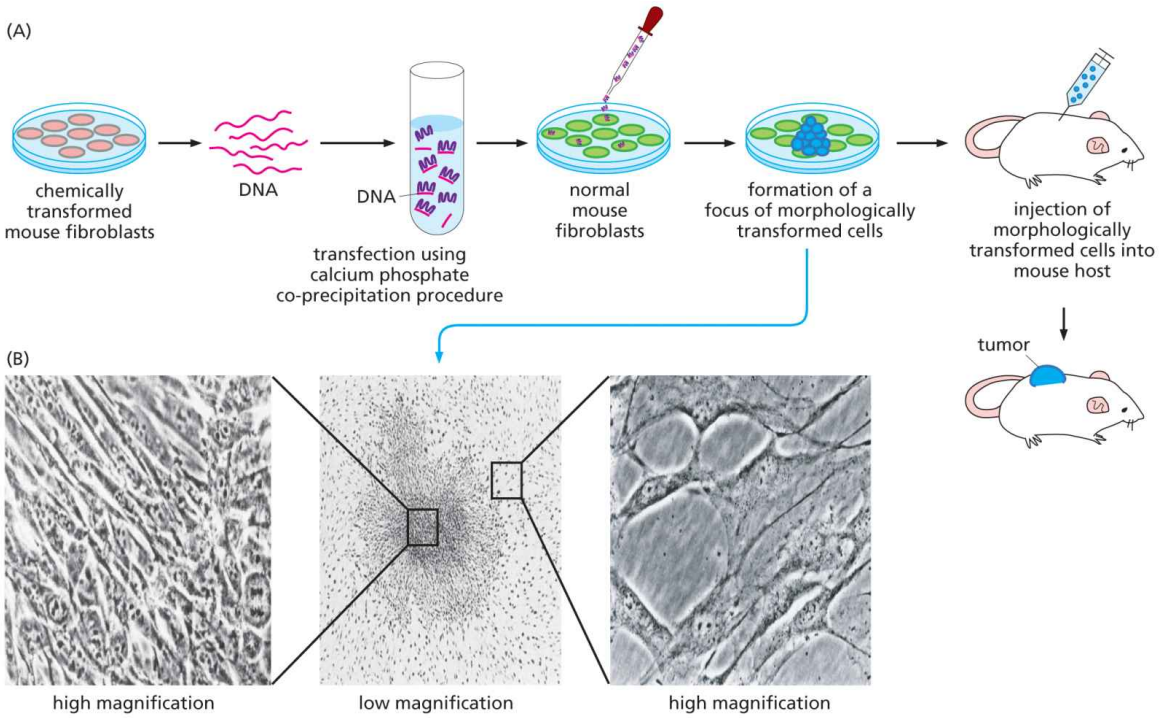
The demise of the endogenous retrovirus theory left one viable theory on the table. According to this theory, carcinogens function as mutagens (see Section 2.9). Whether physical (for example, X-rays) or chemical (for example, tobacco tars), these agents could induce cancer through their ability to mutate critical growth-controlling genes in the genomes of susceptible cells. Such growth-controlling genes might possibly be normal cellular genes, such as the proto-oncogenes discovered by the retrovirologists. Once these genes were mutated, the resulting mutant alleles might thereafter function as active oncogenes, driving the cancerous growth of the cells that carried them. All this could happen without the involvement of tumor viruses and their genomes.

Stated differently, this model—really a speculation—predicted that chemically transformed cells carried mutated cellular genes and that these genes were responsible for programming the aberrant growth of these cells. In fact, the notion that cancer cells were mutant cells traced its origins back to the beginning of the twentieth century and the speculations of the pathologist David von Hansemann and the embryologist Theodor Boveri (**Supplementary Sidebar 4.2**). It was impossible to predict the number of such mutated genes present in the genomes of these cells. More important, experimental proofs of the existence of these cancer-causing genes represented a daunting challenge. If they were really present in the genomes of chemically transformed cells, including perhaps human tumor cells, how could they possibly be found? If these genes were mutant versions of normal

cellular genes, then they were embedded in cancer cell genomes together with tens of thousands, perhaps even a hundred thousand other genes, each present in at least one copy per cell genome. These cancer genes, if they existed, were clearly tiny needles buried in very large haystacks.

To determine whether nonviral oncogenes existed in chemically transformed cells, a novel experimental strategy was devised. It involved introducing DNA (and thus the genes) of cancer cells into normal cells, and then determining whether the recipient cells became transformed in response to the introduced tumor cell DNA. Such transformation could be scored by the appearance of foci in the cultures of recipient cells several weeks after their exposure to tumor cell DNA—essentially the assay that Howard Temin had used to score for the presence of infectious transforming Rous sarcoma virus particles in monolayers of chick embryo fibroblasts (Section 3.2). This strategy depended on several experimental advances, including the development of an effective gene transfer procedure. Additionally, appropriate cancer cells from which to extract DNA and suitable recipient cells needed to be identified.

In 1972, a highly effective gene transfer procedure, soon termed transfection, was developed. This procedure, which made possible the introduction of naked DNA molecules from donor cells directly into mammalian cells serving as recipients (**Figure 4.1**), was based on co-precipitation of DNA with calcium phosphate crystals. Cells of the NIH 3T3 cell line, derived originally from mouse embryo fibroblasts, turned out to be especially adept at taking up and integrating into their genomes the foreign DNA introduced in this fashion.



A two-part figure about transfection of the D N A of transformed cells. In Part A, a tumor is induced in a mouse via transfection of D N A. D N A is initially extracted from chemically transformed mouse fibroblasts grown in a petri dish. Transfection is then achived using a calcium phosphate co-precipitation procedure. The resulting liquid is dripped onto normal normal mouse fibroblasts growing in a petri dish. This results in the formation of a focus of morphologically transformed cells. When some of the morphologically transformed cells are injected into a mouse host, the mouse develops a tumor on its back. Part B shows three micrograph images of human cells that have been morphologically transformed in the same way. A low-magnification image shows a focus consisting of densely packed abnormal cells surrounded by more loosely packed normal cells. A high-magnification image shows that the densely packed abnormal cells are highly elongated. Another high-rmagnification image shows that the less densely packed normal cells are more rounded.

Figure 4.1 Transfection of DNA of transformed cells (A) The procedure of transfection can be used to detect oncogenes in the DNA of cancer cells. DNA is extracted from cancer cells (*pink*) growing in a Petri dish. (For simplicity, the double-stranded DNA is depicted as single lines.) DNA is then introduced into a phosphate buffer. When calcium ions are added, a co-precipitate of DNA and calcium phosphate crystals is formed (*pink and*

purple). These crystals are added to a monolayer culture of normal cells (*green*). The calcium phosphate crystals facilitate the uptake of DNA fragments by cells. If a transforming gene (oncogene) is present in the donor DNA, it may become incorporated into the genome of one of the recipient cells and transform the latter. This transformed cell will now proliferate, and its descendants will form a clump (focus, *blue*) of cells that is visible to the naked eye. Injection of these cells into a host mouse and resulting tumor formation can be used to confirm the transformed state of these cells. (B) In addition to the initially used mouse tumor DNAs (panel A), human tumor DNAs could also yield foci of transformants following transfection. Seen at low magnification (*middle*) is a focus generated by transfection of DNA from the T24 human bladder carcinoma cell line. At high magnification the transformed cells within this focus (*left*), like many transformed fibroblasts, are spindle-shaped, refractile, and piled up densely on one another (see also Figure 3.4A). At the same magnification, the cells in the surrounding monolayer of untransformed NIH 3T3 cells (*right*), like normal fibroblasts, have wide, extended cytoplasms and are not piled on one another. (B, from M. Perucho et al., *Cell* 27:467–476, 1981. With permission from Elsevier.)

Researchers chose donor tumor cells derived from mouse fibroblasts of the C3H10T1/2 mouse cell line; these cells had been treated repeatedly with the potent carcinogen and mutagen 3-methylcholanthrene (3-MC), a known component of coal tars (see Section 2.8), which resulted in their transformation. Importantly, these transformed cells bore no traces of either tumor virus infection or activated endogenous retroviral genomes. Hence, any transforming oncogenes detected in the genome of these donor cells would, with great likelihood, be of cellular origin, that is, mutant versions of normal cellular genes.

In 1978–1979, DNAs extracted from several such 3-MC–transformed mouse cell lines were transfected into cultures of NIH 3T3 recipient cells, yielding large numbers of foci after several weeks. The cells plucked from the resulting foci were later found to be both anchorage-independent and tumorigenic (see Table 3.2). This simple experiment proved that the donor tumor DNA carried one or several genetic elements that were able to convert a non-tumorigenic NIH 3T3 recipient cell into a cell that was strongly tumorigenic.

DNA extracted from normal, untransformed C3H10T1/2 cells used as controls was unable upon transfection to induce foci in the NIH 3T3 cell monolayers. This difference made it highly likely that previous exposure of normal C3H10T1/2

cells to the 3-MC carcinogen had altered the genomes of these cells in some way, resulting in the creation of novel genetic sequences that possessed transforming powers. In other words, it seemed likely that the 3-MC carcinogen had converted a previously normal C3H10T1/2 gene (or genes) into a mutant allele that now could function as a transforming oncogene when introduced into NIH 3T3 recipient cells.

At first, it seemed quite difficult to determine whether the donor tumor cells carried a single oncogene in their genomes or several distinct oncogenes that acted in concert to transform the recipient cells. Careful analysis of the transfection procedure soon resolved this issue. Researchers discovered that when cellular DNA was applied to a recipient cell, only about 0.1% of a cell genome's worth of donor DNA became established in the genome of each transfected recipient cell. The probability of two independent, genetically unlinked donor genes both being concomitantly introduced into a single recipient cell was therefore $10^{-3} \times 10^{-3} = 10^{-6}$, that is, a highly unlikely event. From this calculation they could infer that only a single gene was responsible for the transformation of NIH 3T3 cells following transfection of donor tumor cell DNA. This led, in turn, to the conclusion that, years earlier, exposure of normal C3H10T1/2 mouse cells to the 3-MC carcinogen had caused the formation of a single mutant oncogenic allele; this allele was able, on its own, to transform both the C3H10T1/2 cells in which this mutation arose and, later on, the recipient NIH 3T3 cells into which this allele was introduced by gene transfer.

These transfection experiments provided strong indication that oncogenes can arise in the genomes of cells through mechanisms that have no apparent connection with viral infection. Perhaps human tumor cells, which likewise appeared to arise via nonviral mechanisms, also carried transfectable oncogenes. Would human oncogenes, if present in the genomes of these cells, also be able to alter the behavior of mouse cells?

Both of these questions were soon answered in the affirmative. DNAs extracted from cell lines derived from human bladder, lung, and colon carcinomas, as well as DNA from a human promyelocytic leukemia, were all found capable of transforming recipient NIH 3T3 mouse fibroblasts. This meant that the oncogenes in these cell lines, whatever their nature, were capable of acting across species and tissue boundaries to induce cell transformation. Most important, this work demonstrated directly that chemically transformed cells as well as certain human tumor cells contained mutant genes that were capable of driving such cells into a neoplastic growth state.

OceanofPDF.com

Glossary

endogenous retroviral genome
: The provirus of a retrovirus that is integrated into the germ line DNA of an organism, thereby assuming a configuration much like all cellular genes in the organism's genome.

transfection
: A procedure for introducing DNA or RNA molecules into cells which may thereafter be expressed transiently in such cells or, in the case of DNA, stably in such cells.

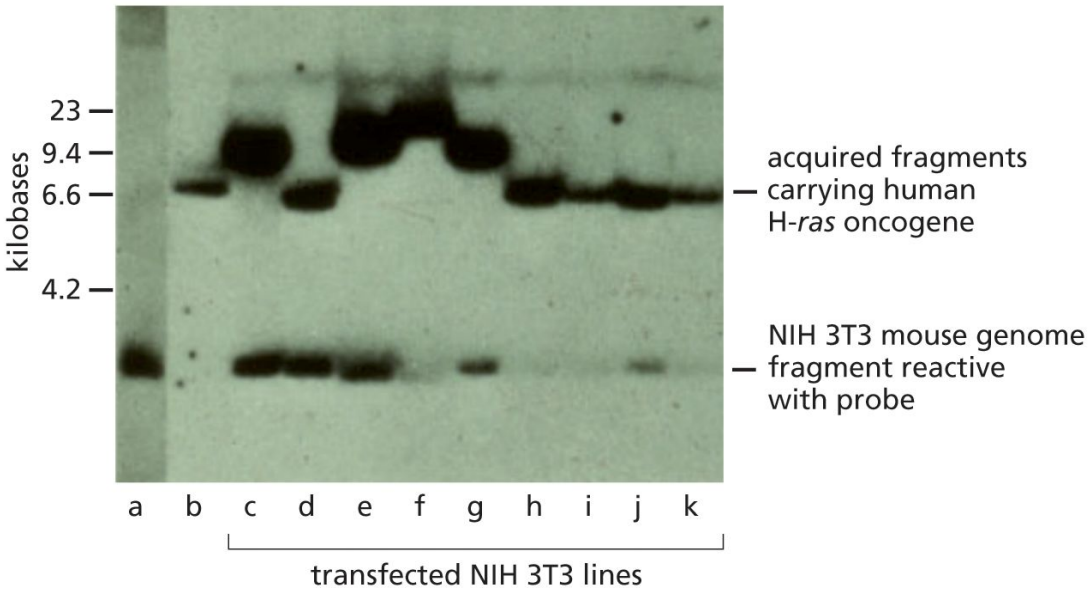
OceanofPDF.com

4.2 Oncogenes discovered in human tumor cell lines are related to those carried by transforming retroviruses

The oncogenes detected by transfection in the genomes of various human tumor cells were ostensibly derived from preexisting normal cellular genes that lacked oncogenic function. This seemed to parallel the process that led to the appearance of transforming retroviruses (see Section 3.9). Recall that during the formation of these viruses, preexisting normal cellular genes—proto-oncogenes—became associated with viral genomes and activated into potent oncogenes, albeit through an entirely different genetic mechanism.

These apparent parallels led to an obvious question: Could the same group of cellular proto-oncogenes become activated into oncogenes by marauding retroviruses in one context and by nonviral mutagens in another? Or, alternatively, did the retrovirus-associated oncogenes and those activated by nonviral mechanisms arise from two very distinct groups of cellular proto-oncogenes?

Use of DNA probes specific for the retrovirus-associated oncogenes provided the answers in short order. Using the Southern blot procedure (**Supplementary Sidebar 4.3**), a DNA probe derived from the H-*ras* oncogene present in Harvey rat sarcoma virus was able to recognize and form hybrids with the oncogene detected by transfection in the DNA of a human bladder carcinoma cell (**Figure 4.2**). A related oncogene, termed K-*ras* from its presence in the genome of Kirsten sarcoma virus, was able to anneal with the oncogene detected by transfection of DNA from a human colon carcinoma cell line.



A Southern blot image with 11 lanes, labeled a through k. Lanes b through j represent transfected N I H 3 T 3 lines. The vertical axis represents molecular weight in kilobases. A straight horizontal band of blots at roughly 2 kilobases is labeled N I H 3 T 3 mouse genome fragment reactive with probe. Higher up, blots at varying heights between 6.6 and 23 kilobases is labeled acquired fragments carrying human H-ras oncogene.

Figure 4.2 Homology between transfected oncogenes and retroviral oncogenes
The Southern blot procedure (see Supplementary Sidebar 4.3) was used to determine whether there was any relatedness between retrovirus-associated oncogenes and those discovered by transfection of tumor cell DNA. Cloned retroviral oncogene DNAs were used to make radiolabeled probes, while the restriction enzyme–cleaved genomic DNAs from transfected cells were analyzed by the Southern blot procedure. Shown here is the annealing between a radiolabeled H-*ras* oncogene probe (cloned from the genome of Harvey murine sarcoma virus; see Section 3.10) and the genomic DNAs from a series of nine lines of NIH 3T3 cells (*lanes b–j*) that had been transformed by transfection of DNA extracted from the EJ/T24 human bladder carcinoma cell line; the DNA of untransfected NIH 3T3 cells was analyzed in channel a and the genomic DNA of T24 human bladder carcinoma cells was analyzed in lane k. In many of the lines of transfected NIH 3T3 cells (*lanes b–j*), in addition to the acquired DNA fragments carrying the transfected oncogene, a lower–molecular-weight fragment representing the endogenous mouse H-*ras* proto-oncogene was also detected. In many of these transfected cell lines, the size of the DNA fragment carrying the transfected H-*ras* oncogene was affected by random DNA breakage events that had occurred in prior rounds of transfection and separated previously linked restriction enzyme cleavage sites from the DNA segment carrying the oncogene.

The human tumor DNA in channel a indicates the size of the restriction fragment carrying the human H-*ras* proto-oncogene. The variable intensity of this band indicates unequal loading of DNA samples in various gel channels. (From L.F. Parada et al., *Nature* 297:474–478, 1982. With permission from Nature.)

The list of connections between the retrovirus-associated oncogenes and oncogenes present in non-virus-induced human tumors soon grew by leaps and bounds (**Table 4.1**). In fact, many of these connections were forged following the discovery that the retrovirus-associated oncogenes were present in increased copy number in human tumor cell genomes. The *myc* oncogene, originally known from its presence in avian myelocytomatosis virus (MC29; see Section 3.10), was found to be present in multiple copies in the DNA of the HL-60 human promyelocytic leukemia cell line. These extra copies of the *myc* gene (about 10–20 per diploid genome) were the result of the process of gene amplification and the apparent cause of the proportionately increased levels of its protein product, the Myc oncoprotein; the excess Myc protein somehow favored the proliferation of the cancer cells. The *erbB* gene, first discovered through its presence in the genome of avian erythroblastosis virus (AEV; refer to Table 3.3), was discovered to be present in increased copy number in the DNAs of human stomach, breast, and brain tumor cells. (Erythroblastosis is a malignancy of red blood cell precursors.) Elevated expression of the homolog of the *erbB* gene is now thought to be present in the majority of human carcinomas.

Table 4.1 Initial examples of retrovirus-associated oncogenes that were discovered in altered form in human cancers

Name of virus	**Species**	**Oncogene**	**Type of oncoprotein**	**Homologous oncogene found in human tumors**
Abelson leukemia	mouse	*abl*	non-receptor TK	CML
Avian erythroblastosis	chicken	*erbB*	receptor TK	gastric, lung, breast[a]
McDonough feline sarcoma	cat	*fms*	receptor TK	AML[b]

Name of virus	Species	Oncogene	Type of oncoprotein	Homologous oncogene found in human tumors
H-Z feline	cat	*kit*	receptor TK[c]	gastrointestinal stromal
Murine sarcoma 3611	mouse	*raf*	ser/thr kinase[d]	bladder carcinoma
Simian sarcoma	monkey	*sis*	platelet-derived growth factor (PDGF)	many types[e]
Harvey sarcoma	mouse/rat	H-*ras*[f]	small G protein	bladder carcinoma
Kirsten sarcoma	mouse/rat	K-*ras*[f]	small G protein	many types
Avian erythroblastosis	chicken	*erbA*	nuclear receptor[g]	liver, kidney, pituitary
Avian myeloblastosis E26	chicken	*ets*	transcription factor	leukemia[h]
Avian myelocytoma	chicken	*Myc* [i]	transcription factor	many types

Name of virus	Species	Oncogene	Type of oncoprotein	Homologous oncogene found in human tumors
Reticuloendotheliosis	turkey	*Rel* [j]	transcription factor	lymphoma

Abbreviations: AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; TK, tyrosine kinase.

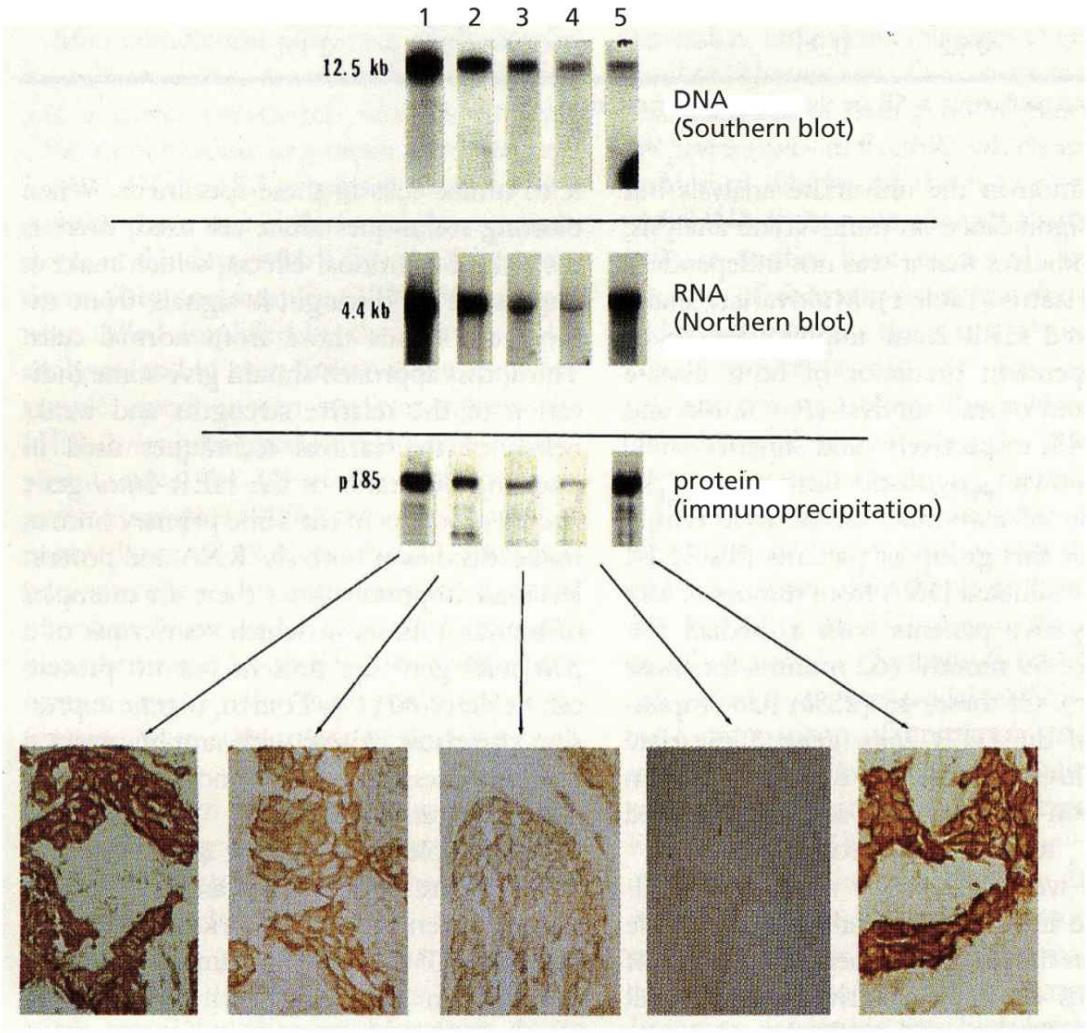
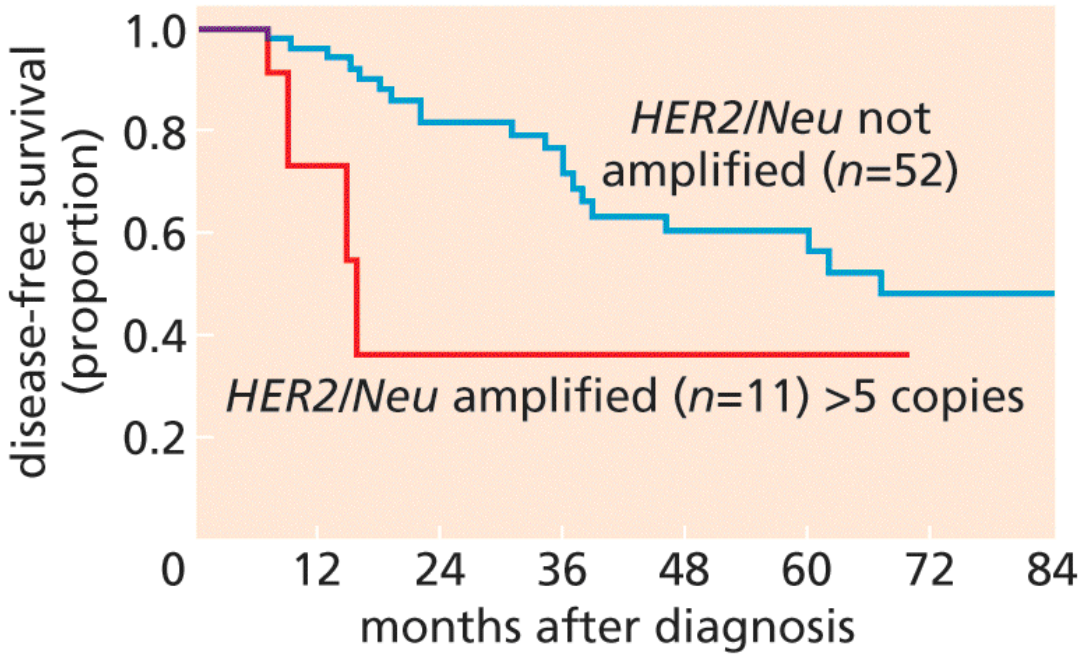
In 1987, amplification of the *erbB*-related gene known variously as *erbB2*, *neu*, or *HER2* was reported in many breast cancers (**Figure 4.3A**). Increases in gene copy number of more than five copies per cancer cell were found to correlate with a decrease in the number of patients who, following initial treatment, survived without recurrence of disease (Figure 4.3B). (Kaplan–Meier plots, like the one in the figure, will be used repeatedly throughout this book. In each case, the status of patients—either disease-free survival, progression-free survival, overall survival, or another clinical parameter—is plotted as a function of the time elapsed following initial diagnosis or treatment.) Significantly, the observed amplification of the *erbB2/HER2* gene was often but not always correlated with an increased expression of its encoded protein (see Figure 4.3A). Among a large group of breast cancer patients, those whose tumors expressed normal levels of this protein showed a median survival of 6 to 7 years after diagnosis, while those patients whose tumors expressed elevated levels had a median survival of only 3 years. This inverse correlation between *erbB2/HER2* expression levels and long-term patient survival provided a strong indication that this gene, in amplified form, was causally involved in driving the malignant growth of the breast cancer cells (but see **Supplementary Sidebar 4.4**).



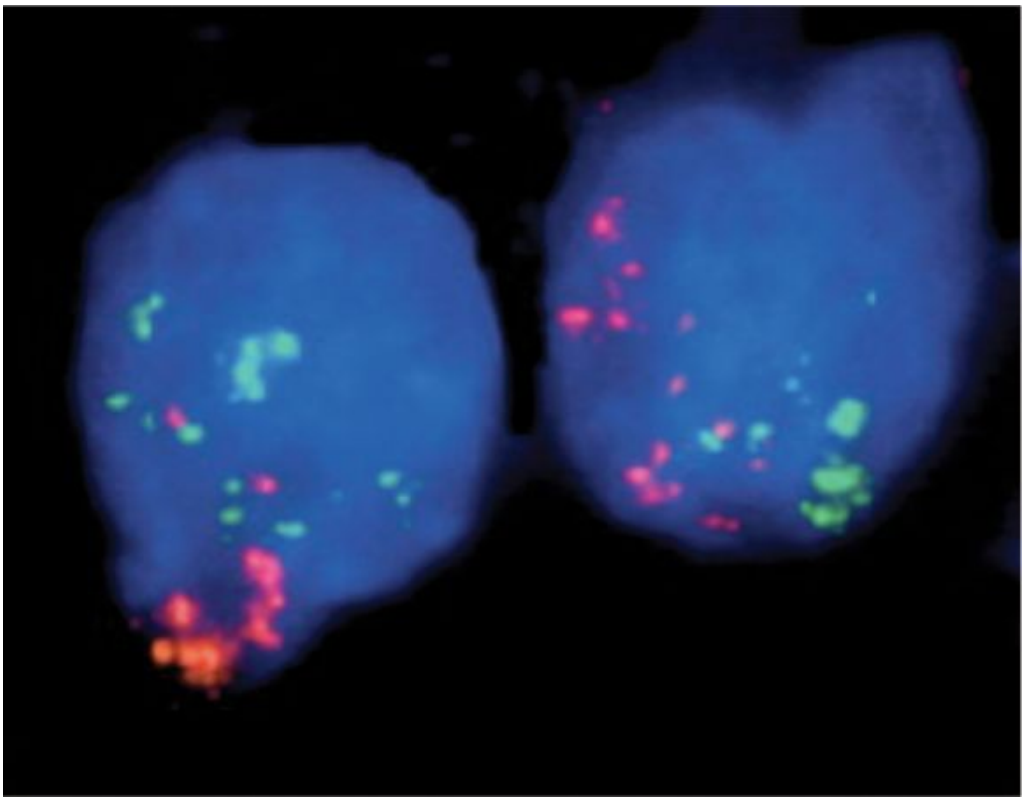
Three photos labeled immunohistochemistry, show three sets of blot images. The first shows five D N A blots using the Southern blot method. The recorded fragments are 12.5 kilobases long. The second image shows five R N A blots using the Northern blot method. The recorded fragments are 4.4 kilobases long. The third image shows five blots of protein p185 obtained using immunoprecipitation. Each of the protein blots is accompanied by a micrograph showing physical appearance of cells. Lanes 1 and 5 have the darkest blots and the darkest red colored clumps in the cells. Lane 4 has the lightest blots and more uniform coloration in the cells.

(A)



A time plot with months after diagnosis on the horizontal axis and disease-free survival proportion on the vertical axis. There are two curves, one red and one blue, which both begin at 1.0 on the vertical axis at 0 months. The red curve, labeled H E R 2 / N e u amplified (n=11) >5 copies, drops to just under 0.4 within about 14 months and then remains flat out to 70 months. The blue curve, labeled H E R 2 / N e u not amplified (n=52), declines more gradually, to just under 0.5 in about 66 months and then remains flat out to 84 months.

(B)



Two cell nuclei at high magnification, each appearing dark blue against a black background but with a few bright red and green fluorescent spots on them.

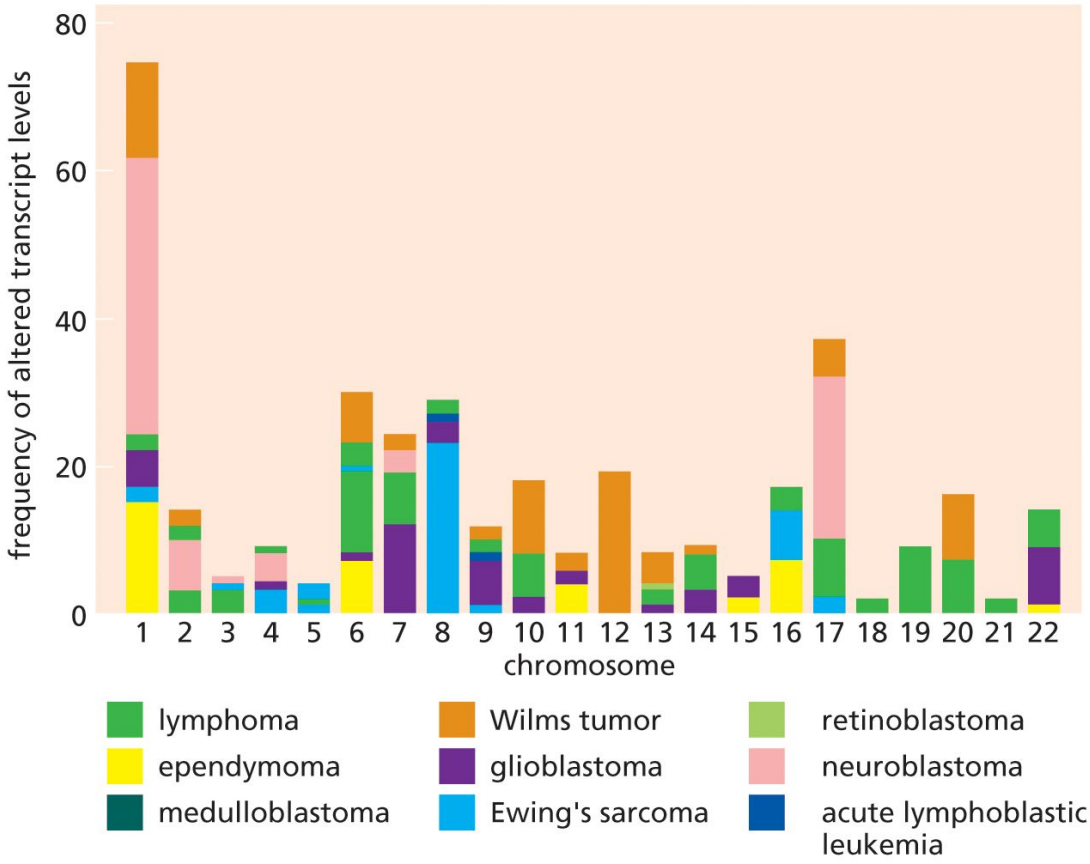
(C)

Figure 4.3 Amplification of the *erbB2/HER2/neu* oncogene in breast cancers
(A) The Southern blotting procedure (see **Supplementary Sidebar 4.3**) was used to determine whether the DNA of five human breast carcinomas carried extra (that is, amplified) copies of the *erbB2/neu* oncogene (also termed *HER2*), a close relative of the *erbB* oncogene. As indicated by the dark bands representing restriction enzyme fragments, some human breast carcinomas carried extra copies of this gene. Subsequent work indicated that while the *erbB2/HER2* oncogene was amplified in some tumors ("DNA," *lanes 1, 2, and 3*), others overexpressed the mRNA without gene amplification ("RNA," *lane 5*). Levels of the encoded ErbB2/HER2 protein could also be gauged via immunoprecipitation and immunohistochemistry (see **Supplementary Sidebar 2.1**) by using an antibody that reacts with this protein; these levels generally correlated with relative levels of the encoding mRNA. (B) This gene amplification is correlated with a poor prognosis for the breast cancer patient, as indicated by this *Kaplan–Meier* plot. Those patients whose tumors carried more than five copies of the *erbB2/neu* gene were far more likely to experience a relapse in the first 18 months after diagnosis

and treatment than were those patients whose tumors lacked this amplification. (All patients in this study had breast cancer cells that had spread to the lymph nodes draining the involved breast. *n*, number of patients.) (C) Use of fluorescence *in situ* hybridization (FISH) has shown that in some human breast cancers, there are multiple spots in each cell nucleus that react with a fluorescence-labeled DNA probe that recognizes the *erbB2/HER2* gene (*light green*) and yet other spots that react with a DNA probe specific for the *CCND1/cyclin D1* gene (*orange/pink*). Each of these probes generates only two spots when used to analyze nuclei of normal diploid cells. (As described in Chapter 8, cyclin D1 promotes progression of cells through their growth-and-division cycles.) (A, from D.J. Slamon et al., *Science* 244:707–712, 1989. B, from D.J. Slamon et al., *Science* 235:177–182, 1987. Both with permission from AAAS. C, from J. Hicks et al., *Genome Res*. 16:1465–1479, 2006. With permission from Cold Spring Harbor Laboratory Press.)

In the years that followed, yet other techniques, including fluorescence *in situ* hybridization (FISH), have been used to determine gene amplification in these and other tumor types. By 2010, a variety of techniques had been brought to bear for validating the oncogenic roles of genes that are amplified in a variety of human cancers; included among these techniques were tests of the transforming powers of these genes. This work resulted in a roster of 77 genes that are, with great likelihood, contributing to tumor development when they are present in amplified form in human cancer cell genomes. (Since the amplification of a gene is often accompanied by the co-amplification of other genes that happen to be located nearby on a chromosome, the gene whose amplification is thought to be causal in fostering tumor development is often termed a driver, while the nearby flanking genes that "may go along for the ride" but are mechanistically unimportant in tumor development are termed passengers.)

As genetic technology has improved, the ability to survey entire tumor cell genomes for chromosomal regions that have suffered changes in copy number has improved immeasurably, and genome-wide surveys of both gene amplifications and deletions have become almost routine. In the case of cancer cells, the amplifications presumably result in the overexpression of growth-promoting genes (that is, proto-oncogenes), while the deletions involve the loss of putative growth-retarding tumor suppressor genes, which are discussed in Chapter 7. As **Figure 4.4** makes clear, different cell types undergo distinct sets of genomic alterations during their transformation into full-fledged tumor cells. The analyses of cancer cell genomes by a variety of methods will be discussed in detail in Chapter 12.



A bar chart listing the 22 human chromosomes left to right. The vertical axis represents frequency of altered transcript levels, in each chromosome, for each of nine different pediatric cancers: lymphoma, ependymoma, medulloblastoma, Wilms tumor, glioblastoma, Ewing's sarcoma, retinoblastoma,, neuroblastoma, acute lymphoblastic, and leukemia. Almost 40 percent of neuroblastoma samples have alterations in chromosome 1, and roughly 20 percent have alterations in chromosome 17. Other alterations occur in chromosomes 2, 3, 4, and 7. Over 20 percent of samples of Ewing's sarcomas have alterations in chromosome 8. Other alterations occur in chromosomes 1, 4, 5, 9, 16, and 17. Just under 20 percent of Wilms tumor samples have alterations in chromosome 12. Other cancers have alterations spread across many chromosomes at small frequecies.

Figure 4.4 Nonrandom amplifications and deletions of chromosomal regions A survey of nine different types of pediatric cancers indicates that each cancer type has characteristic gene amplifications and deletions affecting a specific set of chromosomal regions. This survey examined the transcripts deriving from genes carried by the 22 non-sex chromosomes. For example, neuroblastomas (*pink*) often have changes in the copy numbers of genes on Chromosomes 1 and 17 and corresponding changes in the levels of the transcripts expressed by these genes. In this analysis, measurable changes in the copy number of 493 genes were found to

be paralleled by changes in mRNA expression levels—that is, when DNA copy number of a chromosomal region was increased (that is, amplified) or reduced, there was a parallel change in the level of the corresponding RNA, this being observed in multiple tumors of a given type. (Of these 493 chromosomal sites, which were scattered across the human genome, 440 could be associated with genes of known biological function.) This parallel behavior made it possible to assess changes in gene copy number by measuring levels of RNA transcripts in these tumors rather than by directly measuring DNA copy number of the corresponding genes. (The "altered transcripts" indicated in the ordinate denotes RNAs whose concentrations were significantly increased above or below normal in the tumors being examined.) As is apparent, Chromosome 1 carries regions that are most commonly found to be amplified or deleted in a variety of these tumors, which might be expected from its relatively large size. This does not explain, however, the relatively infrequent amplification or deletion of regions of Chromosomes 2, 3, 4, and 5, which are almost as large. Some tumors, such as lymphomas (*darker green*), show changes at diverse chromosomal sites, while the aforementioned neuroblastomas (*pink*) usually show changes mapping to one or two chromosomes. (From G. Neale et al., *Clin. Cancer Res*. 14:4572–4583, 2008. With permission from the American Association for Cancer Research.)

Ironically, mutant alleles of the c-*src* proto-oncogene (see Section 3.9), the first cellular oncogene to be discovered, proved to be elusive in human tumor cell genomes. More specifically, repeated attempts to find mutant alleles of c-*src* that are present in human cancer cell genomes and affect the structure of the encoded Src protein have consistently failed.

The lesson taught by these numerous cross connections was simple and clear: many (but not all) of the oncogenes originally discovered through their association with avian and mammalian retroviruses could be found in a mutated, activated state in human tumor cell genomes. This meant that a common set of cellular proto-oncogenes might be activated either by retroviruses (in animals) or, alternatively, by nonviral mutational mechanisms operating during the formation of human cancers.

OceanofPDF.com

Glossary

gene amplification
: Genetic mechanism by which the copy number of a gene is increased above its normal level in the diploid genome.

erythroblastosis
: Malignancy of the precursors of red blood cells, usually referring to a condition of birds.

Kaplan–Meier plot
: A convention for graphing various clinical observations in which the percentage of surviving patients (or another clinical parameter such as disease-free or progression-free survival) is plotted on the ordinate (*y*-axis), while the time course after initial diagnosis or treatment is plotted (usually in increments of months or years) on the abscissa (*x*-axis).

driver gene
: A gene that is affected by driver mutations and is identified because the mutations affecting this gene occur more frequently in tumors than would be expected by random chance; driver genes are mutated on a recurring basis in the genomes of multiple, independently arising tumors, ostensibly because these mutations confer advantageous cell phenotypes. *See* **driver mutation**.

passenger gene
: Gene altered by passenger mutation. *See* **passenger mutation**.

tumor suppressor gene
: (1) A gene whose partial or complete inactivation, occurring in either the germ line or the genome of a somatic cell, leads to an increased likelihood of cancer development. (2) Such a gene that is responsible for constraining cell proliferation. *See also* **gatekeeper**.

4.3 Proto-oncogenes can be activated by genetic changes affecting either protein expression level or structure

While a number of proto-oncogenes were found in activated, oncogenic form in human tumor genomes, the precise genetic alterations that led to many of these activations remained unclear. In the case of retrovirus-associated oncogenes, one mechanism became obvious once the organization of the transforming retrovirus genomes was known. In the normal cell, the expression of each proto-oncogene was regulated by its own transcriptional promoter—the DNA sequence that controls the level of its transcription. The promoter of each proto-oncogene enabled the gene to respond to a variety of physiologic signals. Often the needs of the cell, communicated through these signals, caused a proto-oncogene to be expressed at very low levels; however, on certain occasions, when required by the cell, expression of the gene might be strongly induced.

A quite different situation resulted after a proto-oncogene was acquired by a retrovirus. After insertion into the retrovirus genome, expression of this captured gene was now controlled by a retroviral transcriptional promoter (see Figure 3.13), which invariably drove the gene's expression unceasingly and at high levels. Transcription of this virus-associated gene, now an oncogene, was therefore no longer responsive to the cellular signals that had previously regulated its expression. For example, in the case of c-*myc*, expression or repression (that is, shutdown) of this gene in a cell is normally tightly controlled by the changing levels of certain extracellular signals, such as those conveyed by mitogenic growth factors (to be discussed in Chapter 5), to which the cell is exposed. Once incorporated into the genome of avian myelocytomatosis virus (MC29), expression of this gene (now called v-*myc*) is found to be at far higher levels than are seen normally in cells, and this expression occurs at a constant (sometimes termed constitutive) level.

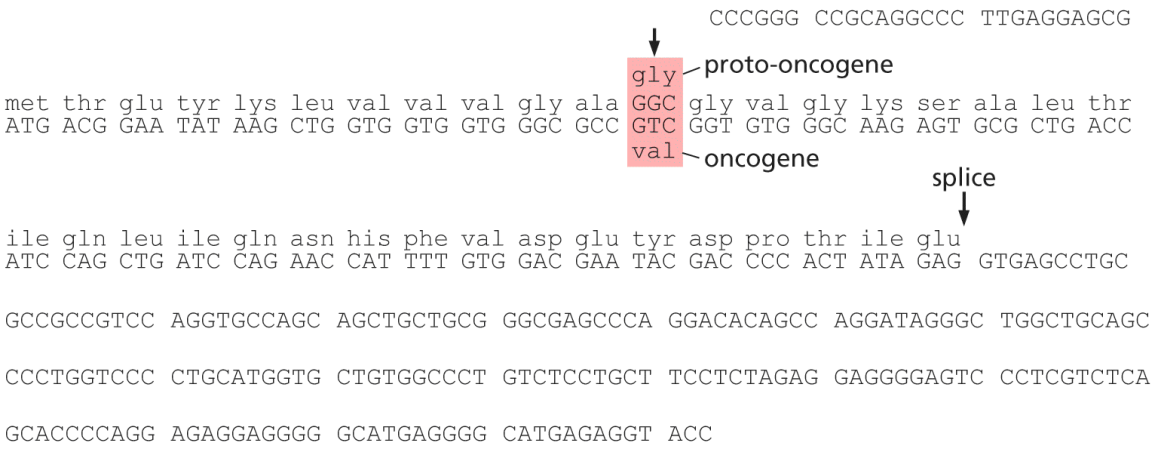
But how did a normal human H-*ras* proto-oncogene become converted into the potent oncogene that was detected by transfection of human bladder carcinoma

DNA (see Sections 4.1 and 4.2)? Gene amplification could not be invoked to explain its activation, since this oncogene seemed to be present in bladder carcinoma DNA as a single-copy gene. The puzzle grew when this H-*ras* bladder carcinoma oncogene was isolated by molecular cloning (**Supplementary Sidebar 4.5**). It was localized to a genomic DNA fragment of 6.6 kilobases in length. Provocatively, an identically sized DNA fragment was found in normal human DNAs. The latter fragment clearly represented the human H-*ras* proto-oncogene —the normal gene that suffered some type of mutation that converted it into an oncogene during the formation of the bladder carcinoma.

While their overall DNA structures were very similar, these two versions of the H-*ras* gene performed in dramatically different ways. The oncogene that had been cloned from human bladder carcinoma cells caused transformation of NIH 3T3 cells, while its normal proto-oncogene counterpart lacked this ability. The mystery deepened when more detailed mapping of the physical structures of these two DNA segments—achieved by making maps of the cleavage sites of various restriction enzymes—revealed that the two versions of the gene had overall physical structures that were indistinguishable from one another.

Yet clearly, the two versions of the H-*ras* gene had some significant difference in their sequences, because they functioned so differently. The critical sequence difference was initially localized by recombining segments of the cloned proto-oncogene with other segments deriving from the oncogene (**Supplementary Sidebar 4.6**). This made it possible to narrow down the critical difference to a segment only 350 base pairs long.

The puzzle was finally solved when the corresponding 350-bp segments from the proto-oncogene and oncogene were subjected to DNA sequence analysis. The critical difference was extraordinarily subtle—a single base substitution in which a G (guanosine) residue in the proto-oncogene was replaced by a T (thymidine) in the oncogene. This single base-pair replacement—a point mutation—appeared to be all that was required to convert the normal gene into a potent oncogene (**Figure 4.5**)! This important discovery was made simultaneously in three laboratories, eliminating all doubt about its correctness.



A 320-nucleotide-long sequence of D N A bases. Bases 27 through 137 are grouped into 37 codons of three bases each, and for each group the amino acid coded for is shown, starting with methionine for A T G. The twelfth codon is highlighted; there, a change from G G C in the proto-oncogene to G T C in the oncogene causes the amino acid coded for to change from glycine to valine. After the last group of three, the sequence of amino acids ends with an arrow labeled splice.

Figure 4.5 Mutation responsible for H-*ras* oncogene activation As described in Supplementary Sidebar 4.6, the critical difference between the human EJ/T24 bladder carcinoma oncogene and its corresponding proto-oncogene could be localized to an intragenic restriction enzyme–generated fragment of 350 base pairs. The sequences of the two 350-nucleotide-long DNA fragments from the oncogene and proto-oncogene were then determined. The two differed at a single nucleotide, which affected the 12th codon of the H-*ras* reading frame (*arrow*), converting the normally present glycine-encoding codon to one specifying valine. (From C.J. Tabin et al., *Nature* 300:143–149, 1982. With permission from Nature.)

The discovery of this point mutation represented a significant milestone in cancer research. It was the first time that a specific mutation was discovered in a gene that contributed causally to the neoplastic growth of a human cancer. Equally important, it seemed that this genetic change arose as a somatic mutation. And finally, this work revealed the powers of the then-recently developed recombinant DNA technology, which could trace a critical oncogene-activating mutation to a change in a single nucleotide out of the ~3.2 billion nucleotides that comprise the haploid human genome.

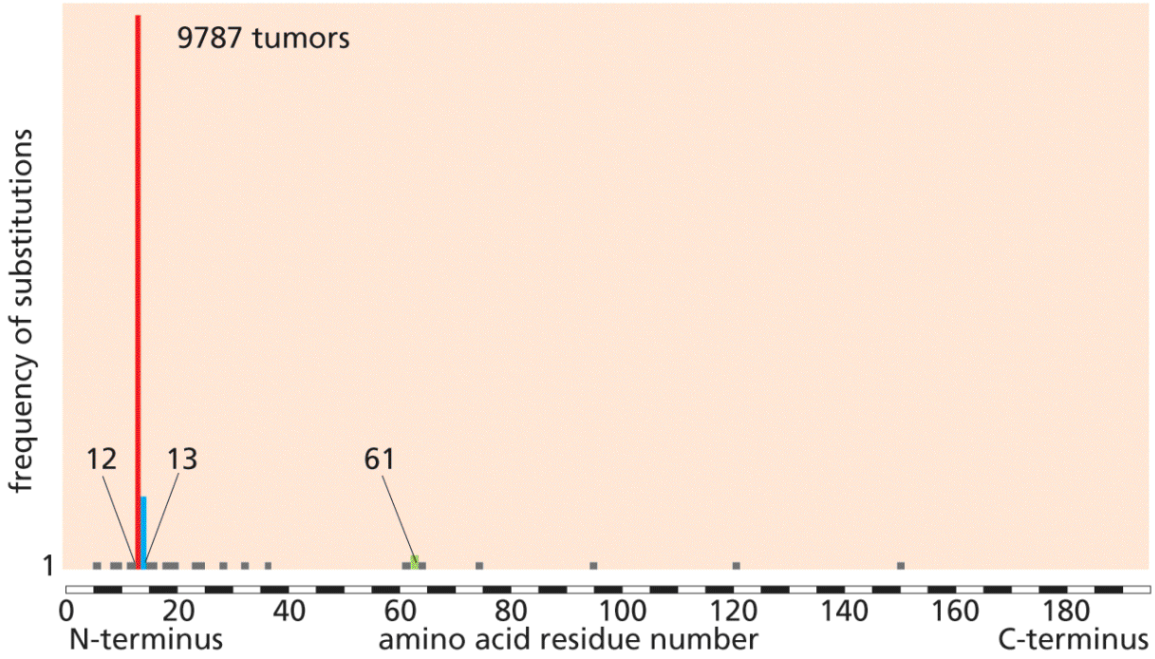
With this information in hand, researchers could devise a likely explanation for the origin of the bladder carcinoma and, by extension, other similar tumors. The particular bladder carcinoma from which the H-*ras* oncogene had been cloned was said to have arisen in a middle-aged man who had been smoking for four decades. During this time, carcinogens present in cigarette smoke were introduced in large amounts into his lungs and passed from there through the bloodstream to his kidneys, which excreted these chemical species with the urine. While in the bladder, some of the carcinogen molecules present in the urine had entered urothelial cells lining the bladder and attacked their DNA. On one occasion, a mutagenic carcinogen introduced a point mutation in the H-*ras* proto-oncogene of a urothelial cell. Thereafter, this mutant cell and its descendants proliferated, being driven by the potent transforming action of the H-*ras* oncogene that they carried. The result, years later, was the large tumor mass that was eventually diagnosed in this patient. [As we will learn later (Chapter 11), acquisition of this H-*ras* mutation must have been followed by additional, subsequently acquired mutations in other growth-controlling genes before these cells could behave in a fully neoplastic manner.]

Importantly, this base-pair substitution occurred in the reading frame of the H-*ras* gene—the portion of the gene dedicated to encoding amino acid sequence (see Figure 4.5). In particular, this point mutation caused the substitution of a glycine residue present at residue position 12 in the normal H-*ras*–encoded protein by a valine residue. The effects of this amino acid substitution on the function of the Ras oncoprotein will be discussed later in Chapters 5 and 6.

The discovery of this point mutation established a mechanism for oncogene activation that was quite different from that responsible for the creation of *myc* oncogenes. In the case of H-*ras*, a change in the structure of the encoded protein appeared to be critical. In the contrasting case of *myc*, deregulation of its expression level seemed to be important for imparting oncogenic powers to this gene.

Within a decade, a large number of human tumors were found that carried point mutations in one of the three *ras* genes present in the mammalian genome: H-*ras*, K-*ras*, and N-*ras*. Significantly, in each of these tumors, the point mutation that was uncovered was present in one of three specific codons in the reading frame of a *ras* gene. Consequently, all Ras oncoproteins (whether made by the H-, K-, or N-*ras* gene) were found to carry amino acid substitutions in residue 12 or, less frequently, residues 13 and 61 (**Figure 4.6**); yet other sites of mutated codons have been reported on occasion. (This striking concentration of mutations

affecting only a small number of residues in the Ras protein occurs in spite of the fact that all of the coding sequences in the *ras* proto-oncogenes presumably have similar vulnerability to mutation. The resolution of this puzzle comes from studying the structure and function of the Ras protein, topics that we will address in the next chapter.) A survey of 40,000 human tumor genomes conducted many years later revealed that 22%, 8.2%, and 3.7% of these tumors had activating mutations in either the K-, N-, or H-*ras* genes, respectively.



A graphic depicting the concentration of point mutations leading to activation of the K-r a s oncogene. The gene, 189 codons long, is laid out horizontally with the N terminus on the left and the C terminus on the right. Vertical bars indicate that when nearly 10,000 tumors were sequenced, 9787 of them had a substitution in codon 12. A much smaller number, but still significant, had a substitution in codon 13. Two had a substitution on codon 60. Substitutions on other codones were each recorded only once, mostly on the N terminus end, in the vicinity of codons 12 and 13.

Figure 4.6 Concentration of point mutations leading to activation of the K-*ras* oncogene The sequencing of almost 10,000 K-*ras* oncogenes in human tumors has revealed that, rather than occurring randomly throughout the reading frame of the gene, which encompasses 189 codons, mutations affect almost exclusively the nucleotides forming codon 12; mutations affect codon 13 only about 12% as frequently and codon 61 only on rare occasions. Since all the codons of the K-*ras* reading frame are likely to suffer mutations at

comparable rates during tumor development, this suggests that an extraordinarily strong selective pressure favors the outgrowth of cells having mutations affecting codons 12, 13, and 61, while mutations altering other codons in the reading frame either have no effect on cell phenotype or are actively disadvantageous for the cells bearing them. (Data from Catalogue of Somatic Mutations in Cancer (COSMIC database), http://www.sanger.ac.uk.)

For unknown reasons, the frequency with which these mutant oncogenes are found varies dramatically from one tissue site to another (**Table 4.2**). One clue, however, has come from genetically engineered mice in which the reading frame of the K-*ras* proto-oncogene has been replaced ("knocked-in") with the reading frame of an H-*ras* oncogene. Wild-type mice usually develop lung tumors carrying K-*ras* oncogenes in response to treatment by a chemical carcinogen; however, the vast majority of the knock-in mice develop lung tumors carrying H-*ras* oncogenes following this treatment. This indicates that the *regulatory sequences* controlling the expression of the K-*ras* proto-oncogene, rather than the *structure* of the encoded protein, determine which *ras* proto-oncogene, following mutation by a carcinogen, appears in mutant form in the genome of a particular type of carcinoma.

Table 4.2 A list of point-mutated *ras* oncogenes carried by a variety of human tumor cells

Tumor type	**Proportion (%) of tumors carrying a point-mutated *ras* gene**[a]
Pancreas	98 (K)
Thyroid (papillary)	60 (H, K, N)
Thyroid (follicular)	55 (H, K, N)
Colorectal	52 (K, N)

Tumor type	**Proportion (%) of tumors carrying a point-mutated *ras* gene**[a]
Seminoma	45 (K, N)
Myeloma	43 (N, K)
Lung (non-small-cell)	32 (K)
Melanoma	30 (N)
Uterine endometrioid	25 (H, K,N)
Acute myelogenous leukemia	11 (N)
Bladder	10 (H, K, N)

Adapted from J. Downward, *Nat. Rev. Cancer* 3:11–22, 2003; N. Vasan et al., *Clin. Cancer Res.* 20:3921–3930; and A.D. Cox et al., *Nat. Rev. Drug Discov.* 13, 828–851.

Both activation mechanisms—regulatory and structural—might collaborate to create an active oncogene. In the case of the *myc* oncogene carried by avian myelocytomatosis virus, for example, expression of this gene was found to be strongly deregulated by the viral transcription promoter as mentioned above. At the same time, some subtle alterations in the reading frame of the *myc* oncogene (and thus changes in the structure of its encoded oncoprotein, Myc) further enhanced the already-potent transforming powers of this oncogene. Similarly, the H-*ras* oncogene carried by Harvey sarcoma virus was found to carry a point mutation in its reading frame (like that discovered in the bladder carcinoma oncogene); at the same time, this viral oncogene was greatly overexpressed

relative to its expression levels in normal cells, being driven by the retroviral transcriptional promoter. Indeed, in many animal and human tumors carrying a mutant, activated *ras* oncogene, the initially arising oncogene is found to subsequently undergo the process of gene amplification (see Section 4.2), enabling the tumor cells to acquire increased signaling from the mutant oncoprotein.

Glossary

repression
: Regulatory mechanism that causes shutdown of the expression (transcription) of a gene. *See also* **expression**.

constitutive
: Describing a state of activity that occurs at a constant level and is therefore not responsive to modulation by physiologic regulators, or a type of control that yields such a constant output. *See also* **conditional**.

point mutation
: Substitution of a single base for another in a DNA sequence.

urothelium
: The specialized epithelial cell lining of the urinary bladder.

reading frame
: (1) The nucleotide sequence within a gene or mRNA that encodes the amino acid sequence of a protein. (2) The registration of triplet codons within this sequence that enables the proper translation of this protein sequence.

knock-in
: A targeted mutation achieved through the homologous recombination of an experimentally introduced, cloned DNA fragment containing, in part, sequences of the targeted gene; the resulting integration of the introduced fragment into the genome of a cell usually results in the addition of novel sequences that affect the function of the targeted gene. *See also* **knock-out**.

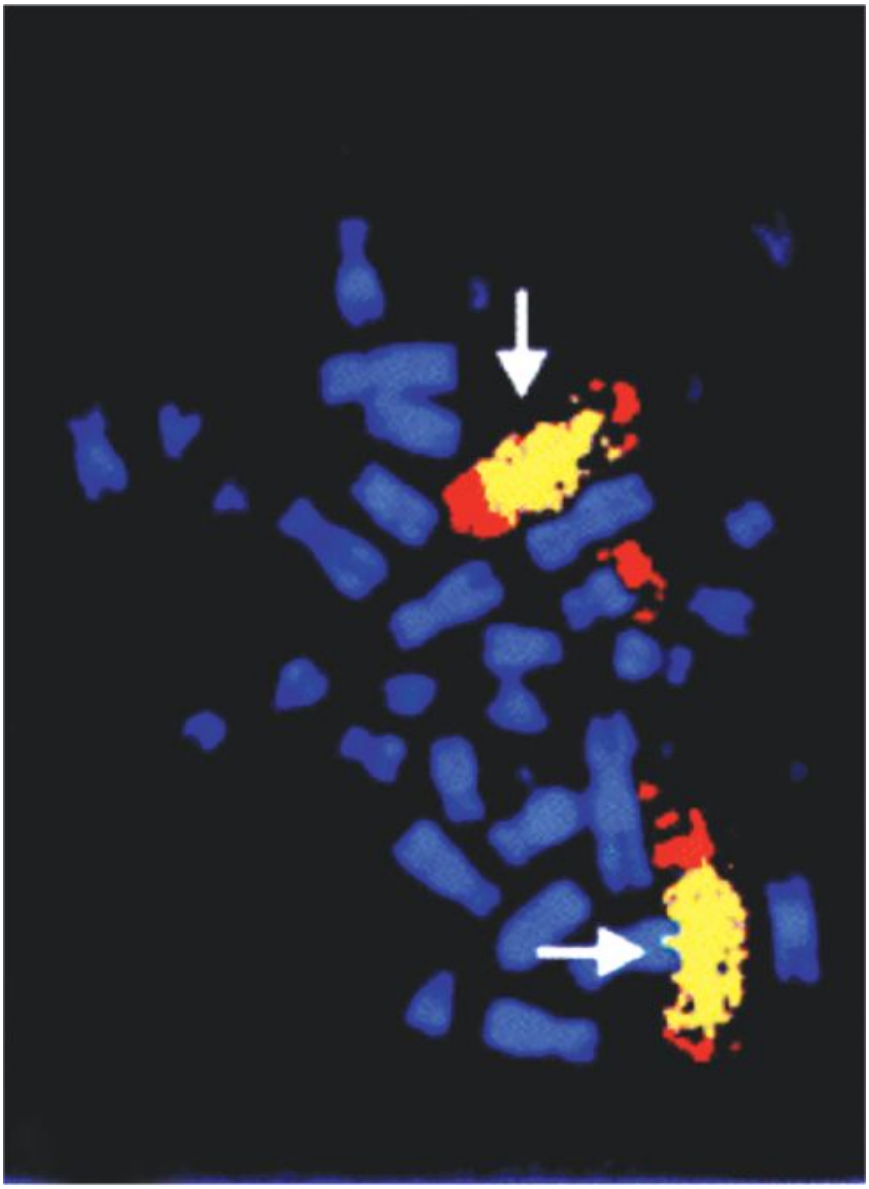
4.4 Variations on a theme: the *myc* oncogene can arise via at least three additional distinct mechanisms

The observation that the v-*myc* oncogene of avian myelocytomatosis virus (MC29) arose largely through deregulation of its expression only hints at the diverse mechanisms that are capable of creating this oncogene. As mentioned in Section 4.2, in some human tumors, expression of the *myc* gene continues to be driven by its own natural transcriptional promoter but the copy number of this gene is found to be elevated to levels many times higher than the two copies present in the normal human genome. In 30% of childhood neuroblastomas, a close relative of the c-*myc* gene, termed N-*myc*, has also been found to be amplified, specifically in the more aggressive tumors of this type (**Sidebar 4.1**). In both instances, the increased gene copy numbers result in corresponding increases in the level of gene products—the Myc and N-Myc proteins. As we will discuss later in Chapter 8, proteins of the Myc family possess potent growth-promoting powers. Consequently, when present at excessive levels, these proteins seem to drive uncontrolled cell proliferation.

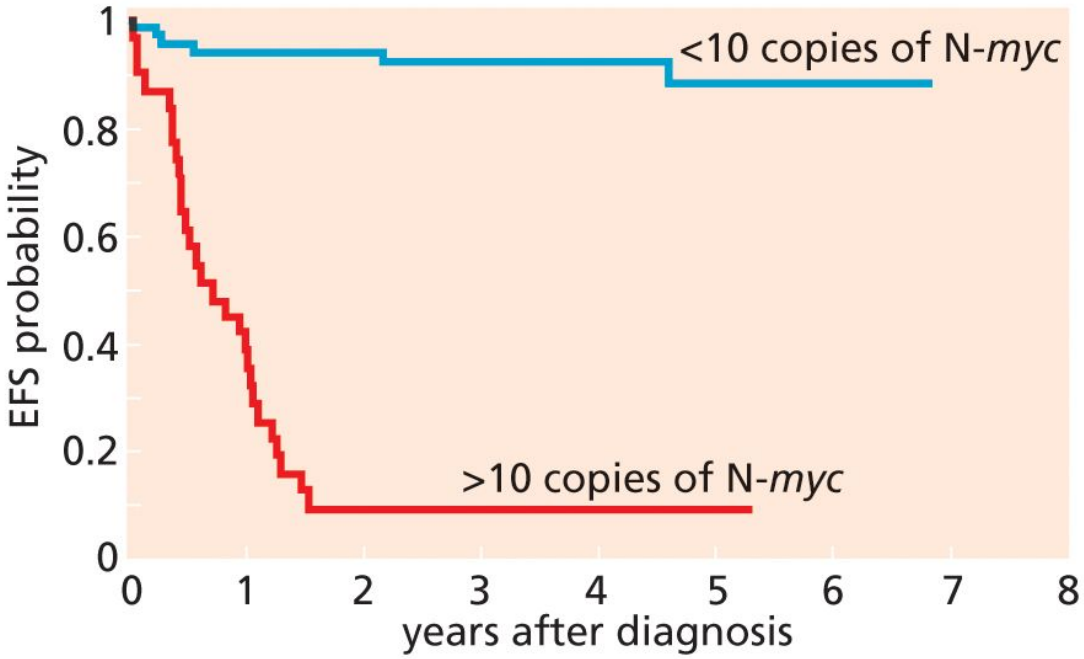
Sidebar 4.1 N-*myc* amplification and childhood neuroblastomas

Amplification of the N-*myc* gene occurs in about 30% of advanced pediatric neuroblastomas, which are tumors of the peripheral nervous system. This amplification, which is associated with the formation of either double minutes (DMs) or homogeneously staining regions (HSRs; see Figure 1.9A and B), represents a bad prognosis for the patient (**Figure 4.7**). The HSRs, which contain multiple copies of the genomic region encompassing the N-*myc* gene, are often found to have broken away from the normal chromosomal mapping site of N-*myc* and, in one study, to have become associated with at least 18 other different chromosomal regions. While N-*myc* amplification was originally thought to be a peculiarity of neuroblastomas (and thus a specific diagnostic marker for this particular disease), it has now been found in a variety of neuroectodermal tumors, including astrocytomas and retinoblastomas; in addition, small-cell lung carcinomas, which have neuroendocrine traits, often exhibit amplified N-*myc* genes.



A fluorescence microscopy image of chromosomes at high magnification. Most appear dark blue against a black background, but two are bright yellow with red ends.

(A)



A time plot with years after diagnosis on the horizontal axis and event-free survival probability on the vertical axis. There are two curves, one red and one blue, which both begin at 1.0 on the vertical axis at 0 years. The red curve, labeled more than 10 copies of N-m y c, drops to just under 0.1 within about 1.5 years and then remains flat out past 5 years. The blue curve, labeled less than 10 copies of N-m y c, declines more gradually, to under 0.9 in about 4.6 years and then remains flat out to just under 7 years.

(B)

Figure 4.7 N-*myc* amplification and neuroblastoma prognosis (A) The N-*myc* gene is often amplified in human childhood neuroblastomas. Here, use of fluorescence *in situ* hybridization (FISH) has revealed multiple copies of this gene (*yellow*). The fact that these N-*myc* gene copies are present as tandem arrays within chromosomes means that they constitute homogeneous staining regions (HSRs) rather than extrachromosomal particles—double minutes (DMs)—which are also frequently seen in these tumors (see also Figure 1.10). (B) This Kaplan–Meier plot illustrates the event-free survival (EFS) of children suffering from neuroblastoma, that is, no clinically significant cancer-related symptoms in the indicated years following initial diagnosis and treatment. Those whose tumor cells have minimal or no N-*myc* amplification have a very good prognosis and minimal clinical events, while those whose tumors exhibit extensive N-*myc* amplification have a dramatically poorer prognosis and therefore short survival times after diagnosis. Note, by the way, the notations that are used here and throughout this text. Nonhuman oncogenes are usually written as uncapitalized three-letter words in italics (for example, *myc*), while their protein products are written in roman font with an initial capital (for example, Myc). The *myc* proto-oncogene itself is often termed c-*myc* to distinguish it from its two cousin genes, N-*myc* and L-*myc*. To make matters more confusing, human genes follow a different nomenclature, so that the human *myc* gene is denoted as *MYC* and its protein product is written as MYC. We will generally use the nonhuman acronym conventions throughout this book.

The gene amplification process, which is responsible for increases in *myc* copy number, occurs through the preferential replication of a limited region of chromosomal DNA, leaving the more distantly located chromosomal regions unaffected (see **Supplementary Sidebar 4.4**). Since the region of chromosomal DNA that undergoes amplification—the amplicon—usually includes a stretch of DNA far longer than the c-*myc* or N-*myc* gene (for example, typically including 0.5 to 10 megabases of DNA), the amplified chromosomal regions are often large enough to be observed at the metaphase of mitosis through a light microscope. Often gene amplification yields large, repeating end-to-end linear arrays of the chromosomal region, which appear as homogeneously staining regions (HSRs) in the microscope (see Figure 1.9A). Alternatively, the chromosomal region carrying a *myc* or N-*myc* gene may break away from the chromosome and can be seen as small, independently replicating, extrachromosomal particles (double minutes; see Figure 1.9B). Indeed, we now know that a number of proto-oncogenes can be found in amplified gene copy number in various types of human tumors (**Table 4.3**). A 2010 survey found that altogether 77 genes in the genomes of human cancer cells are found to be recurrently amplified, indicating that increased copy number of each of these confers an advantageous phenotype on the cells that develop them.

Table 4.3 Some frequently amplified chromosomal regions and the genes they are known to carry

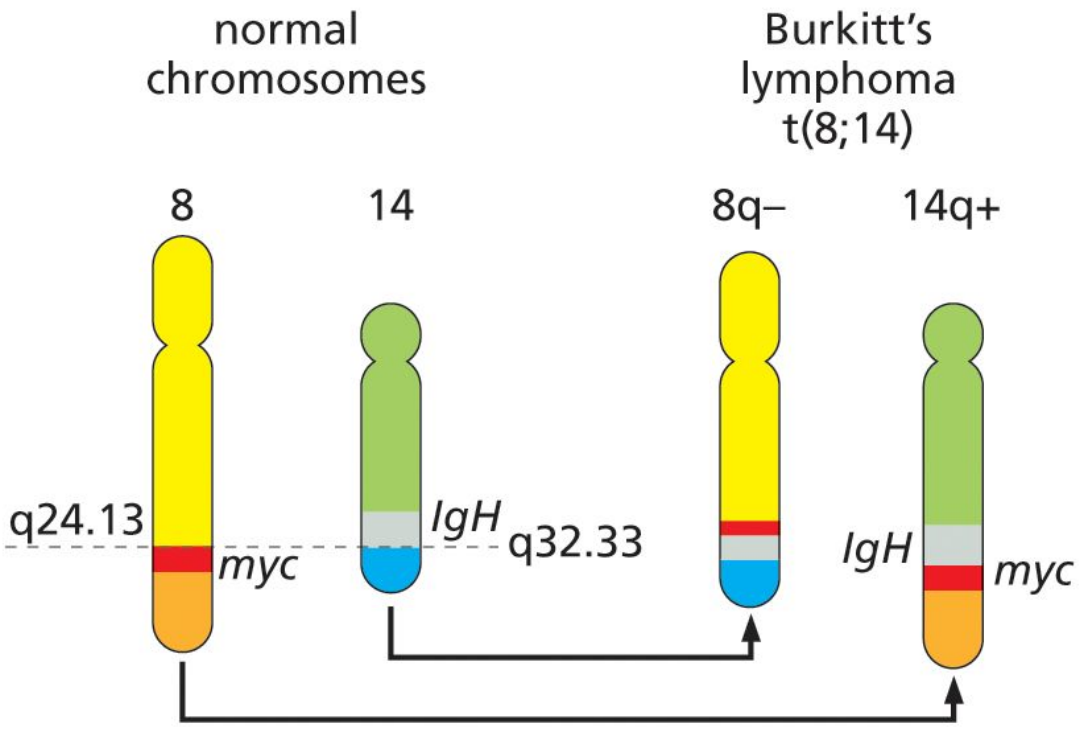
As Figure 4.4 indicates, certain types of tumor, such as Wilms tumor, show multiple regions of chromosomal amplification, while others, such as Ewing's sarcoma, usually exhibit amplification of only a single chromosomal region. In most cases, the identities of the critical growth-promoting genes in these chromosomal regions remain elusive. Even within a single tumor, such as the breast cancers described above, multiple chromosomal regions that have undergone gene amplification are often found (see Table 4.3). As discussed later (Chapter 11), these multiple changes are thought to collaborate with one another to create the fully neoplastic phenotypes of cancer cells. The molecular mechanisms responsible for generating gene amplifications remain poorly understood; however, in the case of tandem duplications that yield HSRs, detailed structural analyses of amplified genes have provided good clues as to how these may occur (see **Supplementary Sidebar 4.4**).

An even more unusual way of deregulating *myc* expression levels has already been cited (see Section 3.11). Recall that the insertional mutagenesis mechanism generated by integrated retrovirus proviruses causes the expression of the c-*myc* proto-oncogene

to be placed under the transcriptional control of an ALV provirus that has integrated nearby in the chromosomal DNA. The resulting constitutive overexpression of c-*myc* RNA and thus Myc protein results, once again, in flooding of the cell with excessive growth-promoting signals.

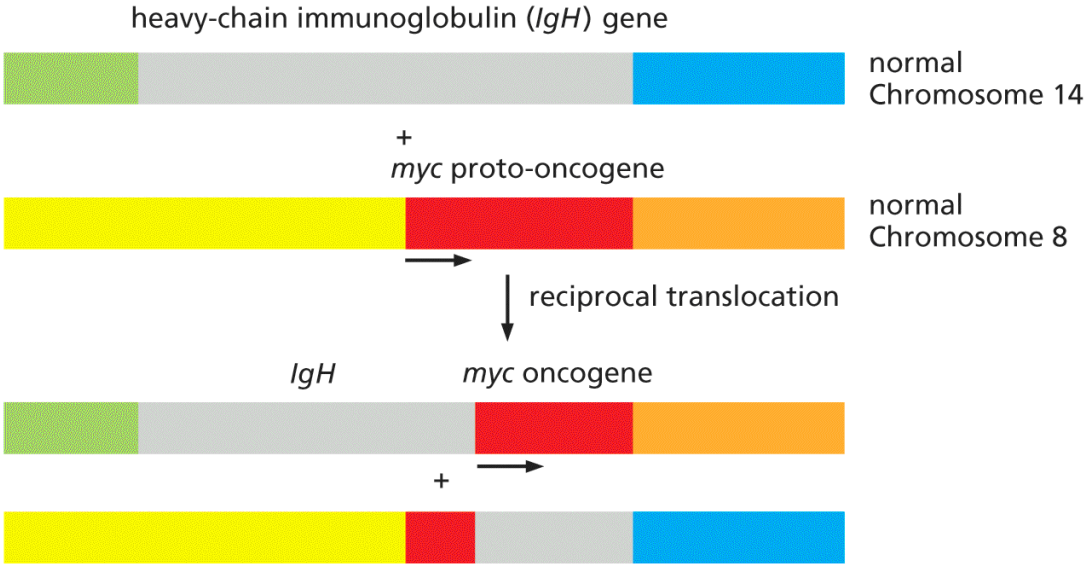
Such activation by provirus integration hinted at a more general mode of activation of the c-*myc* proto-oncogene: even while continuing to reside at its normal chromosomal site, c-*myc* can become involved in cancer development if it happens to come under the control of foreign transcriptional promoters. In the disease of Burkitt's lymphoma (BL), this principle was validated in a most dramatic way. This tumor occurs with significant frequency among young children in East and Central Africa (**Supplementary Sidebar 4.7**). The etiologic agents of this disease include chronic infections both by Epstein–Barr virus (EBV, a distant relative of human herpesviruses; Section 3.4) and by malarial parasites, which appear to contribute to tumor pathogenesis by suppressing the immune response to EBV.

Neither of these etiologic factors sheds light on the nature of a critical genetic change occurring inside Burkitt's lymphoma cells that is responsible for their runaway proliferation. However, careful examination of metaphase chromosome spreads of these tumor cells uncovered a striking clue: the tumor cells almost invariably carried chromosomal translocations (see also Figure 2.20). Such alterations fuse a region from one chromosome with a region from a second, unrelated chromosome (**Figure 4.8**). Translocations were usually found to be *reciprocal*, in the sense that a region from chromosome A lands on chromosome B, while the displaced segment of chromosome B ends up being linked to chromosome A. In the case of Burkitt's lymphomas, three distinct, alternative chromosomal translocations were found, involving human Chromosomes 2, 14, or 22. The three translocations were united by the fact that in each case, a region from one of these three chromosomes was fused to a section of Chromosome 8.



Chromosomes 8 and 14, each in its normal and its translocated state. A dashed line labeled q24.13 on the left and q32.33 on the right indicates where on each chromosome the break occurs, in a t(8;14) translocation that produces abnormal chromosomes 8q minus and 14q plus.

(A)



The t(8;14) translocation more schematically and in greater detail. Normal chromosome 14 contains a heavy-chain immunoglobulin (I g H) gene, shown in gray, followed by a blue end, while normal chromosome 8 contains an m y c proto-oncogene, in red, followed by an orange end. During translocation, most of the red m y c and all of the orange tail moves onto chromosome 14, displacing part of the gray l g H and all of the blue tail, which moves onto chromosome 8. Chromosome 14 now has an m y c oncogene next to l g H.

(B)

Figure 4.8 Chromosomal translocations in Burkitt's lymphomas (A) In the genomes of Burkitt's lymphoma (BL) cells, the expression of the c-*myc* gene is placed under control of the transcription-controlling enhancer sequences (see Figure 1.15) of an immunoglobulin gene as a direct consequence of reciprocal chromosomal translocations. These translocations juxtapose immunoglobulin genes on Chromosomes 2, 14, or 22 with the *myc* gene on Chromosome 8. (Translocations involving either the κ, λ, or heavy immunoglobulin chain occur in 9%, 16%, and 75% of BLs, respectively.) The most common translocation, t(8;14), is shown here. (B) Depicted is a molecular map of the translocation event that places the c-*myc* gene (*red rectangle*) on Chromosome 8 under the control of the immunoglobulin heavy-chain sequences (*IgH; gray rectangle*) on human Chromosome 14. Because the immunoglobulin enhancer sequences (see Figure 1.15) direct high, constitutive expression, the normal modulation of *myc* expression in response to physiologic signals is abrogated. The resulting *myc* oncogene initially makes structurally normal Myc protein but in abnormally high amounts. (Subsequently occurring point mutations in the *myc* reading frame may further potentiate the function of the Myc oncoprotein.) (Data from P. Leder et al., *Science* 222:765–771, 1983.)

In 1982 researchers realized that the *myc* (that is, c-*myc*) proto-oncogene could be found in the region on human Chromosome 8 that is involved in all three of these translocations. On the other side of the fusion site (often termed the chromosomal breakpoint) were found the transcription-promoting sequences from any one of three distinct immunoglobulin (antibody) genes. Thus, the immunoglobulin heavy-chain gene cluster is found on Chromosome 14, the κ antibody light-chain gene is located on Chromosome 2, and the λ antibody light-chain gene is found on Chromosome 22. There is clear evidence that the enzymes responsible for rearranging the sequences of antibody genes during the development of the immune system (described in Chapter 15) occasionally lose specificity and, instead of creating a rearranged antibody gene, inadvertently fuse part of an antibody gene with the *myc* proto-oncogene. Parenthetically, none of this explains the role of EBV in the pathogenesis of Burkitt's lymphoma (**Supplementary Sidebar 4.8**).

Suddenly, the grand design underlying these complex chromosomal changes became clear, and it was a simple one: these translocations separate the *myc* gene from its normal transcriptional promoter and place it, instead, under the control of one of three highly active transcriptional regulators, each part of an immunoglobulin gene (see Figure 4.8). Once its expression is subjugated by the antibody gene promoters, *myc* becomes a potent oncogene and drives the relentless proliferation of lymphoid cells in which these transcriptional promoters are highly active. Hence, the proliferation of the rare cell that happens to acquire such a deregulated *myc* gene will be strongly favored.

Since these discoveries, several dozen distinct chromosomal translocations have been found to cause deregulated expression of known proto-oncogenes; many of these genes remain poorly characterized (**Table 4.4**). Altogether, more than 300 distinct recurring translocations (that is, those that have been encountered in multiple, independently arising human tumors) have been cataloged, and more than 100 of the novel hybrid genes created by these translocations have been isolated by molecular cloning. More often than not, each of these translocations can be found in a small set of hematopoietic tumors. However, solid tumors are increasingly found to harbor specific translocations, some quite common. For example, in 2005, ~70% of prostate carcinomas were found to harbor chromosomal translocations that lead to deregulated expression of one of two transcription factors (termed ERG and ETV1); given the high incidence of prostate cancer in Western populations, these may represent the most frequent translocations in human cancer. (Indeed, the dearth of translocations discovered to date in solid tumors may simply be a consequence of the difficulties of dissociating solid tumors and studying the karyotypes of their constituent cells.) Yet other chromosomal translocations function in an entirely different fashion to foster cancer outgrowth (**Sidebar 4.2**).

Table 4.4 Translocations in human tumors that deregulate proto-oncogene expression and thereby create oncogenes

Oncogene	Neoplasm
myc	Burkitt’s lymphoma; other B- and T-cell malignancies
bcl-2	follicular B-cell lymphoma
bcl-3	chronic B-cell lymphoma

bcl-6	diffuse B-cell lymphoma

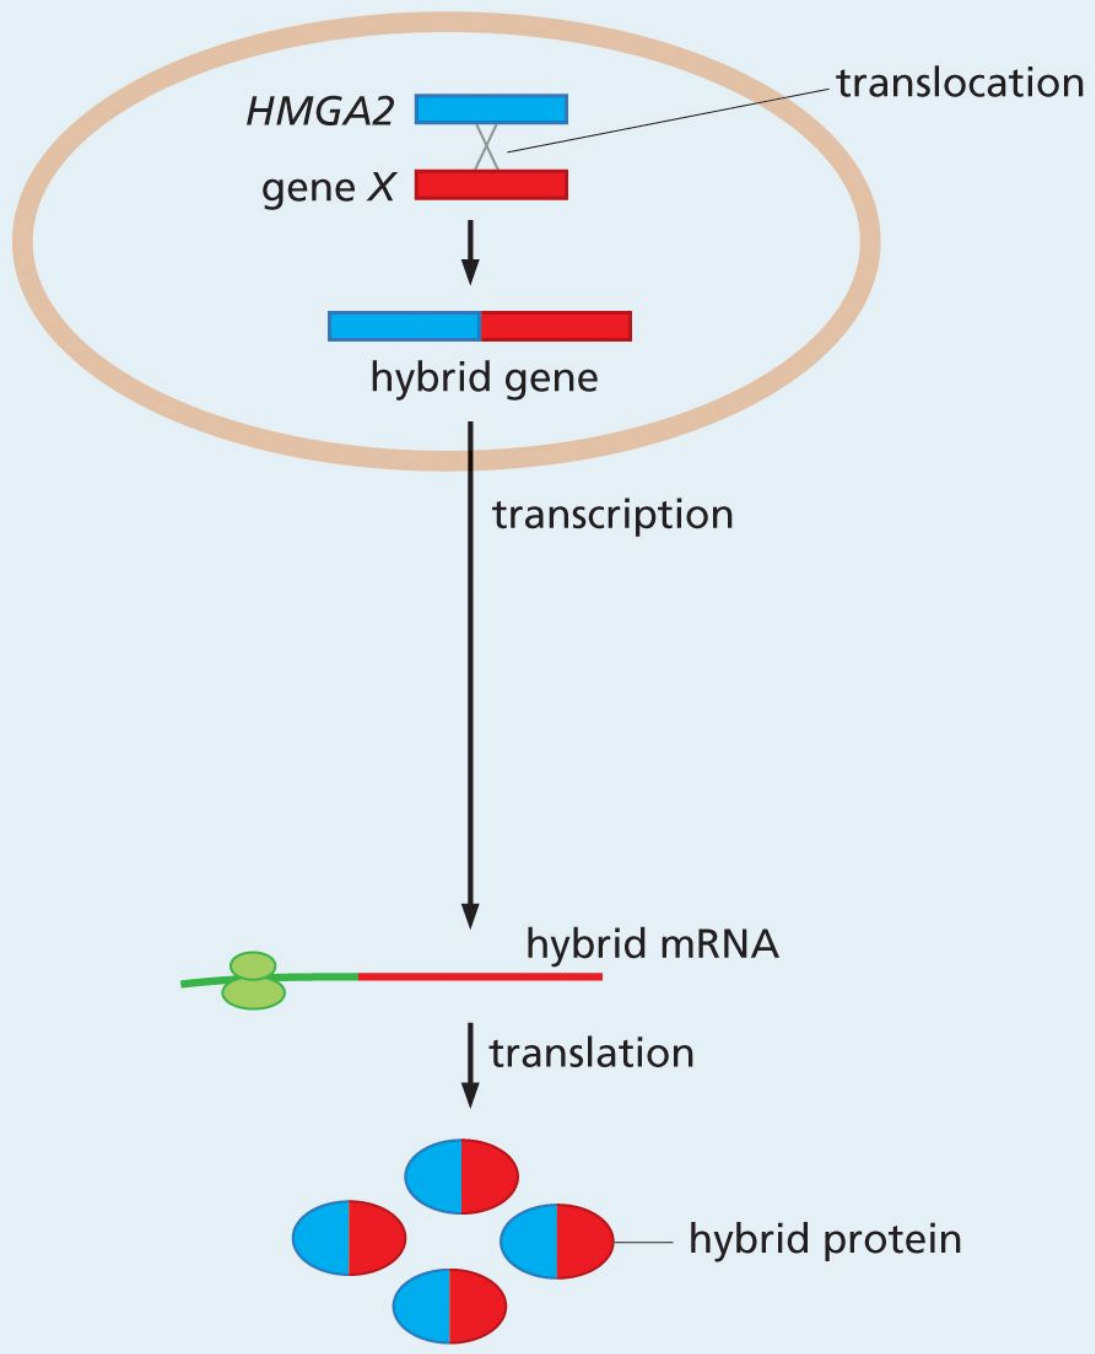
Sidebar 4.2 Chromosomal translocations can act indirectly to perturb levels of gene expression

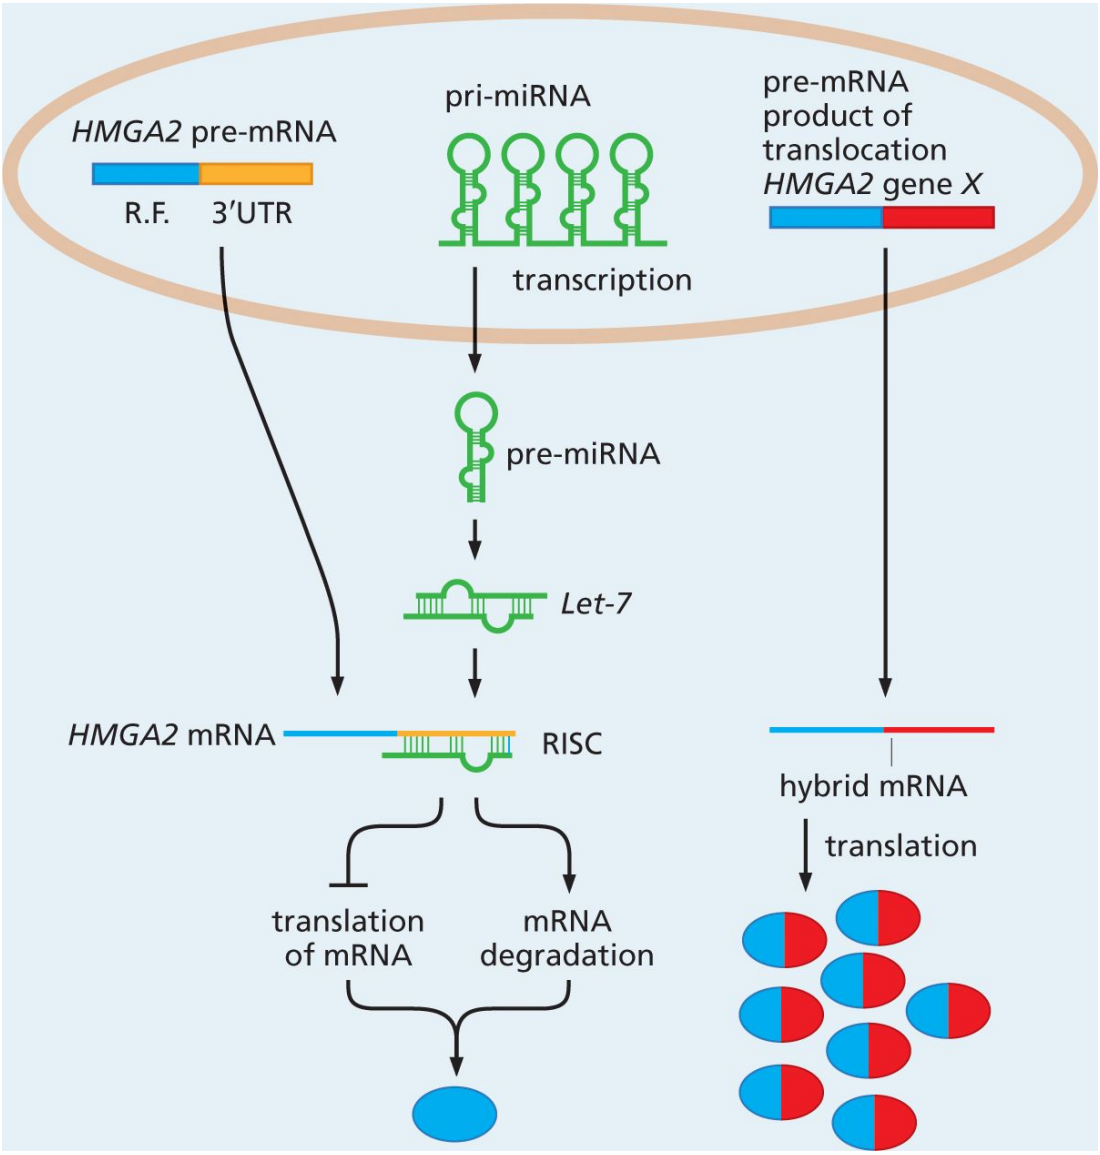
The discovery of microRNAs and the roles they play in gene regulation (see Section 1.9) have made it possible to understand certain chromosomal translocations whose precise molecular mechanisms-of-action were previously obscure. In one case, a small non-histone nuclear protein, termed HMGA2, is known to be overexpressed in a variety of benign and malignant tumors and to be capable of functioning as an oncoprotein. Its gene is frequently found to undergo translocations that sever the

sequences specifying the 3′ untranslated region (3′UTR) from the reading frame of the *HMGA2* mRNA while joining the reading frame of the *HMGA2* gene with that of a second gene (**Figure 4.9**). It was long assumed that the resulting fusion protein enhanced the oncogenic functions of HMGA2 (similar to situations that we will encounter shortly in Section 4.5). However, deletion of the protein sequences that became fused to HMGA2 did not affect the transforming powers of the hybrid protein. This led to the realization that the translocation served another purpose: it caused deletion of seven recognition sites for the *Let-7* microRNA (see Section 1.9) that are normally present in the 3′UTR of the *HMGA2* mRNA. This loss, in turn, enables the resulting mRNA to escape *Let-7*–mediated translational inhibition and eventual degradation. The end result is greatly increased levels of the *HMGA2* mRNA and protein, which proceeds, via still poorly understood mechanisms, to alter chromatin configuration (see Section 1.8) and thereby to facilitate cell transformation. In this instance, translocations serve to liberate a proto-oncogene from negative regulation rather than fusing it with a positive regulator.



A translocation within the nucleus fuses H M G A 2 with gene X to form a hybrid gene. From there, transcription produces hybrid R N A outside the nucleus, and then translation produces multiple copies of a hybrid protein.

(A)



Normally, transcription of p r i-micro R N A within the nucleus produces p r e-micro R N A outside the nucleus, which produces the Let-7 protein. This protein binds to the 3 prime untranslated region of H M G A 2 pre-m R N A to form an R N A-induced silencing complex. This suppresses translation of m R N A and promotes m R N A degradation. The result is production of a small amount of protein corresponding only to the reading frame on H M G A 2. When translocation instead produces p r e-m R N A consisting of H M G A 2 joined to gene X, translation of the resulting hybrid m R N A produces many hybrid proteins.

(B)

Figure 4.9 Translocations liberating an mRNA from miRNA inhibition The *HMGA2* gene encodes a chromatin-binding, proliferation-promoting protein whose biochemical function is still poorly understood; this protein (often present as a hybrid protein in which HMGA2 is fused to the protein encoded by a second gene) is expressed at elevated levels in a variety of cancer cell types in the absence of detectable gene amplification. (A) A chromosomal translocation that fuses the *HMGA2* (*aquamarine*) gene with a second gene (gene *X*, *red*) was initially assumed to create a hybrid fusion protein whose two domains collaborated to form a functional oncoprotein. (B) The true functional consequence of such a translocation was later realized to derive from severing the reading frame (R.F.) of the *HMGA2* mRNA (*blue*) from its 3′ untranslated region (3′UTR, *orange*). In the 3′UTR of this mRNA there are normally seven recognition sites that are bound by the *Let-7* microRNA (*green*); this binding reduces translation of the mRNA and drives its degradation, resulting in suppression of HMGA2 protein synthesis. (Only a single binding site is illustrated here.) These recognition sites are absent in the novel hybrid mRNA, allowing this mRNA to escape inhibition by *Let-7*; this results in synthesis of greatly increased amounts of the hybrid protein (right). Importantly, the domain of the novel protein that is encoded by the fusion partner gene (gene *X*, *red*) does not contribute to the oncogenic functions of the resulting protein. (Adapted from A.R. Young and M. Narita, *Genes Dev*. 21:1005–1009, 2007. With permission from Cold Spring Harbor Laboratory Press.)

In another case, chromosomal translocations, like those involving *myc*, have been found to drive enhanced expression of a microRNA by fusing the miRNA-encoding gene with a foreign transcriptional promoter. In tumors with such translocations—myelodysplasia and associated acute myelogenous leukemias—the resulting overexpressed miRNA blocks differentiation of cells, trapping them in a phenotypic state where they can evolve into highly aggressive tumors. This discovery, along with others that followed, resolves the long-standing mystery of how it is possible for chromosomal translocations that do not involve protein-encoding genes to affect cell behavior.

Returning to *myc*, we see that there are three alternative ways of activating the c-*myc* proto-oncogene—through provirus integration, gene amplification, or chromosomal translocation—all converging on a common mechanistic theme. Invariably, the gene is deprived of its normal physiologic regulation and is forced instead to be expressed at high, constitutive levels.

In general, the mechanisms leading to the overexpression of genes in cancer cells remain poorly understood. Some overexpression, as indicated here, is achieved through gene amplification and chromosomal translocation. But even more frequently,

genes that are present in normal configuration and at normal copy number are transcribed at excessively high levels in cancer cells through the actions of deregulated transcription factors; the latter are largely uncharacterized. To complicate matters, gene amplification does not always lead to overexpression. Instead, only 40 to 60% of the genes that are found to be amplified in cancer cell genomes show corresponding increases in their RNA transcripts (and thus proteins). Such observations indicate that the expression levels of many genes are regulated by complex negative-feedback mechanisms that ensure physiologically appropriate levels of expression even in the presence of excess copies of these genes.

OceanofPDF.com

Glossary

amplicon
: A defined stretch of (chromosomal) DNA that undergoes amplification flanked on both sides by DNA segments that are present in normal copy number.

translocation
: (1) Rearrangement of chromosomes that results in the fusion of two chromosomal segments that are not normally attached to one another, often resulting in a microscopically visible alteration of karyotype. (2) Movement of a physical entity from one part of the cell to another. (3) Movement of a ribosome down an mRNA being translated.

breakpoint
: Location in a chromosomal region or gene at which it becomes fused through chromosomal translocation with another chromosomal region or gene.

immunoglobulin
: An antibody molecule assembled from two heavy and two light chains.

myelodysplasia
: Condition in which incompletely differentiated cells of one or another myeloid lineage accumulate in the blood, often accompanied by a reduction in the concentration within the circulation of properly differentiated cells of bone marrow origin.

negative feedback
: A regulatory process whereby a stimulatory signal upstream in a signaling pathway activates a downstream target that proceeds to inhibit the source of the initial upstream signal, thereby reducing further overall signaling. *See also* **positive feedback**.

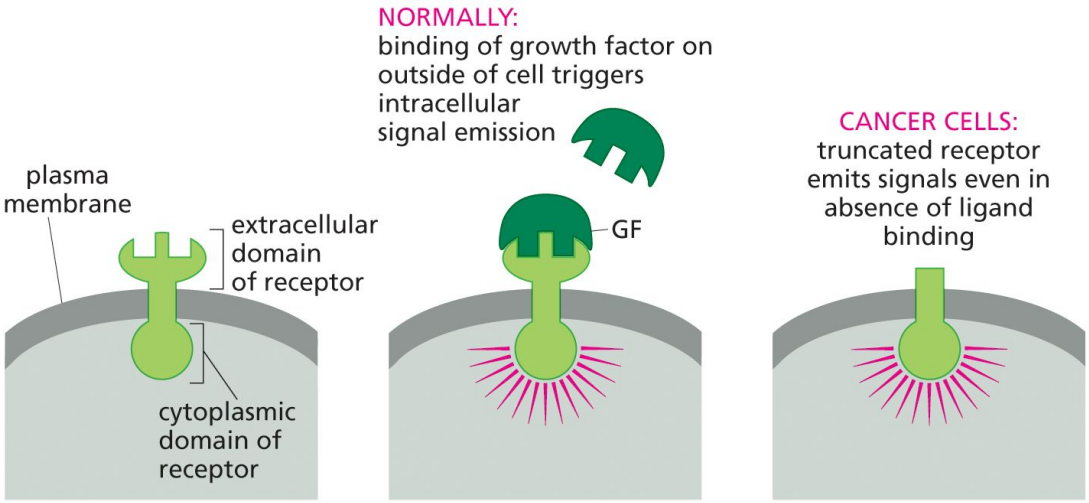
4.5 A diverse array of structural changes in proteins can also lead to oncogene activation

The point mutation discovered in *ras* genes was the first of many mutations that were found to affect the structures of proto-oncogene–encoded proteins (rather than their expression levels), converting them into active oncoproteins. As an important example, the formation of certain human tumors, such as gastric and mammary carcinomas and glioblastoma brain tumors, involves the protein that serves as the cell surface receptor for epidermal growth factor (EGF). As we will discuss in detail in the next chapter, this receptor protein extends from the extracellular space through the plasma membrane of cells into their cytoplasm. Normally, the EGF receptor, like almost 60 similarly structured receptors, recognizes the presence of one of its cognate ligands (notably EGF) in the extracellular space and, having bound this ligand, informs the cell interior of this encounter. In about one-third of glioblastomas, however, the EGF receptor has been found to be decapitated, lacking most of its extracellular domain (**Figure 4.10**). We now know that such truncated receptors send growth-stimulatory signals into cells, even in the absence of any EGF. In so doing, they act as oncoproteins to drive cell proliferation. In Chapter 5, we will describe more precisely how structural alterations of growth factor receptors convert them into potent oncoproteins.

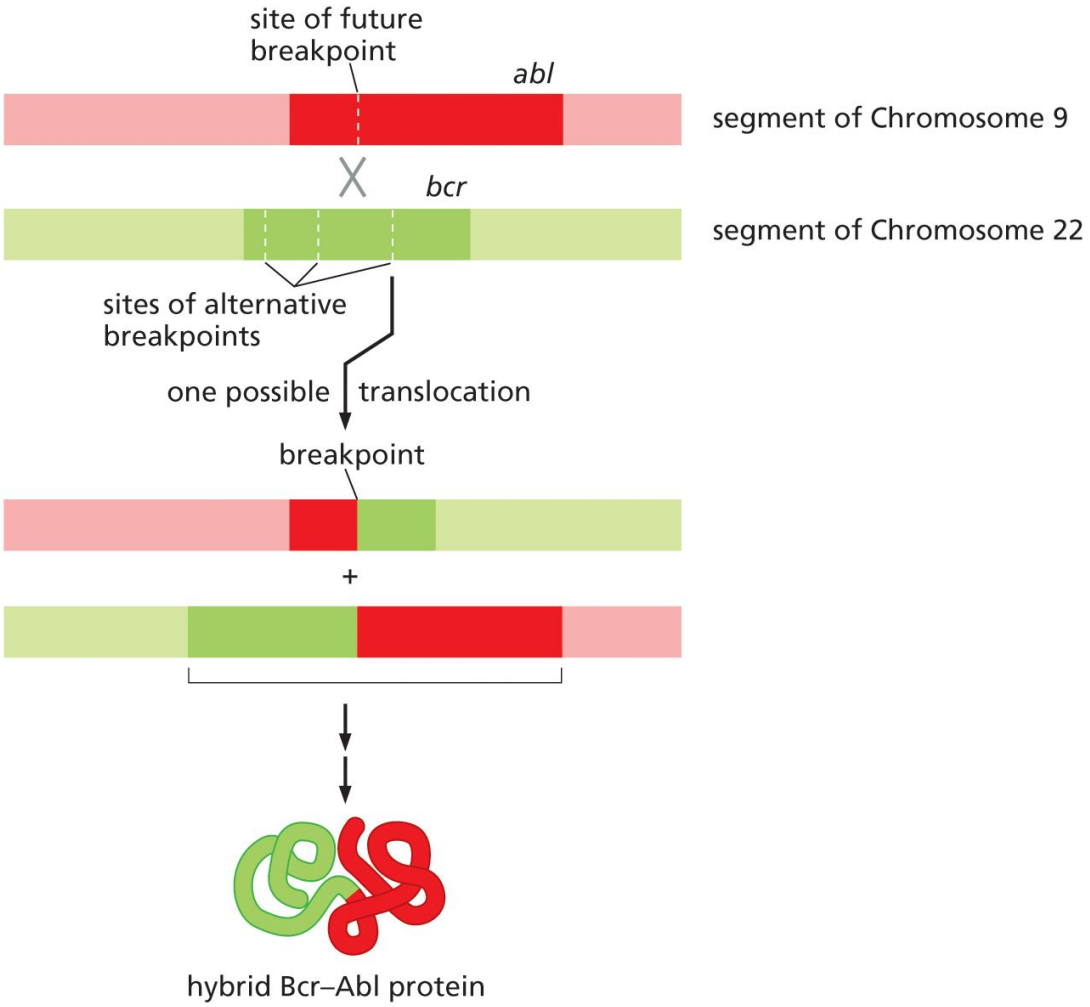


An illustration shows the behavior of growth factor surface receptors in normal cells and in cancer cells. A surface receptor within a plasma membrane has a cytoplasmic domain at one end and an extracellular domain at the other end.

Normally, the extracellular domain corresponds, in lock-and-key fashion, to a particular growth factor, and it is the binding of that growth factor to the extracellular domain which triggers signal emission on the cytoplasmic side. In cancer cells, the extracellular domain is truncated, and signal emission on the cytoplasmic side occurs even in the absence of any growth factor ligand binding.
Figure 4.10 Deregulated firing of growth factor receptors Normally, growth factor receptors displayed on the plasma membrane of a cell release signals into the cell interior only when the extracellular domain of the receptor has bound the appropriate growth factor (GF; i.e., the *ligand* of the receptor, *dark green*). However, if the extracellular domain of certain receptors is deleted because of a mutation in the receptor-encoding gene or alternative splicing of the receptor pre-mRNA, the resulting truncated receptor protein then emits signals into the cell without binding its growth factor ligand.

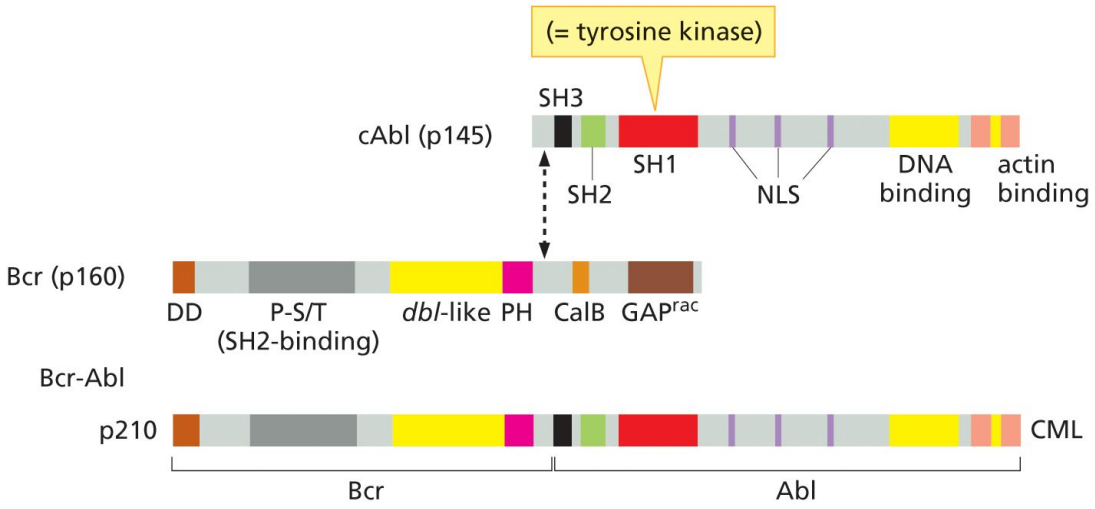
The chromosomal translocations cited in the previous section result, in one way or another, in *deregulated expression* of oncogenic proteins or microRNAs; even more common are translocations that lead to the formation of *novel hybrid proteins* and thereby create functionally altered proteins. The best known of these are the chromosomal translocations found in more than 95% of the cases of chronic myelogenous leukemia (CML; see Figure 2.20). These CML translocations, which result in the synthesis of hybrid proteins, contrast with those found in Burkitt's lymphomas (see Figure 4.8), in which the *transcription-regulating* sequences of one gene are juxtaposed with the reading frame of a second gene.

To the right of the CML translocation breakpoint illustrated in **Figure 4.11** are sequences that encode the protein made by the *abl* proto-oncogene. The *abl* gene was originally discovered by virtue of its presence as an acquired oncogene in **Abe**l**l**son murine leukemia virus, a rapidly tumorigenic retrovirus (refer to Table 3.3). The *abl* gene, which maps to Chromosome 9q34 (that is, the fourth band of the third region of the long arm of human Chromosome 9), was found, upon examination of various CMLs, to be fused with sequences that are clustered in a narrow region in Chromosome 22q11. [The standard notation used here is t(9;22)(q34;q11), where t signifies a translocation, q the long arm, and p the short arm of a chromosome.] This area on Chromosome 22 was called the **b**reakpoint **c**luster **r**egion. Subsequently, all of these breakpoints were found to lie within the gene that came to be called *bcr*. The resulting fusion of Abl with Bcr amino acid sequences deregulates the normally well-controlled Abl protein, causing it to emit growth-promoting signals in a strong, deregulated fashion. (Two other alternative breakpoints in the *bcr* gene result in the formation of the slightly different Bcr–Abl fusion proteins found in other hematopoietic malignancies; these alternative Bcr–Abl proteins are not illustrated in Figure 4.11.)



The translocation of segments of chromosomes 9 and 22. A segment of chromosome 9 contains the a b l gene, within which a future breakpoint site is marked, and a segment of chromosome 22 contains the b c r gene, within which three possible alternative breakpoint sites are marked. One of the three possible translocations is shown to result in a hybrid B c r–A b l protein.

(A)



The domain structures of three proteins. The first, p145, is encoded by c A b l. It contains S H 3 and S H 2 segments, an S H 1 segment which is tyrosine kinase, then three N L S segments followed by a D N A binding segment, and finally an actin binding segment. The second protein, p160, is encoded by B c r. It contains a D D segment, a P-S slash T d b l-like S H 2-binding segment, a P H segment, and finally Cal B and G A P r a c segments. The third protein, p210, is the Ba hybrid protein. It contains all the named segments from p145 and segments D D through P H from p160.

(B)

Figure 4.11 Formation of the *bcr–abl* oncogene (A) Reciprocal chromosomal translocations between human Chromosomes 9 and 22, which carry the *abl* and *bcr* genes, respectively, result in the formation of fused, hybrid genes that encode hybrid Bcr–Abl proteins commonly found in chronic myelogenous leukemias (CML). Two other alternative breakpoint sites in the *bcr* gene are involved in *bcr–abl* translocations (*not shown here*) arising in certain other hematopoietic malignancies. (B) The domain structures of the proteins encoded by the normal *bcr* and *abl* genes are shown here (*above and middle*). Each is a multidomain, multifunctional protein, as indicated by the labels attached to the colored areas. The chromosomal translocation found in almost all cases of CML results in the fusion of most of the reading frame of the *Bcr* gene with most of the reading frame of the *Abl* gene (*below*). The approximate locations of the translocation breakpoint are indicated by the double-headed arrow. The fusion causes deregulated firing of the tyrosine kinase of the fusion protein, which is equivalent to the SH1 domain labeled here; this firing (to be discussed in Section 6.3) is responsible for most of the transforming effects of the newly formed oncoprotein. (B, adapted from A.M. Pendergast, in A.M. Carella, Chronic Myeloid Leukaemia:

Biology and Treatment. London: Martin Dunitz, 2001. With permission from Taylor and Francis.)

Since the discovery of the *bcr–abl* translocation, dozens of other, quite distinct translocations have been documented that also result in the formation of hybrid proteins, most but not all of which are encountered in small subsets of hematopoietic tumors (for examples, see **Table 4.5**). Possibly the greatest diversity derives from the *MLL1* (mixed-lineage leukemia) gene, occasionally termed *ALL1*, which encodes a histone methylase (see Section 1.8); it participates in translocations with at least 50 distinct fusion-partner genes, resulting in a diverse array of hybrid proteins, all of which appear to affect chromatin structure and function. Because each type of translocation is found only rarely, the functions of many of the resulting hybrid proteins remain obscure. In the case of solid tumors, an example of such fusion proteins comes from a class of pediatric tumors—alveolar rhabdomyosarcomas—80% of which are found to harbor a translocation that fuses the domains of two transcription factors (PAX3 or PAX7 and FKHR), thereby yielding a protein with far more potent transcription-activating powers than either of its two normal precursors possessed. (This novel transcription factor seems to expand the population of skeletal muscle progenitor cells, thereby setting the stage for acquisition of additional mutations that then lead to the eruption of highly aggressive tumors.) Yet other less common chromosomal rearrangements, such as inversions of discrete segments of DNA, may also serve to generate novel oncogenes and often novel oncoproteins.

Table 4.5 Translocations in human tumors that cause the formation of oncogenic fusion proteins of novel structure and function

Oncogene	**Neoplasm**
bcr/abl	chronic myelogenous leukemia; acute lymphocytic leukemia
dek/can	acute myeloid leukemia
E2A/pbx1	acute pre-B-cell leukemia
PML/RAR	acute promyelocytic leukemia

Oncogene	**Neoplasm**

Every chromosomal rearrangement, even those occurring repeatedly in many tumors of a given type, appears to represent the product of an exceedingly rare genetic accident. Some of these accidents generate deregulated gene or protein expression while others encode novel hybrid proteins. However, once formed, these translocations clearly favor the outgrowth of the cells that carry them, this being indicated by the presence of these chromosomal translocations in all of the neoplastic cells within resulting tumors.

Glossary

receptor
: Protein found on the plasma membrane or in the nucleus within a cell that is capable of specifically binding a signaling molecule (its cognate ligand). Most types of receptors emit signals, such as those inducing cell proliferation, in response to such binding. *See also* **ligand**.

ligand
: Molecule that binds specifically to a receptor and thereby activates its signaling powers. *See also* **receptor**.

chronic myelogenous leukemia
: An excess of the cells originating in the bone marrow that are precursors of granulocytes; these cells accumulate in large numbers in the blood of patients. *See also* **granulocyte**.

4.6 Synopsis and prospects

By the late 1970s, disparate lines of evidence concerning cancer genes coalesced into a relatively simple idea. The genomes of mammals and birds contain a cohort of proto-oncogenes, which function to regulate normal cell proliferation and differentiation. Alterations of these genes that affect either the control of their expression or the structure of their encoded proteins can lead to overly active growth-promoting genes, which appear in cancer cells as activated oncogenes. Once formed, such oncogenes proceed to drive cell multiplication and, in so doing, play a central role in the pathogenesis of cancer.

Many of these cellular genes were originally identified because of their presence in the genomes of rapidly transforming retroviruses, such as Rous sarcoma virus, avian erythroblastosis virus, and Harvey sarcoma virus. Subsequently, transfection experiments revealed the presence of potent transforming genes in the genomes of cells that had been transformed by exposure to chemical carcinogens and cells derived from spontaneously arising human tumors. These tumor cells had no associations with retrovirus infections. Nonetheless, the oncogenes that they carried were found to be related to those carried by transforming retroviruses. This meant that a common repertoire of proto-oncogenes could be activated by two alternative routes: retrovirus acquisition or somatic mutation.

The somatic mutations that caused proto-oncogene activation could be divided into two categories—those that caused changes in the structure of encoded proteins and those that led to elevated, deregulated expression of these proteins. Mutations affecting structure included the point mutations affecting *ras* proto-oncogenes and the chromosomal translocations that yielded hybrid genes such as *bcr–abl*. Elevated expression could be achieved in human tumors through gene amplification or chromosomal translocations, such as those that place the *myc* gene under the control of immunoglobulin enhancer sequences.

These revelations about the role of mutant cellular genes in cancer pathogenesis eclipsed for some years the observations that certain human cancers, some of them quite common, are associated with and likely caused by infectious agents, notably viruses and bacteria. With the passage of time, however, the importance of infections in human cancer pathogenesis became clear. We now know that about one-fifth of human deaths from cancer worldwide are associated with tumors triggered by infectious agents. Thus, most of the 9% of worldwide cancer mortality caused by stomach cancer is associated with long-term infections by *Helicobacter pylori* bacteria. Six percent of cancer mortality is caused by carcinomas of the liver (hepatomas), almost all of which are associated with chronic hepatitis B and C virus infections. And the 5% of cancer mortality from cervical carcinomas is almost entirely attributable to human papillomavirus (HPV) infections (**Table 4.6**).

Table 4.6 Viruses implicated in human cancer causation

Virus[a]	**Virus family**	**Cells infected**	**Human malignancy**	**Transmission route**
EBV[b]	Herpesviridae	B cells	Burkitt's lymphoma	saliva
		oropharyngeal epithelial cells	nasopharyngeal carcinoma	saliva
		lymphoid	Hodgkin's disease[c]	?
HTLV-I	Retroviridae	T cells	non-Hodgkin's lymphoma	parenteral, venereal[d]

Virus[a]	Virus family	Cells infected	Human malignancy	Transmission route
HHV-8[e]	Herpesviridae	endothelial cells	Kaposi's sarcoma, body cavity lymphoma	venereal, vertical[d]
HBV	Hepadnaviridae	hepatocytes	hepatocellular carcinoma	parenteral, venereal
HCV	Flaviviridae	hepatocytes	hepatocellular carcinoma	parenteral
HPV	Papillomaviridae	cervical epithelial	cervical carcinoma	venereal
JCV[f]	Polyomaviridae	central nervous system	astrocytoma, glioblastoma	?
MCV	Polyomaviridae	Merkel cells in skin	Merkel cell carcinoma	?

Adapted in part from J. Butel, *Carcinogenesis* 21:405–426, 2000.

Somehow, we must integrate the carcinogenic mechanisms activated by these various infectious agents into the larger scheme of how human cancers arise—the scheme that rests largely on the discoveries, described in this chapter, of cellular oncogenes. In the case of most of the cancer-causing

viruses, it is clear that they introduce viral oncogenes into cells that contribute to the transformation phenotype. Included here are HPV, MCV, Epstein–Barr virus (EBV) and human herpesvirus type 8 (HHV-8).

Most of these viruses carry at least one gene that alters the physiology of the cells that it infects. In each case, it seems that these virus-induced changes are driven by the need of the virus to create an intracellular environment that is more hospitable for its own replication. Of note, the viral genes that induce these changes, which can fairly be termed viral oncogenes, have resided in viral genomes for millions—if not hundreds of millions—of years rather than being rare aberrations of the sort that have led to the formation of transforming retroviruses like Rous sarcoma virus (RSV). Hence, cancer, to the extent that it ensues from infections by these viruses, is an unintended side-effect of the changes favoring viral replication. In Chapters 8 and 9 we shall see precisely how several of these viral oncogenes function to deregulate cell proliferation and protect cells from apoptosis (programmed cell death), two critical changes that contribute to the formation of human cancers. Only in Chapter 11 do we return to HBV and HCV and the mechanisms by which they induce cancer without deploying viral oncogenes and oncoproteins.

In the next two chapters we focus on the cellular genes that trigger cancer as a consequence of somatic mutations and the various biochemical mechanisms-of-action of the encoded oncoproteins. At first, the discoveries of cellular oncogenes seemed, on their own, to provide the definitive answers about the origins and growth of human tumors. But soon it became clear that cellular oncogenes and their actions could explain only a part of human cancer development. Yet other types of genetic elements were clearly involved in programming the runaway proliferation of cancer cells. Moreover, a definitive understanding of cancer development depended on understanding the complex machinery inside cells that enables them to respond to the growth-promoting signals released by oncoproteins. So, the discovery of cellular oncogenes was a beginning, a very good one, but still only a beginning. Two decades of further work were required before a more complete understanding of cancer pathogenesis could be assembled.

Key concepts

- Unable to find tumor viruses in the majority of human cancers, researchers in the mid-1970s were left with one main theory of how most human cancers arise: the mutation by carcinogens of normal growth-controlling genes, converting them into oncogenes.
- To verify this model's prediction that transformed cells carry mutated genes functioning as oncogenes, a novel experimental strategy was devised: DNA from chemically transformed cells was introduced into normal cells—the procedure of transfection—and the recipient cells were then monitored to determine whether they too had become transformed.
- Cultures of NIH 3T3 cells that had been transfected with DNA from chemically transformed mouse cells yielded numerous transformants, which proved to be both anchorage-independent and tumorigenic; this indicated that the chemically transformed cells carried genes that could function as oncogenes and that oncogenes could arise in the genomes of cells independently of viral infections.
- Further experiments using human tumor donor cells transfected into murine cells showed that the oncogenes could act across species and tissue boundaries to induce cell transformation.
- The oncogenes detected in human tumor cells by transfection experiments and the oncogenes of transforming retroviruses were both found to derive from the same group of preexisting normal cellular genes. This meant that normal proto-oncogenes could be activated either by retrovirus-induced modifications or by somatic mutations.
- Proto-oncogenes were often found to be present in increased copy number in human tumor cell genomes, which suggested that gene amplification resulted in increased levels of protein products that favored the proliferation of cancer cells, an example being the amplification of the *myc* gene in a variety of human cancer types.
- The activation of proto-oncogenes via deregulation by retro viral transcriptional promoters was well documented. However, the mechanism(s) by which normal human proto-oncogenes became converted into oncogenes in the absence of viruses was not evident

until the discovery of a point mutation in the H-*ras* gene that yielded a structurally altered protein with aberrant behavior. This established a new mechanism for oncogene activation based on a change in the structure of an oncogene-encoded protein rather than the expression levels of such a protein.

- Both activation mechanisms—regulatory and structural—might collaborate to create an active oncogene.
- The *myc* oncogene was initially discovered in the genome of an avian retrovirus. This oncogene was found to be activated through three alternative mechanisms in cancer cells: provirus integration, gene amplification, and chromosomal translocation.
- Gene amplification occurs through preferential replication of a segment (an amplicon) of chromosomal DNA. The result may be repeating end-to-end linear arrays of the segment, which appear under the light microscope as homogeneously staining regions (HSRs) of a chromosome. Alternatively, the region carrying the amplified segment may break away from the chromosome and be seen as small, independently replicating extrachromosomal particles (double minutes, DMs).
- Translocation involves the fusion of a region from one chromosome to a nonhomologous chromosome. Translocation can place a gene under the control of a foreign transcriptional promoter and lead to its overexpression, as is the case with the *myc* oncogenes in Burkitt's lymphomas. Translocation may also free an mRNA from inhibition by a microRNA by removing mRNA sequences normally recognized by the miRNA. Alternatively, a translocation can result in the fusion of two protein-coding sequences, leading to a hybrid protein that functions differently than the two normal proteins from which it arose, as is seen in the Bcr–Abl protein encountered in chronic myelogenous leukemias.
- Besides the amino acid substitutions that activate signaling by the Ras oncoprotein and the fusion of protein domains, as is seen in the Bcr–Abl protein, yet other changes in protein structure can lead to oncogene activation. For example, truncation of the EGF receptor leads this protein to emit growth-promoting signals in an unremitting fashion.

Thought questions

1. What evidence do we have that suggests that endogenous retrovirus genomes play little if any role in the development of human cancers?
2. Why might an assay like the transfection-focus assay fail to detect certain types of human tumor–associated oncogenes?
3. What molecular mechanisms might cause a certain region of chromosomal DNA to accidentally undergo amplification?
4. How many distinct molecular mechanisms might be responsible for converting a single proto-oncogene into a potent oncogene?
5. How many distinct molecular mechanisms might allow chromosomal translocations to activate proto-oncogenes into oncogenes?
6. What experimental search strategies would you propose if you wished to launch a systematic screening of a vertebrate genome in order to enumerate all of the proto-oncogenes that it harbors?
7. Since proto-oncogenes represent distinct liabilities for an organism, in that they can incite cancer, why have these genes not been eliminated from the genomes of chordates?

Supplementary Sidebars

Supplementary Sidebar 4.1 Endogenous viruses can explain tumor development in the absence of infectious viral spread

The exposure of a mouse or chicken to a retrovirus often results in the infection of a wide variety of cell types in the body including, on occasion, the cells in the gonads—ovaries or testes. Infections of cells in these organs can result in the integration of a retroviral provirus into the chromosomes of cells that serve as precursors to either sperm or egg. Such proviruses become established in a genetic configuration that is equivalent to that of the cellular genes carried by the sperm or egg. Therefore, when these gametes participate in fertilization, the provirus can be transmitted to a fertilized egg and thus to all of the cells of a resulting embryo and adult (**Figure S4.1**). This provirus might now become ensconced in the genome of all animals that descend from the initially infected animal. Such a provirus is termed an endogenous virus to distinguish it from infectious viruses that are transmissible from one individual to the next via conventional infectious cycles.

Figure S4.1 Origin of endogenous retroviruses (A) These viral genomes arise when retroviruses (*red dots*) succeed in establishing a systemic infection in an

organism (for example, a mouse) and infect, among other cells, a precursor cell of gametes—sperm or eggs. Once a resulting provirus (*green rectangle*) becomes integrated in the genome of a gamete (in this case sperm), it may be introduced into the genome of a fertilized egg and thereafter be distributed to all cells (*green dots*) of the organism arising from this zygote. This organism can in turn transmit the provirus to its descendants via the normal route of sexual reproduction. Activation of expression of the endogenous provirus in an animal (*red dot*) can lead to infectious spread throughout the body, viremia, and eventually leukemia (*bottom*). (B) The presence of endogenous retrovirus (ERV) genomes can be detected by probing the genomic DNA of a species using the DNA of an infectious retrovirus as the probe. Shown is a Southern blot (see Figure S4.3) of the ERV genomes present in the DNAs of a variety of mouse strains and subspecies. In this case, only the subclass of ERV genomes related to xenotropic murine retroviruses is being probed. Each band in a gel channel represents a restriction fragment in a cell genome that carries part or all of an ERV genome together with nonviral cellular DNA flanking the integrated proviral genome. The variability of ERV integration sites from one lab strain to another indicates that numerous novel ERVs have been integrated into the mouse germ line since the speciation of *Mus musculus*, from which all these strains derive. (C) In contrast to the mouse ERV genomes, those detected [using as a probe a fragment (K10) of the clone of a human ERV, *above*] in a collection of human DNAs show rather similar integration sites across the species, indicating their germ-line integration before the emergence of the human species; the polymorphic differences (*black arrows*) are largely the results of recombination between the pair of long terminal repeat (LTR) sequences at the ends of individual ERV proviruses and resulting deletion of the intervening stretches of proviral DNA. (B, from K. Tomonaga and J.M. Coffin, *J. Virol.* 73:4327–4340, 1999. With permission from American Society for Microbiology. C, from J.F. Hughes and J.M. Coffin, *Proc. Natl. Acad. Sci. USA* 101:1668–1672, 2004. With permission of National Academy of Sciences, U.S.A.)

(Of relevance here are other viral infections that also appear to be inherited genetically within families, simply because they are present in multiple generations of such families. Such vertical transmission between multiple generations, on its own, proves little, since conventional viral infections—often between mother and offspring—may actually be responsible for the presence of certain viruses in multiple generations of a kindred.)

Responding to the discoveries of endogenous viruses, some adherents of the viral theory of cancer development proposed in the early 1970s a novel mechanism of cancer's origins. This new scheme derived from the peculiar biology of endogenous viruses. Almost always endogenous proviruses are transcriptionally silent and their presence in all of the cells of an organism is not apparent. On rare occasions, however,

it is possible to awaken the expression of such latent endogenous proviruses, which, at least in murine cells, often retain the ability to encode infectious retrovirus particles.

In fact, activation of endogenous retroviral (ERV) genomes—achieved by the transcriptional activation of these normally silent proviruses—could actually be accomplished experimentally by culturing certain types of mouse fibroblasts in the presence of the thymidine analog bromodeoxyuridine (BrdU). In response, these connective tissue cells, which were ostensibly free of retroviral infection, suddenly began to release retrovirus particles, due to the transcriptional de-repression of their normally silent, endogenous proviruses. Similarly, latent endogenous proviruses might be activated spontaneously *in vivo* in a relatively small number of cells in a living mouse. Once infectious virus particles—so the thinking went—were released from these few cells, they could multiply by cell-to-cell infection, spreading rapidly throughout the body, inducing viremia and ultimately leukemias in these animals.

Knowing this behavior of endogenous murine retroviruses, some suspected that human cancers might arise in a similar fashion. For example, mutagenic carcinogens, such as those present in tobacco tar, might provoke the transcription of previously silent endogenous retroviruses. The resulting virus particles would then begin multiplying, spread throughout an individual's body, and, like the endogenous retroviruses in some mouse strains, cause cancers to form in one or another susceptible tissue. At the same time, while capable of spreading throughout a person's tissues, such endogenous viruses might be unable to spread horizontally to another individual, explaining the repeated observations that cancer does not behave like a communicable disease. Another related scheme postulated that retroviruses had inserted viral oncogenes into the germ lines of various species, and that these latent viral oncogenes became activated by various types of carcinogens.

While attractive in concept, these models of human cancer causation soon collapsed because supporting evidence was not forthcoming. Reports of infectious retroviral particles in human tumors could not be verified. Even reverse transcriptase–containing virus particles were difficult to find in human tumors.

It became clear that most endogenous retroviral genomes present in the human genome are relics of ancient germ-line infections that occurred 5 million years ago and earlier in ancestral primates. Since that time, these proviruses mutated progressively into sequences that were no longer capable of specifying infectious retrovirus particles and thereby joined the ranks of the "junk DNA" sequences that form the bulk of our genome (see Figure 1.3). Even though as much as 8% of the human genome derives from endogenous retroviral genomes (ERVs), only several of its approximately 40,000 retrovirus-derived segments have ever been shown to be genetically intact and capable, in principle, of specifying infectious virus particles. More recently, it became clear that one subfamily of these retroviruses, termed HERV-K, had entered into the human germ

line relatively recently and thus had not yet suffered the inactivating mutations that have inactivated almost all ERVs in our genome; accordingly, several of the HERV-K proviruses were seemingly intact. However, even these proviruses could not be found to produce infectious viruses or to become mobilized in cancer cells. (It remains unclear why the germ lines of other mammalian species have continued to acquire new endogenous proviruses during recent evolutionary times while ours has not.) So cancer researchers began to look elsewhere for the genetic elements that might be triggering human cancer formation.

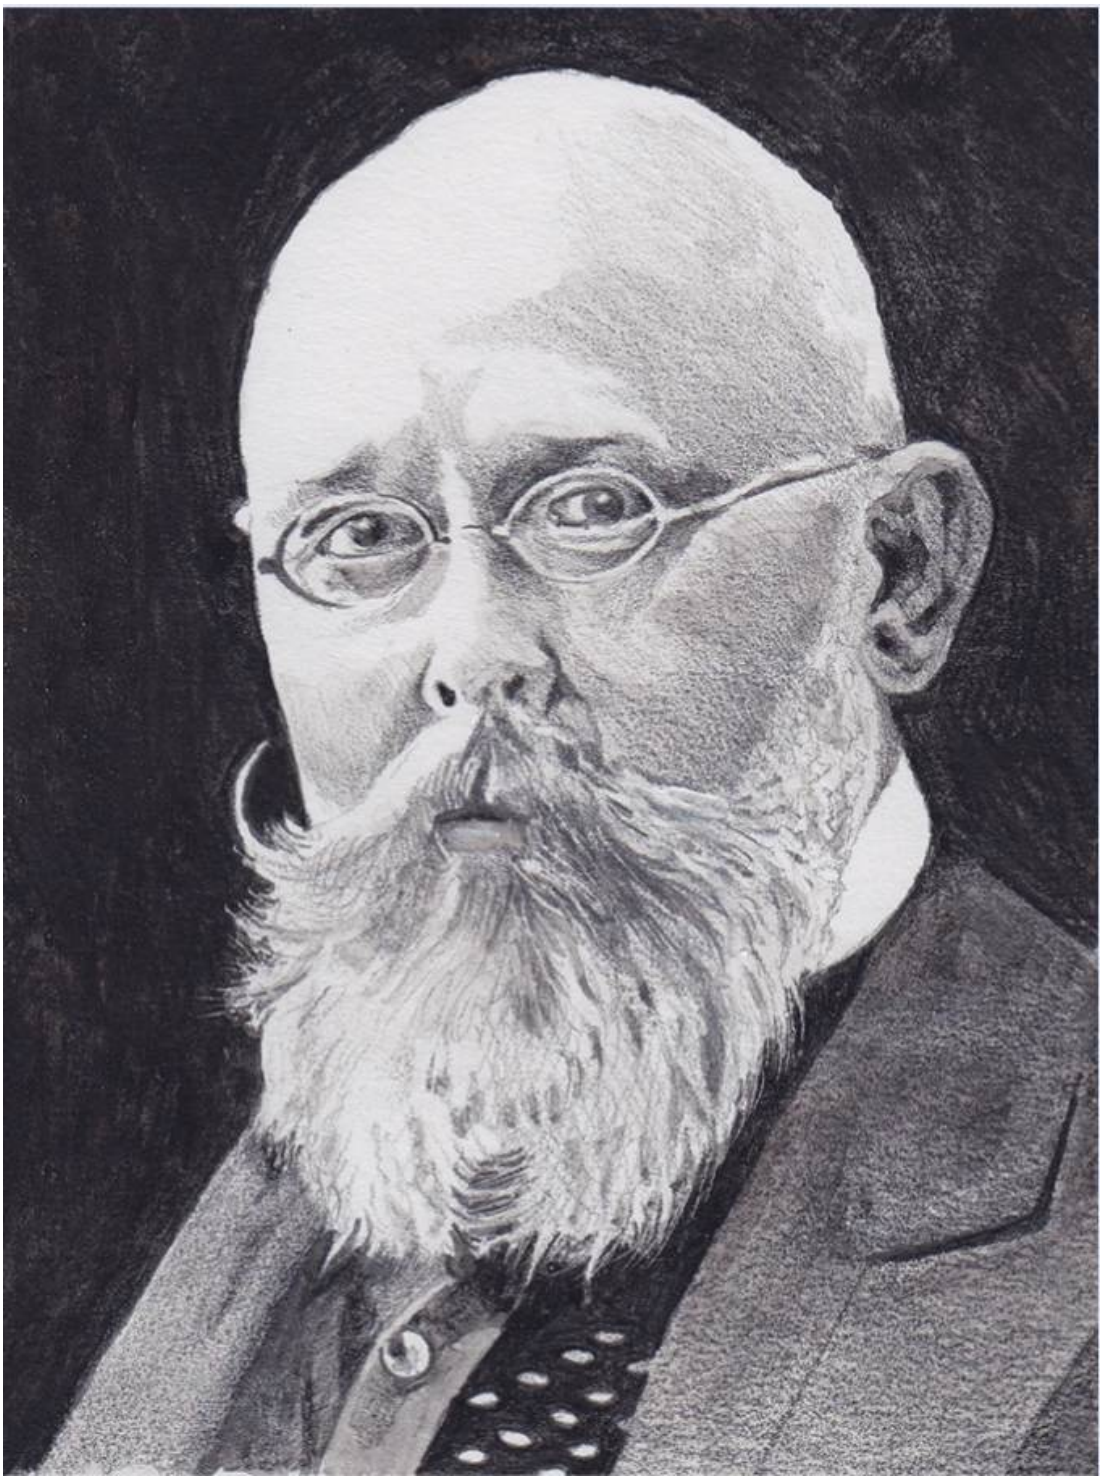
In theory, endogenous proviruses that are actively transcribed in an animal's tissues may create a viremia and, following millions of replication cycles, may induce cancer in that animal. Such disease-inducing endogenous proviruses are therefore disadvantageous and, during the course of evolution, will be eliminated from a species' gene pool. This explains why the endogenous proviruses found in the germ lines of most species are, with rare exception, either transcriptionally silent or incapable of encoding infectious virus particles because of disabling mutations.

However, a small subset of endogenous viral genomes, notably those that have been recently inserted into a species' germ line, may remain genetically intact. Given the proper stimulus, these previously latent proviruses may suddenly be transcribed in one or another cell, generating virus particles that spread via infection from this cell throughout the body and eventually trigger some type of malignancy, usually of hematopoietic cells (see Section 3.11). For example, the high rate of leukemia in mice of the AKR strain is attributable to the frequent spontaneous activation of an endogenous murine leukemia provirus, the subsequent infectious spread of virus throughout the mouse, viremia, and, finally, via insertional mutagenesis, the activation of a proto-oncogene and the eruption of a leukemia.

Such germ-line transmission of viral genomes was thought to be nothing more than a laboratory curiosity until reports, beginning in 2006, revealed that certain people carry loads of human herpesvirus type 6 (HHV-6) in their peripheral mononuclear cells (for example, lymphocytes, monocytes, macrophages) that are 1000 to 10,000 times higher than the average person carries. (Latent HHV-6 infections are widespread in the general population.) Subsequent studies revealed that these high loads of HHV-6 were often present in multiple members of a family and that in these families, HHV-6 genomes were inherited in the germ line integrated in certain chromosomes, specifically in telomeric DNA. Thus, a mechanism that HHV-6 usually employs in order to enter into a latent state (that is, by integrating its genome into one or another chromosome; see Section 3.6) occasionally results in germ-line transmission. The clinical consequences of inherited HHV-6 genomes remain unclear.

Supplementary Sidebar 4.2 Boveri and Hansemann independently hypothesized genetic abnormality as the cause of cancer cells' malignant behavior

The discovery that cancers arise as a consequence of aberrations in genetic material is widely attributed to the work of Theodor Boveri (1862–1915), a dominant figure in early twentieth-century German biology. This story, like many accounts of scientific history, is actually a bit more complicated and more interesting than conventional accounts depict. The roots of this notion actually reach back to an earlier set of observations by Boveri's contemporary David Paul von Hansemann (1858–1920; **Figure S4.2A**). In 1890, Hansemann, a pathologist, first reported his observations that the mitotic figures of cancer cells contained a variety of abnormal chromosomal configurations, including multipolar mitotic spindles—unusual arrays of chromosomes at anaphase—and asymmetric mitoses. He also proposed that the cells within tumors underwent partial dedifferentiation, another theme that anticipated twentieth-century histopathological studies of tumors. Hansemann continued to report his observations in the decade that followed, but at the time had little insight into the cell-biological consequences of abnormal chromosome number and configuration.



(A)

(B)

Figure S4.2 The first clues to the genetic origins of human tumor development (A) David Paul von Hansemann described the abnormal mitotic

figures and chromosomes in human cancer cells without knowing their significance. (B) Theodor Boveri drew on Hansemann's observations and his own to propose that abnormal chromosomes somehow were responsible for the abnormal behaviors of cancer cells. (B, courtesy of the Biocenter, University of Würzburg.)

In 1900, the work of Mendel, long forgotten, was rediscovered by three geneticists. They popularized the idea that cells are essentially diploid, with pairs of genetic determinants being separated from one another during meiosis. In the several years that followed, the behaviors of Mendel's genetic determinants were realized to parallel that of chromosomes, leading many to conclude that the chromosomes were the seat of heredity. Hence, cells with abnormal numbers of chromosomes were perceived as being genetically mutant, though the term "mutant" had not yet come into currency.

Unlike Hansemann, Boveri (see Figure S4.2B) was a zoologist and worked largely with early sea urchin embryos. He hardly acknowledged the work of Mendel and minimally that of Hansemann. Instead, his own work in manipulating metaphase figures in early sea urchin embryos led him to propose that the karyotypic aberrations observed occasionally in otherwise-normal cells represented genetic abnormalities, that each chromosome carries a distinct subset of the genetic information present in the genome as a whole, and that the karyotypic abnormalities within cancer cells were responsible, in some fashion, for the aberrant behavior of cancer cells. The corrupted information content present in one cell was, he proposed, heritable from one cell generation to the next.

Boveri's posthumously published 1916 monograph, in which he laid out these ideas, was followed 13 years later by an English translation, carried out by his widow, the former Marcella O'Grady of Boston, Massachusetts, a biologist and accomplished experimentalist, who was the first female graduate of the Biology Department of the Massachusetts Institute of Technology (MIT) in Cambridge. Hansemann lacked a loyal widow and translator, and so awareness of his pioneering contributions in connecting an abnormal genetic constitution of cells with the development of tumors receded. Boveri's personality also may have helped impress on the scientific community his unique role in many of these advances; an otherwise-uncritical colleague described him as "vehement, inflexible, and [a] relentless assailant." Today, few remember that Hansemann began the charge that led to the now widely embraced notion that cancer cells are genetically abnormal, and that these cells' chromosomes are responsible for their malignant behavior.

Supplementary Sidebar 4.3 Southern and Northern blotting

Southern blotting was invented in 1973 by the British molecular biologist Edwin Southern as a means of detecting specific DNA fragments that are generated by restriction enzyme cleavage of DNA; these fragments may be present amid a millionfold excess of other concomitantly generated DNA fragments, revealing the sensitivity of this procedure (**Figure S4.3**). Within several years, the procedure was adapted to detect specific mRNA molecules resolved by gel electrophoresis, once again present amid a vast excess of unrelated mRNA species; for want of a better name, this newer procedure was dubbed Northern blotting. Thereafter, a further adaptation of the procedure was developed in order to detect individual proteins, once again resolved by gel electrophoresis, amid a vast excess of unrelated proteins and termed the Western blotting procedure (not shown in the figure). While the Southern and Northern blots use radiolabeled nucleic acid probes, the Western blotting procedure uses specific antibodies, usually monoclonal antibodies, to detect proteins that have been adsorbed to filters and for this reason is also termed immunoblotting. The binding of these "primary" monoclonal antibodies to their cognate antigens is usually detected by the use of a "secondary" antibody that recognizes the constant region of the primary antibody molecule and is itself labeled with a fluorescent reporter or an enzyme that can generate a visible dye or deposit.

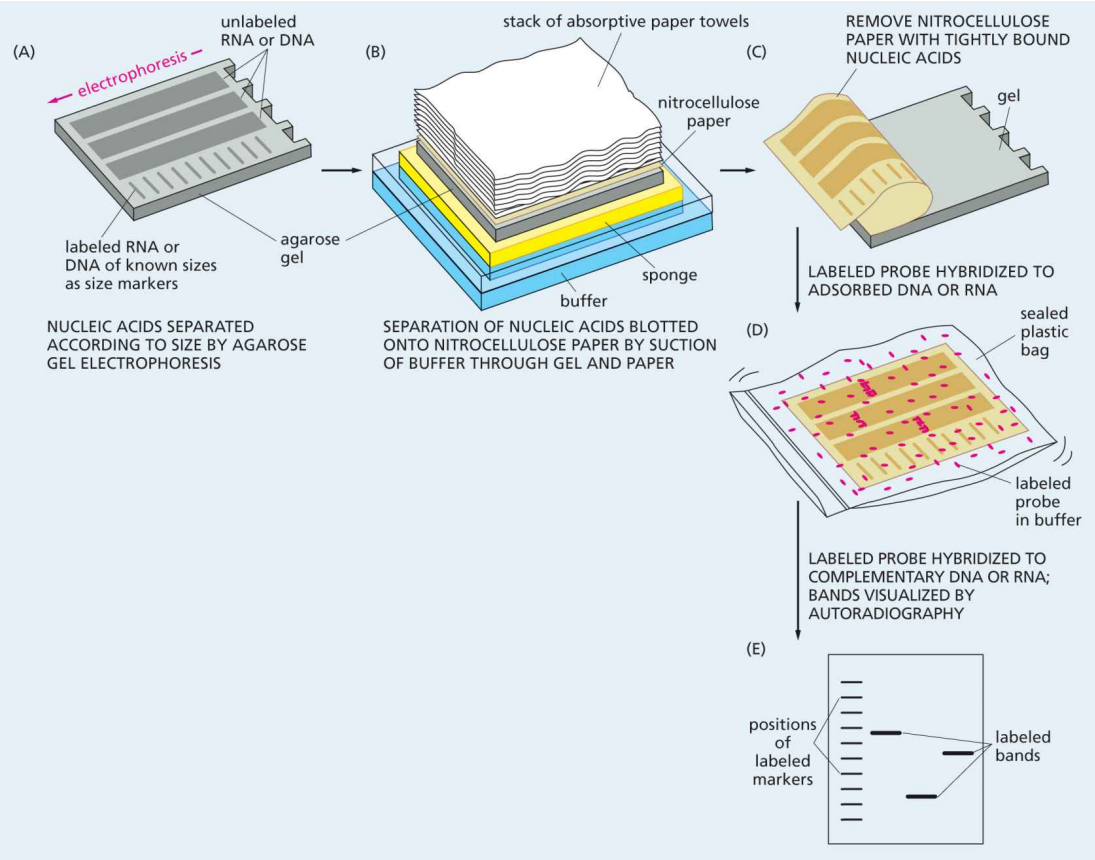


Figure S4.3 Southern and Northern blotting procedures Use of these blotting procedures makes possible the detection of specific fragments of the cell genome (or specific RNA transcripts) if an appropriate radiolabeled DNA probe is available. (A) Either DNA fragments that have been generated by restriction enzyme cleavage of genomic DNA (in a Southern blot) or a mixture of cellular RNAs (in a Northern blot) are resolved by gel electrophoresis. (B) The gel slab is then placed beneath a nitrocellulose filter, and paper towels (or other absorptive material) are used to wick fluid upward through the gel, allowing the DNA (or RNA) molecules to adsorb to the filter paper, creating a replica pattern of their previous positions in the gel. (C) The filter paper is peeled away from the gel and (D) placed in a plastic bag together with a solution of radiolabeled probe (*pink*). (E) Hybridization of the probe with complementary DNA (or RNA) molecules adsorbed on the filter and subsequent autoradiography with a photographic emulsion allow the detection of DNA fragments (or RNA molecules) that were present in the initial DNA (or RNA) preparation; these are manifested by bands of silver grains on the film. (From B. Alberts et al., Molecular Biology of the Cell, 5th ed. New York: Garland Science, 2008.)

Supplementary Sidebar 4.4 Increases in gene copy number and their interpretation

The process of gene amplification is defined as a preferential increase in the copy number of a discrete chromosomal region (an amplicon), rather than increases in the ploidy of the genome, as may occur in certain specialized mammalian cells during the course of normal development. In the latter case, the entire complement of chromosomes will increase coordinately, resulting in multiple copies of the entire genome and the state of polyploidy. Such polyploidy seems to occur only in a small number of highly differentiated mammalian cell types that have a requirement for producing large amounts of specialized gene products, notably the megakaryocytes (precursors of blood platelets) and the trophoblast giant cells of the placenta. In both cell types, such endoreduplication occurs through repeated passages through S phase of the cell cycle without subsequent mitoses (M phase; see Chapter 8).

Alternatively, reduplication can be focal, where increases in the copy number of discrete chromosomal regions can be observed. This can occur during cancer pathogenesis through the process of unequal crossing over as illustrated in **Figure S4.4**. Alternatively, such focal reduplication leading to gene amplification can occur through the multiple successive firings of specific DNA replication origins in the absence of passage through mitosis (**Figure S4.5**). Such directed, localized gene amplification often results in proportional increases in the expression of the corresponding mRNA and protein. For example, in the fruit fly *Drosophila*

melanogaster, genes specifying chorion proteins normally undergo amplification during the development of ovarian follicle cells, doing so in order to enable the synthesis of massive amounts of these proteins required for oogenesis.

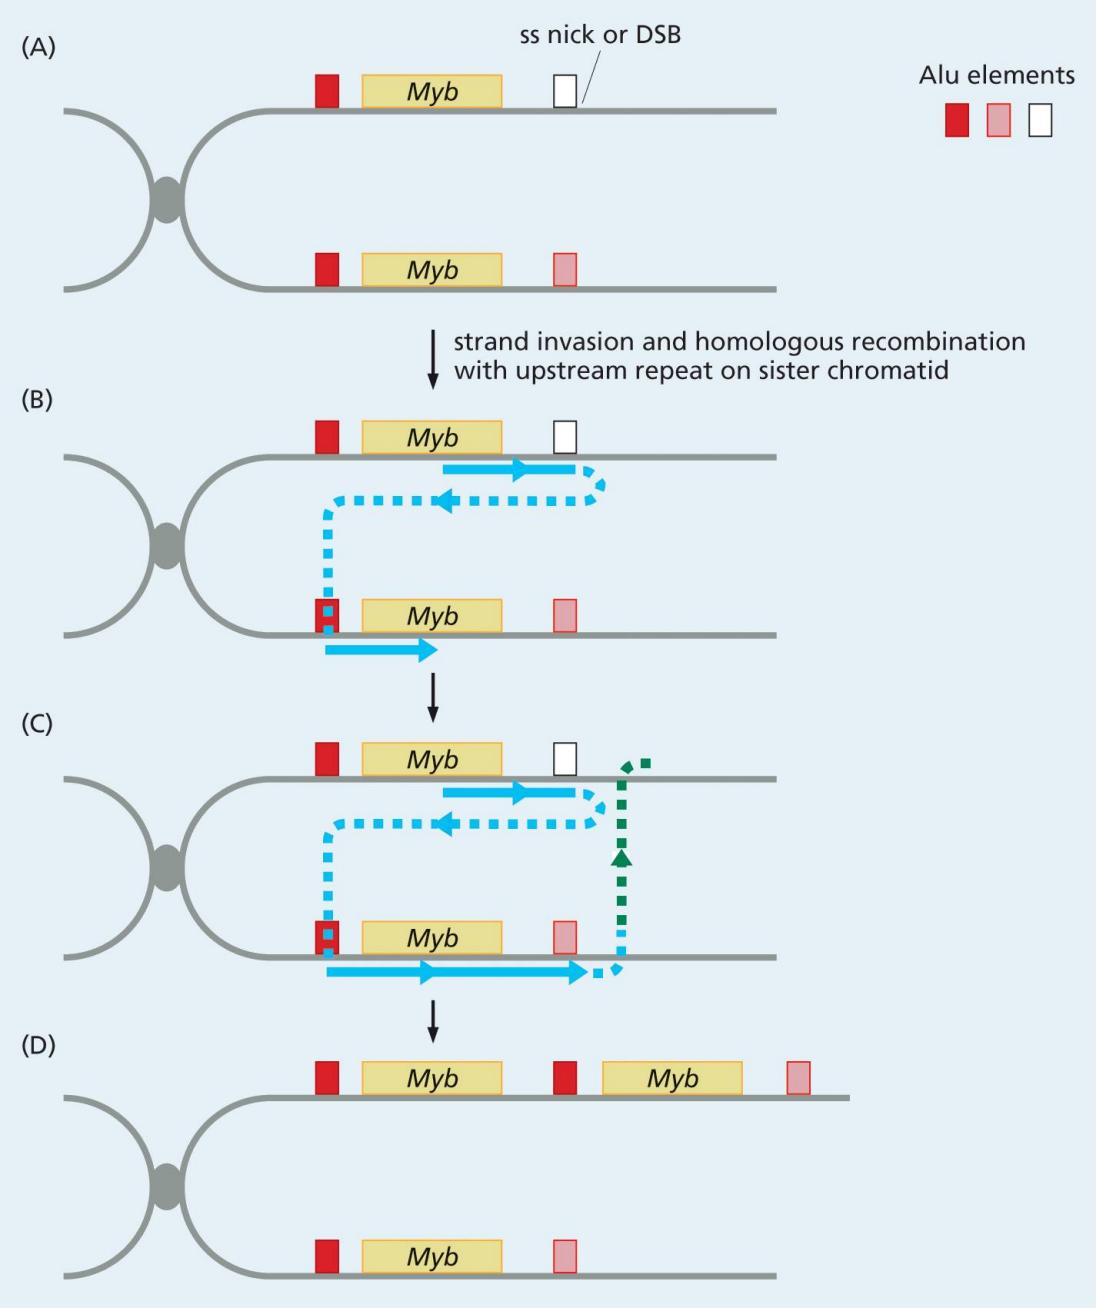

Figure S4.4 Mechanism of generating tandemly duplicated genes A number of molecular mechanisms have been proposed to explain the generation of tandemly duplicated genes, such as those that form the homogeneously staining regions (HSRs) that create oncogene amplification. In the example presented here, the mechanism of amplification of the *Myb* oncogene via tandem duplication was

studied in a human T-cell acute lymphoblastic leukemia. The amplification mechanism was traced, with high likelihood, to the presence of *Alu* elements, which are present in about 1 million copies scattered throughout the human genome (see Figure S4.7). In this case, the normal human *Myb* gene is flanked by two *Alu* repeat sequences. (A) When the *Myb* gene underwent replication during the S phase of the cell cycle, a single-strand (ss) nick or double-strand break (DSB) in the newly synthesized upper sister chromatid allowed the resulting free end (which contains an *Alu* sequence; *empty rectangle*) to invade the double-strand helix of the lower sister chromatid and anneal to another *Alu* sequence (*dark red rectangle*) that lies upstream of the *Myb* gene on the lower sister chromatid (B). The 3′ end of the newly synthesized, annealed strand could then be elongated using as a template this lower sister chromatid (*light blue*). (C). Subsequently, this elongating strand could jump back to the upper sister chromatid (*dark green*) and continue elongation, generating two head-to-tail tandem copies (D) of the *Myb* gene. This process might then be repeated, leading to an exponential expansion of this chromosomal region. (From J. O'Neil et al., *J. Exp. Med.* 204:3059–3066, 2007. With permission from Rockefeller University Press.)

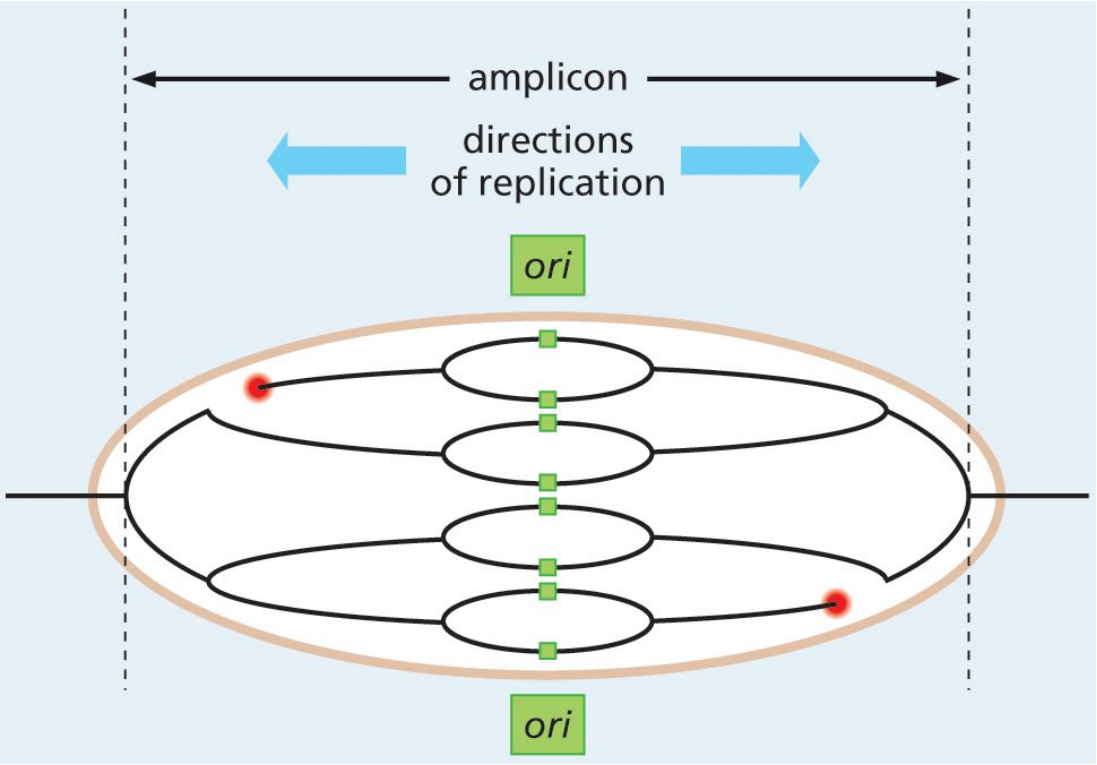

Figure S4.5 Mechanism of generating amplified chromosomal regions The focal amplification of a very short segment of chromosomal DNA, achieved by unequal crossing over (see Figure S4.4), can be contrasted with an alternative

mechanism of generating amplified regions that often are much longer than those resulting from unequal crossing over. This mechanism depends on the fact that in normal replication (occurring in the S phase of the cell cycle) an origin of replication (*ori*) is fired only once, resulting in the bidirectional out-migration of two replication forks that proceed until they encounter replication forks or replicated DNA in adjacent regions, thereby creating two identical complete copies of a replicon. However, under pathological conditions, an *ori* may be re-fired on multiple occasions during a single S phase, resulting in the re-replication of a chromosomal region that should be replicated only once during that S phase. This creates multiple identical copies of a chromosomal region that are termed an amplicon. These multiple copies may then recombine in complex ways and resolve the complex structure seen here, causing it to regenerate a chromosomal region that contains, once again, only a single double-helix of DNA but bears the multiple copies joined in head-to-tail or head-to-head orientation.

The discoveries that certain proto-oncogenes similarly undergo amplification revealed an important mechanism of mutation that contributes to tumor pathogenesis. (Thus, gene amplification represents a mutation in the same sense that intragenic alterations do.) Figure 4.3B illustrates the fact that amplification of the *erbB2/HER2* gene, which occurs in about 30% of human breast cancers, is correlated with poor prognosis. This amplification would seem to explain how many highly malignant breast cancers acquire their aggressive phenotypes. It is known that elevated signaling by the *erbB2/HER2*-encoded protein drives cells into endless rounds of growth and division and also protects them from programmed cell death—apoptosis (see Chapter 9).

As illustrated in **Figure S4.6**, a gene that appears to be the object of gene amplification (that is, confers proliferative advantage on a cell that harbors it in multiple copies) may often be co-amplified with flanking chromosomal DNA, resulting in increased copy number of neighboring genes. This creates an ambiguity, since it is not always clear precisely which gene in an amplified multi-genic region is functionally important in conferring benefit on an incipient cancer cell. One example of this dilemma came from analyses of the involvement of the c-*src* gene in human colorectal cancer (CRC) development. Thus, in about 10% of human CRCs, a chromosomal region containing c-*src* undergoes readily detectable amplification. In these cases, however, it is not obvious whether the c-*src* gene itself or other nearby genes in this chromosomal region are the actual objects of the gene amplification that confers proliferative advantage on evolving pre-neoplastic cells.

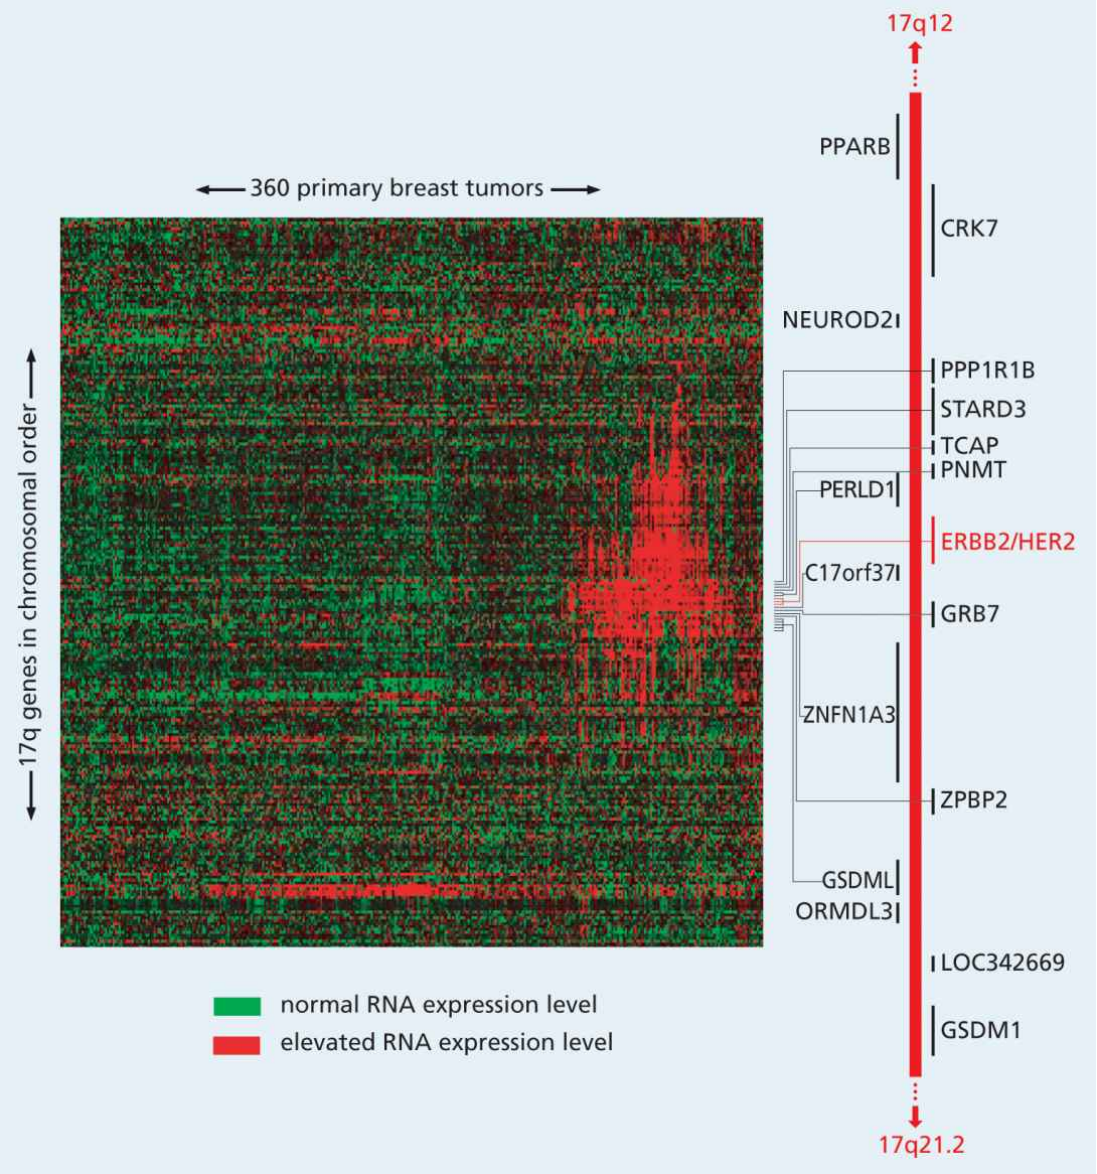

Figure S4.6 Interpretation of amplified chromosomal regions The discovery that the *erbB2/neu/HER2* gene is amplified in about 30% of human breast cancers, and that this amplification is correlated with poor prognosis (see Figure 4.3), would seem to explain how many highly malignant breast cancers acquire their aggressive phenotypes. It is known that elevated signaling by this protein drives cells into endless rounds of growth and division and also protects them from programmed cell death—apoptosis. However, analyses of gene expression patterns yield more complex interpretations. The map of some of the genes identified that flank *HER2* on both sides is provided (*red vertical bar, right*). In the expression array analysis shown here, the expression levels of a cohort of 160 genes that flank this gene (labeled here ERBB2/HER2) on both sides along human Chromosome 17q, together with the expression of this gene itself, were monitored

in a series of 360 human breast cancers. Elevated expression is indicated in *red* while normal expression is indicated in *green*. As is apparent, in about one-fourth of these breast cancers (*right quarter of array*), expression of *erbB2/neu/HER2* RNA was elevated, as might be expected from the amplification that this gene had undergone in many of these tumors. At the same time, in many of these tumors, expression of closely linked genes mapping to both sides of this gene was also elevated. This reflects the fact that the unit of DNA amplification—the amplicon (see Figure S4.5)—almost always included a stretch of chromosomal DNA that was far longer than the *erbB2/neu/HER2* gene itself, leading to co-amplification of these neighboring genes. Among these genes are several that may also positively influence cell proliferation and survival, including *GRB7* and *PPARB*, whose protein products interact with ErbB2 (see Chapter 6) and with the apoptosis circuitry (see Chapter 9), respectively. Hence, in such cases, a number of co-amplified genes may be collaborating to orchestrate the malignant phenotype of human breast cancer cells, and it becomes difficult to ascribe specific cancer cell phenotypes to the elevated expression of only a single gene, such as the *erbB2/neu/HER2* discussed here. (Courtesy of L.D. Miller, Genome Institute of Singapore.)

In childhood neuroblastomas, amplification of the N-*myc* proto-oncogene is known to play a central role in the development of aggressive disease (see Figure 4.7). In some tumors, the co-amplification of the linked *Alk* proto-oncogene is observed, raising the question whether this co-amplification contributes to the aggressiveness of this disease.

Supplementary Sidebar 4.5 Cloning of transfected oncogenes

The oncogene of the T24/EJ human bladder carcinoma cell line was cloned by two research groups before its relationship with the H-*ras* oncogene of Harvey sarcoma virus (see Figure 4.2) was known. These groups faced the challenge of isolating a gene without knowing anything about its sequence or structure. One group of researchers transfected DNA of the human bladder carcinoma cells into NIH 3T3 mouse cells (**Figure S4.7**). (During the course of transfection, the genomic DNA being transfected undergoes shearing at random sites, yielding fragments tens of kilobases long that become integrated into the genomes of recipient cells. On average, about 0.1% of a genome's worth of donor DNA becomes integrated into the genome of a recipient cell.) This research group used Southern blotting (see **Supplementary Sidebar 4.3**) to detect the donor DNA by exploiting probes that were specific for the *Alu* repeat sequences, which are scattered randomly about the human genome in about 1 million sites but are absent from the mouse genome. (More precisely, distantly related mouse

repeat sequences are not recognized by DNA probes that are specific for the human *Alu* repeats.) Thus, *Alu* sequences are present in the human genome, on average about every 3–4 kb or so. Accordingly, it was likely that the human bladder carcinoma oncogene carried with it some linked human *Alu* sequences into recipient mouse cells during the transfection procedure.

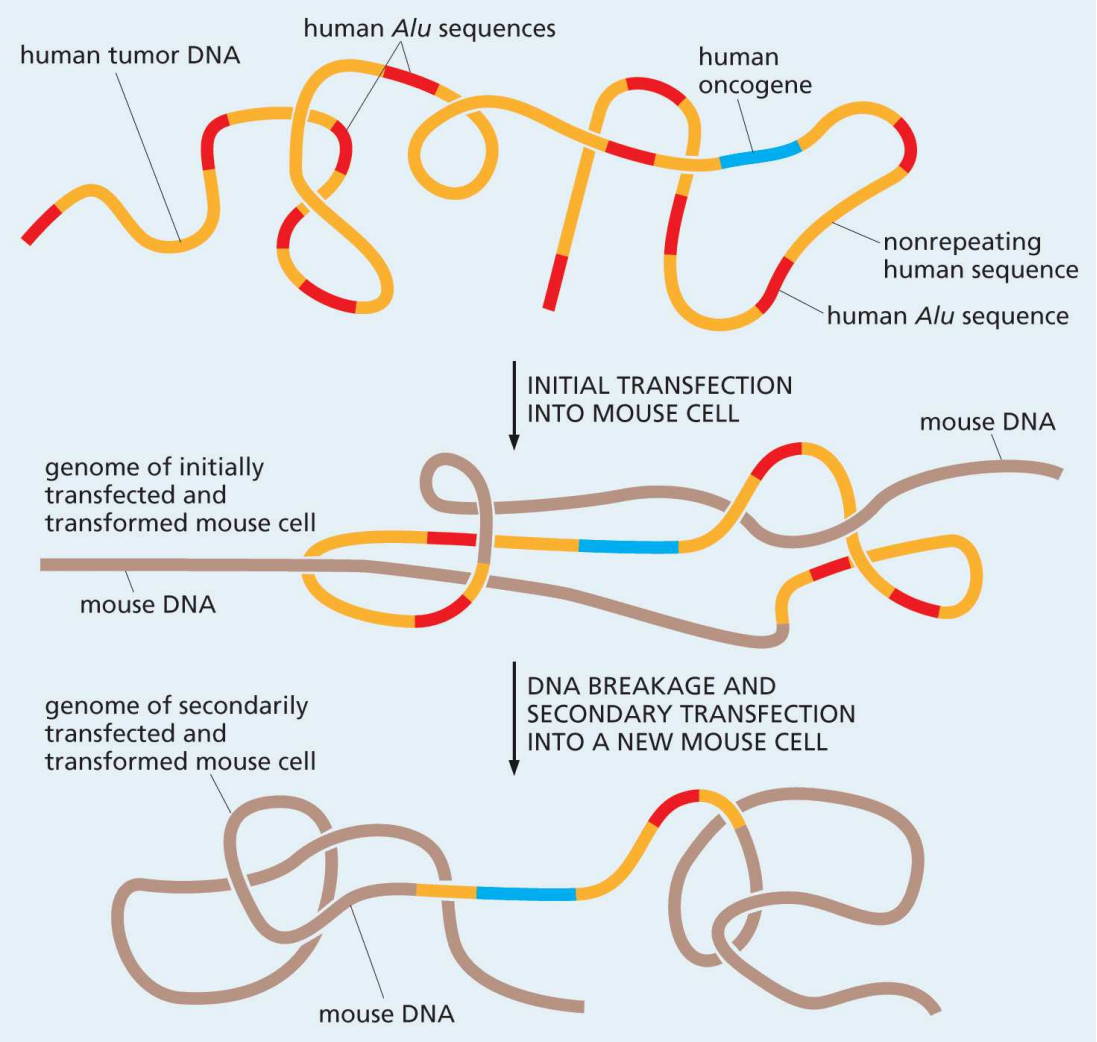

Figure S4.7 Cloning of transfected human oncogenes This strategy for cloning the oncogene present in a human bladder carcinoma depended on *Alu* sequences of ~280 bp length (*short red segments*), which are present in almost a million copies scattered throughout the human genome (*orange segments*). As a consequence, virtually all human genes are closely linked to one or more of the *Alu* sequences. If the genomic DNA of a human tumor cell bearing an oncogene (*blue segment*) is fragmented and transfected into a mouse cell [whose DNA (*light brown line*) lacks sequences closely related to human *Alu* sequences], the introduced human DNA can be detected by use of an *Alu*-specific probe in the Southern blotting procedure (see Supplementary Sidebar 4.3). In the case of the

transfections described here, only about 0.1% of the donor DNA genome became established in the initially transfected, transformed mouse cells, indicating that these cells carried both the transforming oncogene and perhaps 10^3 co-transfected human *Alu* sequences. Because so many human *Alu* sequences were co-introduced with the human oncogene into these initially transfected, transformed cells, the DNA of cells descended from them was extracted, fragmented, and used in a second cycle of transfection into mouse cells. Once again, only about 0.1% of the donor DNA (from the initially transfected cells) survived in the secondary transfectants, dictating that the only human DNA and associated *Alu* sequences that were present in the secondarily transformed cells were those that were closely linked to the human oncogene (whose presence was detected because of the transformed phenotype that it caused in these cells). A genomic library (see Supplementary Sidebar 1.4) could then be made from the DNA of these secondary transformants, and the DNA clone containing the bladder carcinoma oncogene could be identified (using an *Alu*-specific probe) and retrieved.

Indeed, the researchers found a relatively small number of human *Alu* sequences (about 0.1% of the total *Alu* sequences in a human genome) in the genomes of initially transfected, transformed mouse cells. They then prepared whole genomic DNA from these transformed NIH 3T3 cells and transfected it once again into fresh NIH 3T3 cells and isolated transformed cells that arose following this second cycle of transfection. Once again, as before, only about 0.1% of the donor DNA (prepared from the initially transfected cell) was transferred from donor to recipient (see Figure S4.7). In these secondarily transfected cells, the only human *Alu* sequences that had survived the two cycles of transfection were those that were closely linked to the oncogene responsible for the observed transformation. These researchers then used a human *Alu*-specific sequence probe to identify the presence of an *Alu*-containing DNA fragment in a collection (a genomic library) of DNA fragments prepared from the genomic DNA of the secondarily transfected cells. They then retrieved this fragment using standard gene cloning procedures. The cloned *Alu*-containing DNA segment was found to carry, in addition, the long-sought bladder carcinoma oncogene.

The other research group used an elegant procedure that caused the bladder carcinoma gene to become closely linked to a bacterial gene during the initial transfection event. They then followed the fate of this bacterial segment through another cycle of transfection and, by using a probe specific for it, were able to isolate both this bacterial segment and the linked bladder carcinoma cell from transfected cells by molecular cloning.

Supplementary Sidebar 4.6 Localization of the oncogene-activating mutation in the H-*ras* gene

Physical mapping of the restriction enzyme cleavage sites in the clone of the transfected H-*ras* oncogene (derived from a human bladder carcinoma) and in the corresponding proto-oncogene present in normal human DNA revealed that the two versions of this gene shared an apparently identical overall structure. This dictated that the differences between the two allelic versions of the gene—one of which carried transforming information whereas the other lacked it—were very subtle. The functionally important difference between the two cloned segments could be localized by recombining fragments of the two alleles and testing the recombinant genes for biological activity. This revealed that the differences between the two alleles lay in a 350-nucleotide fragment toward the left ends of the 6.6 kb-long clones (**Figure S4.8**).

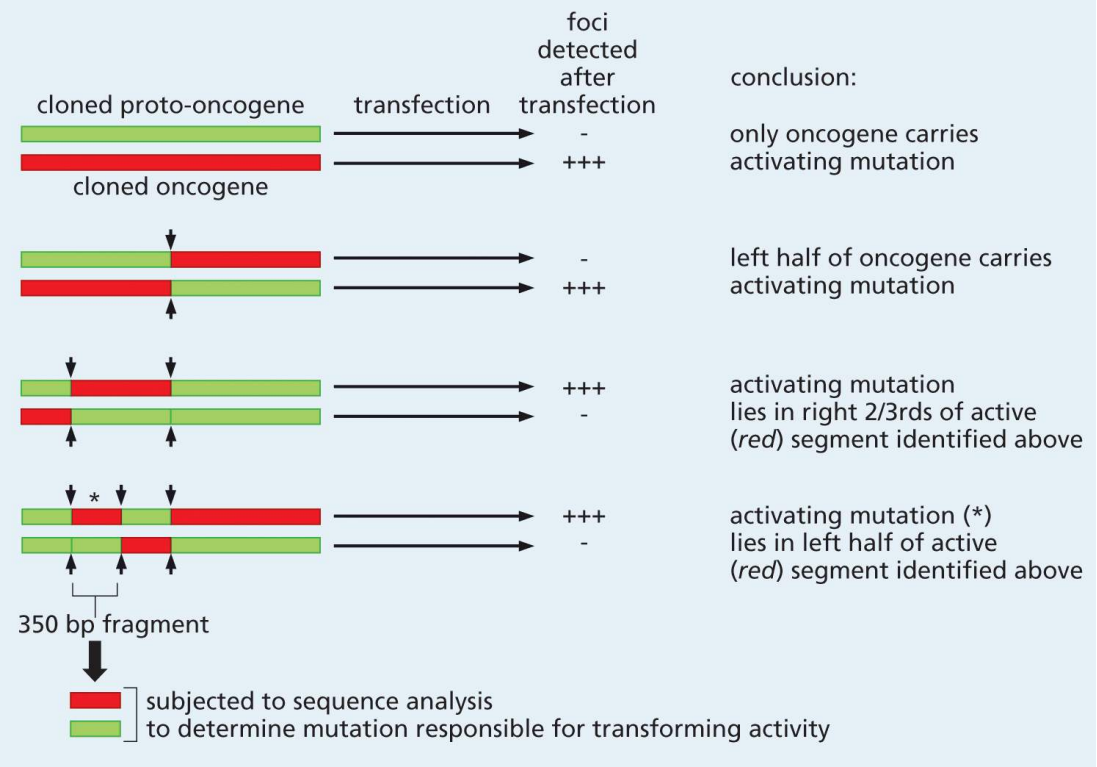

Figure S4.8 Localization of an oncogene-activating mutation The cloned DNAs of a human bladder carcinoma oncogene (*red segments*) and the closely related human H-*ras* proto-oncogene (*green segments*) were cleaved by restriction enzymes at the sites indicated (*vertical arrows*) and recombinant genes were made by ligating (linking) the resulting DNA fragments from the two sources and testing the hybrid DNA molecules for their transforming activity using the transfection-focus assay (see Figure 4.1). This made it possible to progressively localize the mutation responsible for oncogene activation to a small 350-base-pair

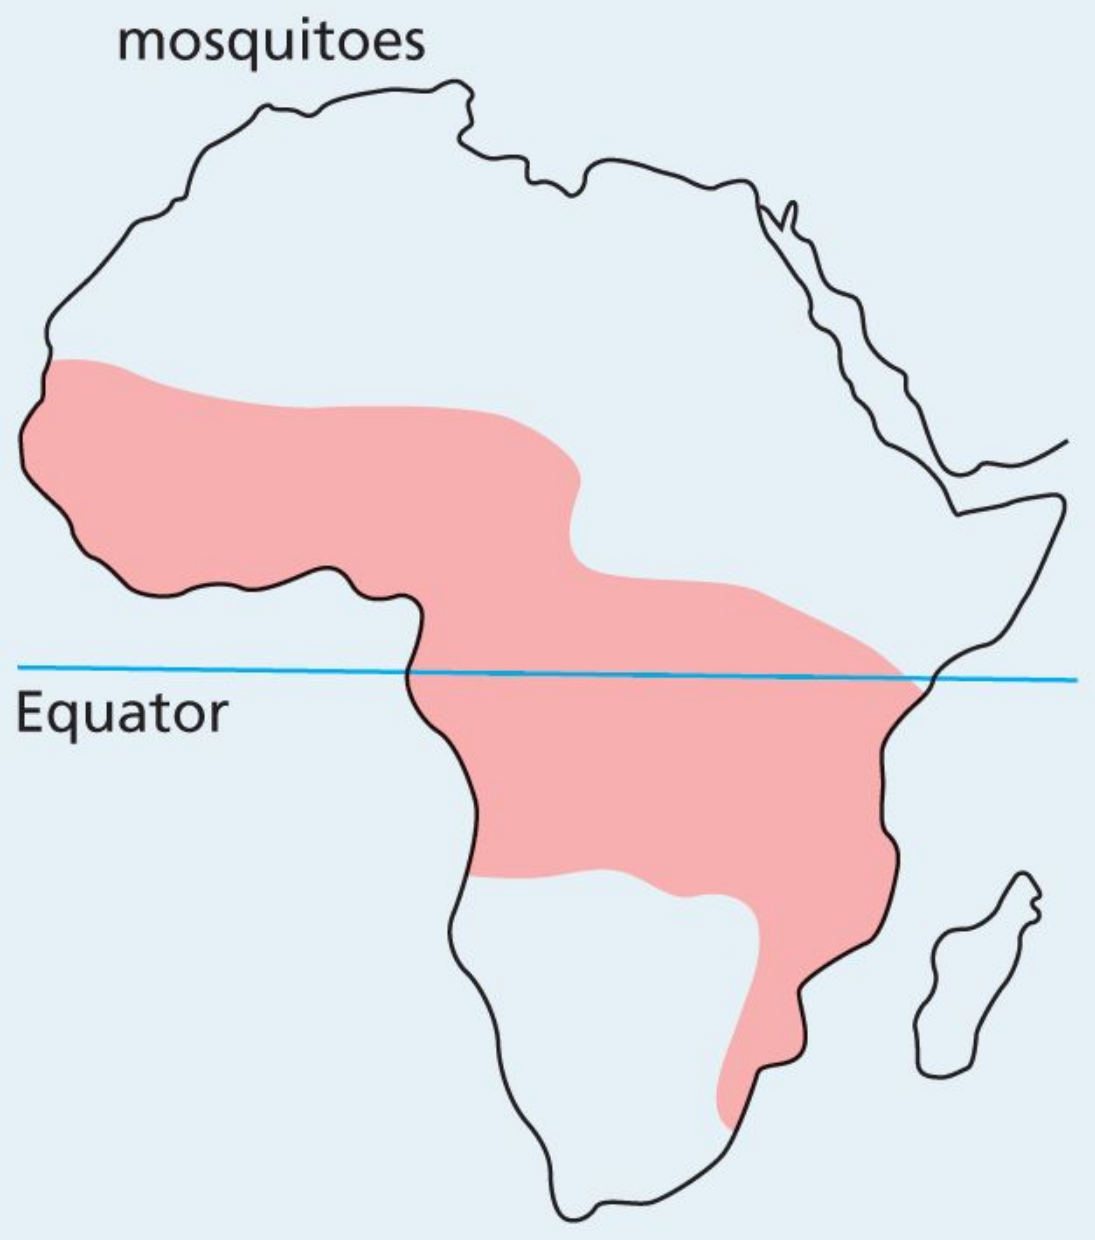
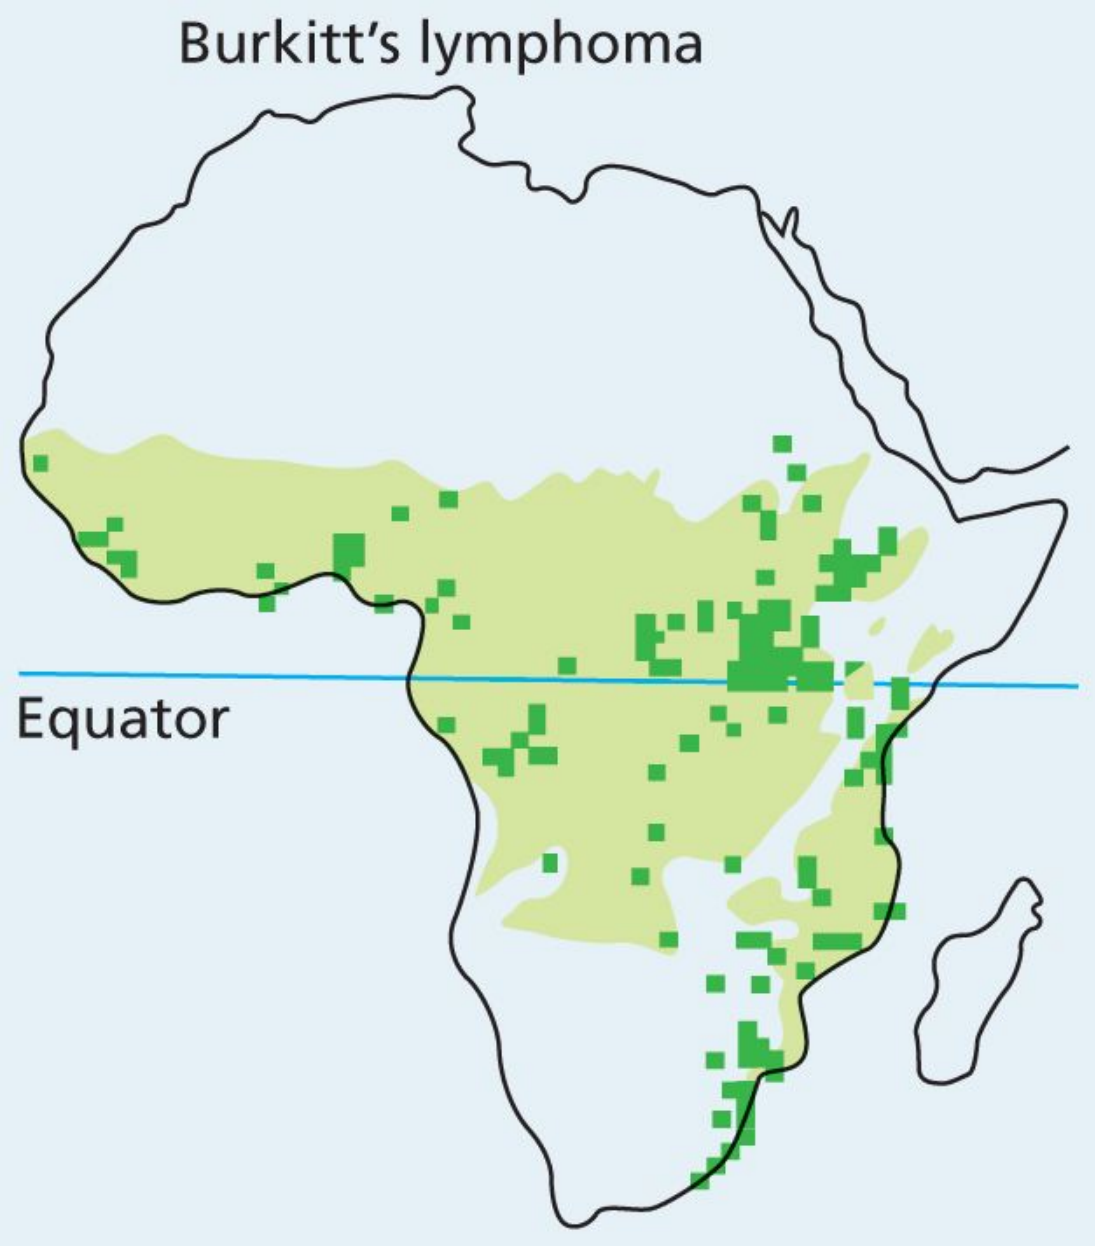
segment, which could then be subjected to sequence analysis in order to determine the precise sequence change that distinguished the two allelic versions of this gene. (From C.J. Tabin et al., *Nature* 300:143–149, 1982. With permission from Nature.)

Supplementary Sidebar 4.7 Distribution of mosquitoes, malaria, and Burkitt's lymphoma

The disease of Burkitt's lymphoma, described in 1958 in East Africa by Denis Burkitt, generally affects children in equatorial regions where malaria is endemic. The tumors, derived from lymphocytes with B-cell characteristics, are often found in the jaw or other facial bones, and in the ileum, cecum, kidneys, and ovaries. The geographic distribution of the disease maps closely to the distribution of mosquito-borne malaria (**Figure S4.9**). The tumors are invariably associated with infections by Epstein–Barr herpesvirus (EBV), which is also associated as an etiologic agent with the pathogenesis of mononucleosis and nasopharyngeal carcinomas. The immunologic stresses caused by repeated infectious cycles launched by mosquito-borne malarial parasites are thought to conspire with EBV to trigger the B cell translocations observed in patients afflicted with Burkitt's lymphoma (see **Supplementary Sidebar 4.8**).



(A)



(B)

Figure S4.9 Burkitt's lymphoma incidence in Africa (A) The geographic distribution in Africa of the *Anopheles gambiae* mosquito, a known vector in the transmission of malaria. (B) The geographic distribution of childhood Burkitt's lymphoma (BL), as originally documented by Denis Burkitt. The congruence of these two distribution maps suggested that malarial infection was likely an etiologic factor in this disease. In addition, the invariable presence of the Epstein–Barr virus (EBV) genome in the BL tumor cells indicates a second etiologic factor. As the tumor cells evolve, a chromosomal translocation involving the c-*myc* gene

develops, which contributes to the neoplastic proliferation of the EBV-infected B lymphocytes. (A and B, from I. Magrath, in E.S. Robertson (ed.), Burkitt's Lymphoma. Edinburgh and London: Springer, 2012. With permission from Springer.)

Supplementary Sidebar 4.8 How does Epstein–Barr virus (EBV) cause cancer?

The 1982 discovery of the Burkitt's lymphoma–associated chromosomal translocations shed little light on the precise mechanism by which the etiologic factors (chronic EBV and malarial parasite infections; see **Supplementary Sidebar 4.7**) favor the formation of these tumors. The contributions of each of these agents to lymphoma pathogenesis are still not totally clear. It appears that chronic malarial infection together with malnutrition can compromise the immune defenses of children and thereby render them susceptible to runaway EBV infections that further debilitate their already-weakened immune systems. These EBV infections can lead to the accumulation of large pools of EBV-immortalized B lymphocytes that are driven to proliferate continuously by the virus. (As we will learn in Chapter 10, the process of immortalization enables cells that previously are able to proliferate for only a limited number of cell doublings in culture to do so indefinitely. Immortalization also appears to be a critical component of the overall proliferative program of neoplastic cells *in vivo*.)

In some EBV-infected cells, the enzymatic machinery dedicated to organizing normal immunoglobulin gene rearrangement (as described in Chapter 15) misfires and, in so doing, occasionally creates inappropriate juxtapositions of segments of antibody genes with the c-*myc* proto-oncogene. The resulting *myc* oncogenes, working together with several genes (possible oncogenes) expressed by EBV, then drive the cell proliferation that leads eventually to the eruption of lymphomas. An additional puzzle comes from the involvement of EBV in nasopharyngeal carcinomas (NPCs) in Southeast Asia, where this viral infection, together with certain lifestyle factors (possibly the consumption of Chinese-style salted fish early in life), has been implicated as an etiologic agent. Even more puzzling is the fact that in Western populations, EBV infection is common and causes mononucleosis in immunocompetent individuals (that is, those with a fully functional immune system), triggering malignancies only in rare instances.

OceanofPDF.com

Glossary

endogenous provirus
: The provirus of a retrovirus that is integrated into the germ line DNA of an organism, thereby assuming a configuration much like all cellular genes in the organism's genome.

vertical transmission
: The transmission of an agent, such as an infectious agent, from parent to offspring. *See also* **horizontal transmission**.

endogenous provirus
: The provirus of a retrovirus that is integrated into the germ line DNA of an organism, thereby assuming a configuration much like all cellular genes in the organism's genome.

viremia
: Presence of high concentrations of virus in the bloodstream.

horizontal transmission
: Transmission of an agent, such as an infectious agent, throughout a population in ways that do not depend on parent-offspring interactions. *See also* **vertical transmission**.

constant region
: Portion of an antibody molecule that is present identically by all members of a class of these molecules, e.g., all immunoglobulin gamma molecules. *Compare* **variable region**.

amplicon
: A defined stretch of (chromosomal) DNA that undergoes amplification flanked on both sides by DNA segments that are present in normal copy number.

polyploid
: Referring to a genome in which the entire haploid array of chromosomes is represented in copy numbers larger than two. *See also* **haploid**, **diploid**.

endoreduplication
: Process whereby a genome or chromosomal segment is replicated without subsequent segregation of the replicated copies during mitosis.

endoreduplication

Process whereby a genome or chromosomal segment is replicated without subsequent segregation of the replicated copies during mitosis.

focal

Referring to a change that affects only a small region or area, such as a relatively short segment of a chromosome.

intragenic

Process, event, or DNA sequence occurring within the genomic boundaries of a gene. *Compare* **intergenic**.

Alu repeat

Sequence block of about 300 bp that is found in almost 1 million copies scattered throughout the human genome.

immunocompetent

Referring to an organism whose immune system is fully functional.

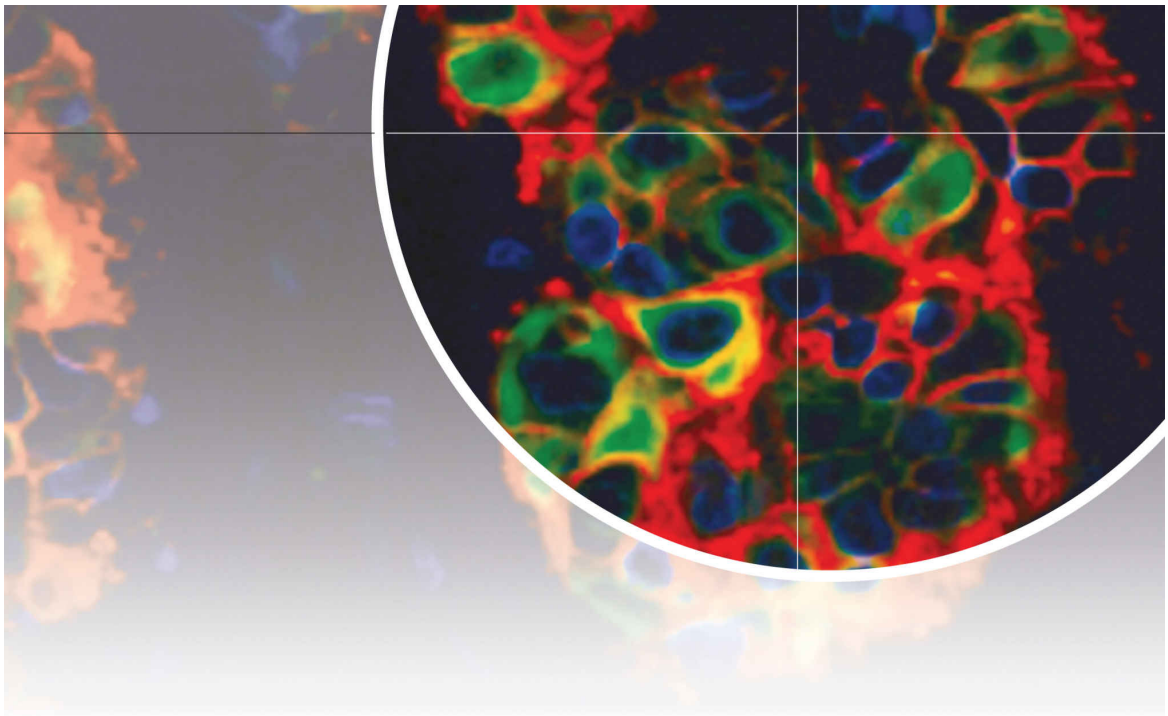
Chapter 5
Growth Factors, Receptors, and Cancer



Breast cancer cells stained in red and green, with non-staining nuclei appearing as blue.

Chapter opener photo: From J.S. de Jong et al., *J. Pathol* . 184:44–52, 1998. With permission from John Wiley & Sons.

The ability of certain fetal serums to stimulate cell growth and the decreased requirement for such factors by transformed cells may be due to the fact that these serum factors are the same or similar to the transforming factors synthesized by some embryonic or neoplastic cells.

David E. Comings, geneticist, 1973

The discovery of oncogenes and their precursors, the proto-oncogenes, stimulated a variety of questions. The most pointed of these centered on the issue of how the oncogenes, acting through their encoded protein products, succeed in perturbing cell behavior so profoundly. A variety of cell phenotypes were concomitantly altered by the actions of oncoproteins such as Src and Ras, the products of the *src* and *ras* oncogenes. How could a single protein species succeed in changing so many different cellular regulatory pathways at the same time?

The vital clues about oncoprotein functioning came from detailed studies of how normal cells regulate their growth and division. Normal cells receive growth-stimulatory signals from their surroundings. These signals are processed and integrated by complex circuits within the cell, which decide whether or not cell growth and division are appropriate.

This need to receive extracellular signals at the cell surface and to transfer them into the cytoplasm creates a challenging biochemical problem. The extra- and intracellular spaces are separated by the lipid bilayer that is the plasma membrane. This membrane is a barrier that effectively blocks the movement of virtually all but the smallest molecules through it, resulting in dramatically differing concentrations of many types of molecules (including ions) on its two sides. How have cells managed to solve the problem of passing (transducing) signals through a membrane that is almost impervious? And given this barrier, how can the inside of the cell possibly know what is going on in the surrounding extracellular space?

These signaling processes are part of the larger problem of cell-to-cell communication. Indeed, the evolution of the first multicellular animals (metazoa) more than 600 million years ago depended on the development of biochemical mechanisms that allow cells to receive and process signals arising from their neighbors within tissues. Without effective intercellular communication, the behavior of individual cells could not be coordinated, and the formation of architecturally complex tissues and organisms was inconceivable. Obviously, such communication depended on the ability of some cells to emit signals and of others to receive them and respond in specific ways. By necessity, these signals must pass through extracellular spaces en route from signal-emitting cells to those cells that are destined to receive these signals.

In very large part, the signals passed between cells are conveyed by proteins. This fact also required evolutionary innovations: signal emission requires an ability by some cells to release proteins into the nearby extracellular space. Such release—

the process of protein secretion—is also complicated by the imperviousness of the plasma membrane. Once released into the extracellular space, the designated recipient cells must be able to *sense* the presence of these proteins in their surroundings. Much of this chapter is focused on this second problem—how normal cells receive signals from the environment that surrounds them. As we will see, the deregulation of this signaling is central to the formation of cancer cells.

OceanofPDF.com

Glossary

transduction

(1) Process whereby a signaling element, such as a protein, receives a signal and, in response, processes the signal and emits another signal. (2) Process by which a gene is introduced into a cell, usually by a vector such as a viral vector.

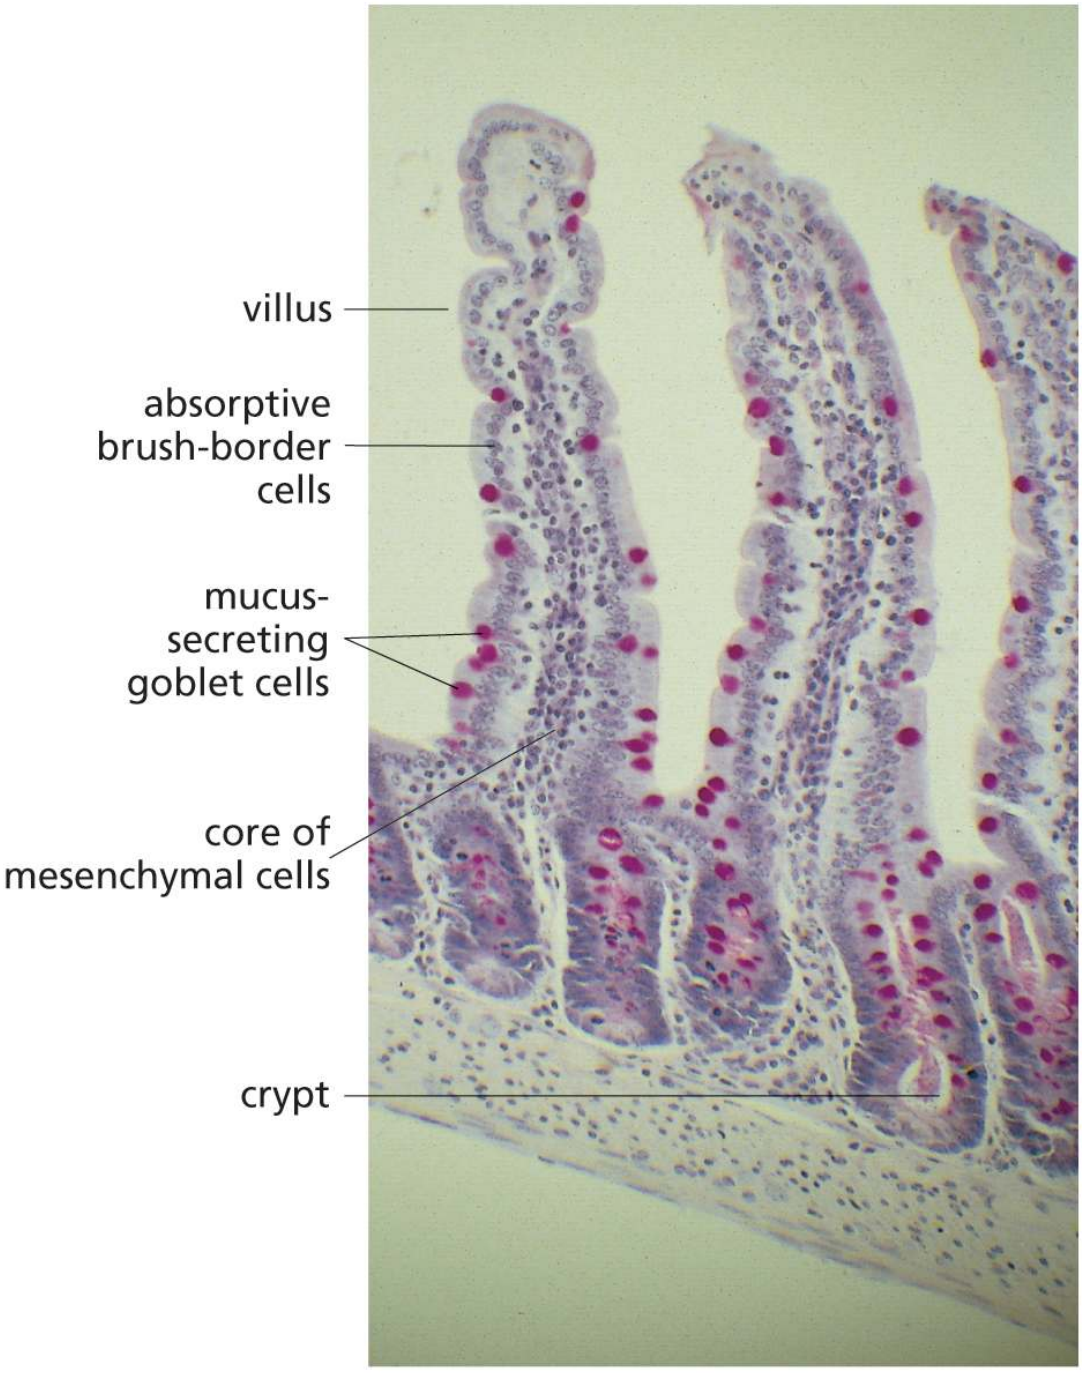
5.1 Normal metazoan cells control each other’s lives

As already implied, the normal versions of oncogene-encoded proteins often serve as components of the machinery that enables cells to receive and process biochemical signals regulating cell proliferation. Therefore, to truly appreciate the complexities of oncogene and oncoprotein function, we need to understand the details of how normal cell proliferation is governed.

Our entrée into this discussion comes from a basic and far-reaching principle. Proper tissue architecture depends absolutely on maintaining appropriate proportions of different constituent cell types within a tissue, on the replacement of missing cells, and on discarding extra, unneeded cells (**Figure 5.1**). Wounds must be repaired, and attacks by foreign infectious agents must be warded off through the concerted actions of many cells within the tissue.



Stained intestinal epithelial tissue. Columnar villi rise vertically, attached at their bases to the horizontal submucosal layer. On the surface of a villus, mucus-secreting goblet cells appear as red dots distributed among the violet absorptive brush-border cells. The core of each villus is made up of mesenchymal cells. Around the bases of the villi are crypts, which are pocket-like depressions.

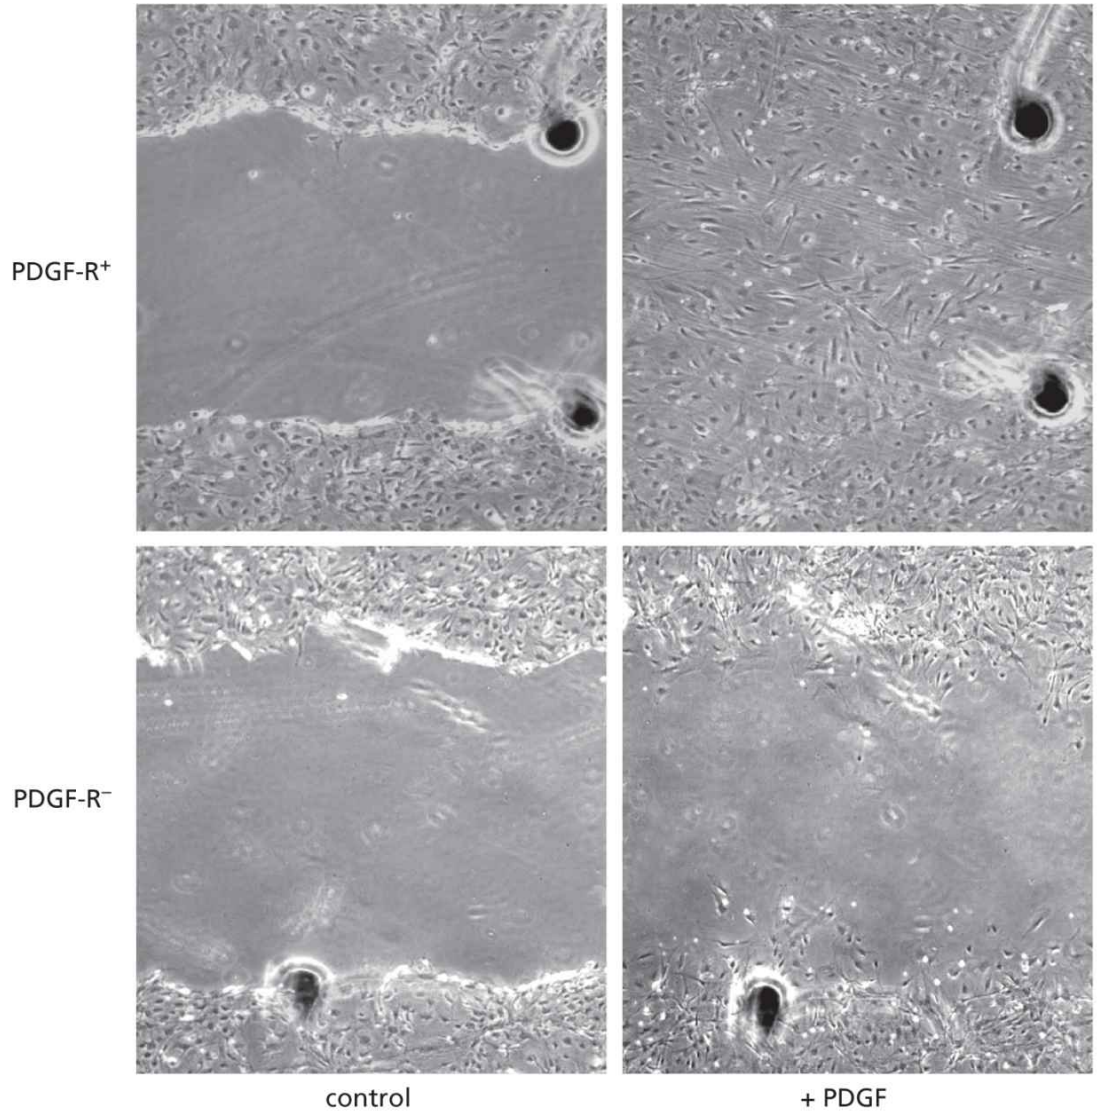
Figure 5.1 Maintenance of tissue architecture The epithelial lining of the small intestine shown here illustrates the fact that a number of distinct cell types coexist within a tissue. The relative numbers and positions of each cell type must be tightly controlled in order to ensure proper tissue structure and function. This control is largely achieved via the exchange of signals between neighboring cells within the tissue. In this particular epithelium, cell-to-cell signaling also ensures that new epithelial cells—termed *enterocytes* in the intestine—are continually being generated in the crypts (at the bases of fingerlike villi) in order to replace others that have migrated up the sides of the villi to the tips, where they are sloughed off. Included among the epithelial cells are mucus-secreting goblet cells (*dark red*) and absorptive cells, as well as enteroendocrine cells and Paneth cells (*not shown*). In addition, in the middle of each villus is a core of mesenchymal cell types, which together constitute the stroma and include fibroblasts, endothelial cells, pericytes, and macrophages. (From B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton, 2015.)

Decisions about growth versus no-growth must be made for the welfare of the entire tissue and whole organism, not for the benefit of its individual component cells. For this reason, no single cell within the condominium of cells that is a living tissue can be granted the autonomy to decide on its own whether it should proliferate or remain in a nongrowing, quiescent state. Instead, this weighty decision can be undertaken only after consultation with other cells within the tissue. These neighbors may provide a particular cell with growth-stimulating signals that stimulate its proliferation or release growth-inhibitory signals that discourage it. In the end, all the decisions made by an individual cell about its proliferation must, by necessity, represent a consensus decision shared with the cells that reside in its neighborhood. Much of this incessant back-and-forth chatter is conveyed by growth factors (GFs). These are relatively small proteins that are released by some cells, make their way through intercellular space, and eventually impinge on yet other cells, carrying with them specific biological messages. Growth factors convey many of the signals that tie the cells within a tissue together into a single community, all members of which are in continuous communication with their respective neighbors.

The dependence of individual cells on their surroundings is illustrated nicely by the behavior of normal cells when they are removed from living tissue and propagated in a Petri dish—the procedures that are termed tissue culture (see **Supplementary Sidebar 3.2**). Even though the liquid medium placed above the cells contains all the nutrients required to sustain their growth and division, including amino acids, vitamins, glucose, and salts, such medium, on its own, does not suffice to induce these cells to proliferate. Instead, this decision depends upon the addition to the medium of serum, usually prepared from the blood of calves or fetal calves. Serum contains the growth factors that persuade cells to multiply.

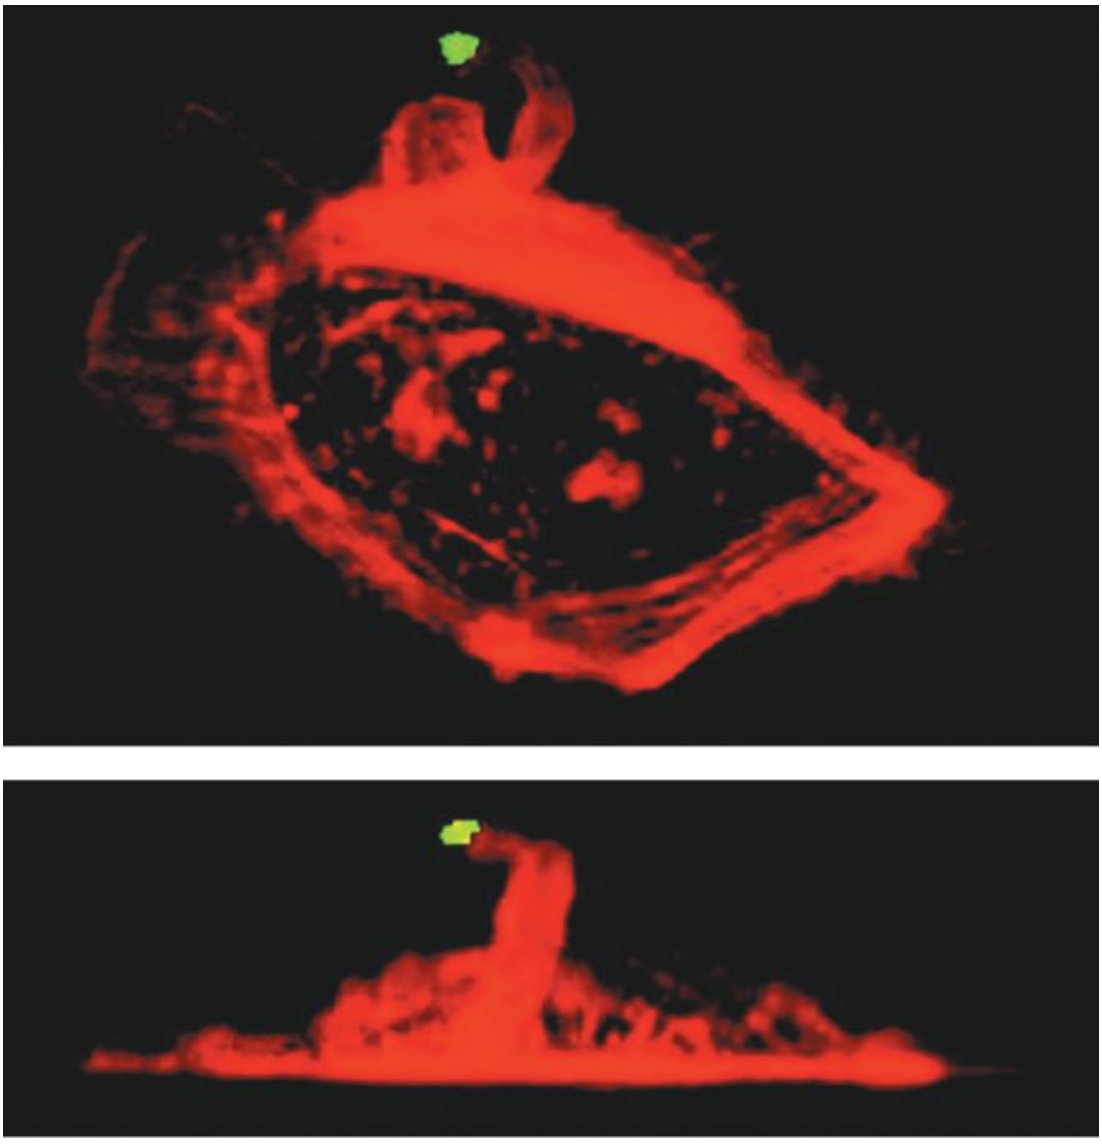
Serum is produced when blood is allowed to clot. The blood platelets adhere to one another and form a matrix that gradually contracts and traps most of the cellular components of the blood, including both the white and red cells. In the context of a wounded tissue, this clot formation is designed to stanch further bleeding. The clear fluid that remains after clot formation and retraction constitutes the serum.

While the platelets in a wound site aggregate as part of clot formation, they also initiate the wound healing process. This process is mediated via the release into the extracellular space of granules carrying a complex mixture of GFs (see Figure S5.1), notably platelet-derived growth factor (PDGF), epidermal growth factor (EGF), transforming growth factor-β1 (TGF-β1), vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF), and fibroblast growth factor 2 (FGF-2) (**Figure 5.2**), which act on diverse cell types in the damaged tissue, all of which must be enlisted in the task of reconstructing the damaged tissue. Portrayed differently, this complex mixture of released GFs hints at the complexity of the wound-healing process, in which the proliferation of these multiple distinct cell types must be coordinated.



A 2 by 2 block of micrographs shows the results of an experiment with cell cultures that have been physically damaged. When P D G F is added, the culture of cells that have P D G F-R can be seen to repair itself, whereas the culture of cells that are missing P D G F-R does not exhibit repair.

(A)



Two views of a red cellular mass that is extending an arm up toward a bright green dot.

(B)

Figure 5.2 Effects of growth factors on cells (A) The PDGF released by platelets upon clotting is a potent attractant and mitogen for fibroblasts, which swarm into a wound site in order to reconstruct the tissue. In this *in vitro* model of wound healing, two monolayers of fibroblasts in Petri dishes have been wounded by the tip of a pipette (*left two panels*) and one form of PDGF (PDGF-BB) has been added to their growth medium. While large numbers of wild-type fibroblasts (*top left*) proliferate and migrate into the wound site within 48 hours (*top right*), mutant fibroblasts that have been rendered unresponsive to PDGF (through the loss of a

PDGF cell-surface receptor, PDGF-R, that enables them to sense and respond to the presence of PDGF; *lower left*) fail to do so (*lower right*). (B) Five minutes after epidermal growth factor (EGF) that has been immobilized on a bead (*green dot*) is applied to a mouse mammary carcinoma cell, the cell has reorganized its actin cytoskeleton (*red*) and extended an arm of cytoplasm toward the growth factor (*above*, top view; *below*, side view). (A, from Z. Gao et al., *J. Biol. Chem.* 280:9375–9389, 2005. Copyright © 2005 ASBMB. This article is distributed under a Creative Commons Attribution 4.0 International license. B, from S.J. Kempiak et al., *J. Cell Biol.* 162:781–787, 2003. With permission from Rockefeller University Press.)

Secreted proliferation-stimulating factors, such as most of these GFs, are often termed mitogens, to indicate their ability to induce cells to proliferate. PDGF, for its part, is a potent stimulator of fibroblasts, which form much of the connective tissue including the cell layers beneath epithelia (see Figure 2.4). Its release during clot formation attracts fibroblasts into the wound site and then stimulates their proliferation (see, for example, Figure 5.2A). Other released GFs, such as epidermal growth factor (EGF), can cause dramatic changes in cell shape in addition to stimulating the proliferation of epithelial cells (see Figure 5.2B). Without stimulation by serum-derived PDGF, cultured fibroblasts will remain viable and metabolically active for weeks in a Petri dish, but they will not grow and divide.

This dependence of fibroblasts on growth-stimulating signals released by a second cell type, in this case, blood platelets, mirrors hundreds of similar cell-to-cell communication routes that operate within living tissues to encourage or discourage cell proliferation. Moreover, as discussed in greater detail below, PDGF and EGF are only two of a large and disparate group of growth factors that help to convey important growth-controlling messages from one cell to another (**Sidebar 5.1**).

Sidebar 5.1 Cell-to-cell communication involves far more than secreted growth factors

In fact, soluble growth factors represent only a small subset of the proteins that are secreted by cells and potentially contribute to the intercommunication between them. Most important is the network of secreted proteins that assemble to form the extracellular matrix (ECM) as discussed in Chapter 1 (see Figure 1.11C). More than 250 distinct proteins form the structural backbone of the ECM with up to three times as many additional secreted proteins associating in various ways with the ECM and modifying its structure. Some of the latter, largely proteases, continuously remodel the ECM and the GFs that are present in the extracellular space. We focus in this chapter largely on the GFs. Nevertheless, our narrative overlooks many of the still-poorly

understood functions of almost all ECM components, ECM-associated proteins, and secreted proteases. Together, they form the secretomes of cells.

As developed in the rest of this chapter, many oncogene-encoded proteins usurp the signaling molecules that enable cells to sense the presence of growth factors in their surroundings, to convey this information into the cell interior, and to process this information. By taking charge of the natural growth-stimulating machinery of the cell, oncoproteins are able to delude a cell into believing that it has encountered growth factors in its surroundings. Once this deception has taken place, the cell responds slavishly by beginning to proliferate, just as it would have done if abundant growth factors were actually present in the medium around it.

OceanofPDF.com

Glossary

mitogen
: (adj., - **genic**) An agent that provokes cell proliferation.

secretome
: The collection of proteins that are released by a cell into the extracellular space under specific physiological conditions or states of differentiation, often focused on signaling proteins.

growth factor
: Secreted protein that is able to stimulate the growth and/or proliferation of a cell by binding to a specific cell-surface receptor displayed by that cell.

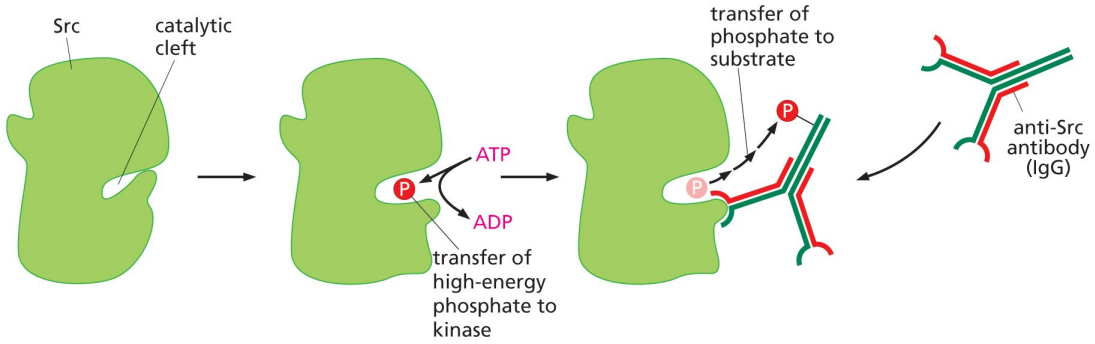
5.2 The *Src* protein functions as a tyrosine kinase

The first clues to how cell-to-cell signaling via growth factors operates came from biochemical analysis of the v-*src* oncogene and the protein that it specifies. The trail of clues led, step-by-step, from this protein to the receptors used by cells to detect growth factors and, in turn, to the intracellular signaling pathways that control normal and malignant cell proliferation.

The initial characterization of the v-*src*–encoded oncoprotein attracted enormous interest. This was the first cellular oncoprotein to be studied and therefore had the prospect of giving cancer researchers their first view of the biochemical mechanisms of cell transformation. After the molecular cloning of the *src* oncogene, the amino acid sequence of its protein product was deduced directly from the nucleotide sequence of the cloned gene. This sequence revealed that the encoded protein was synthesized as a polypeptide chain of 533 amino acid residues and had a mass of almost precisely 60 kilodaltons (kD).

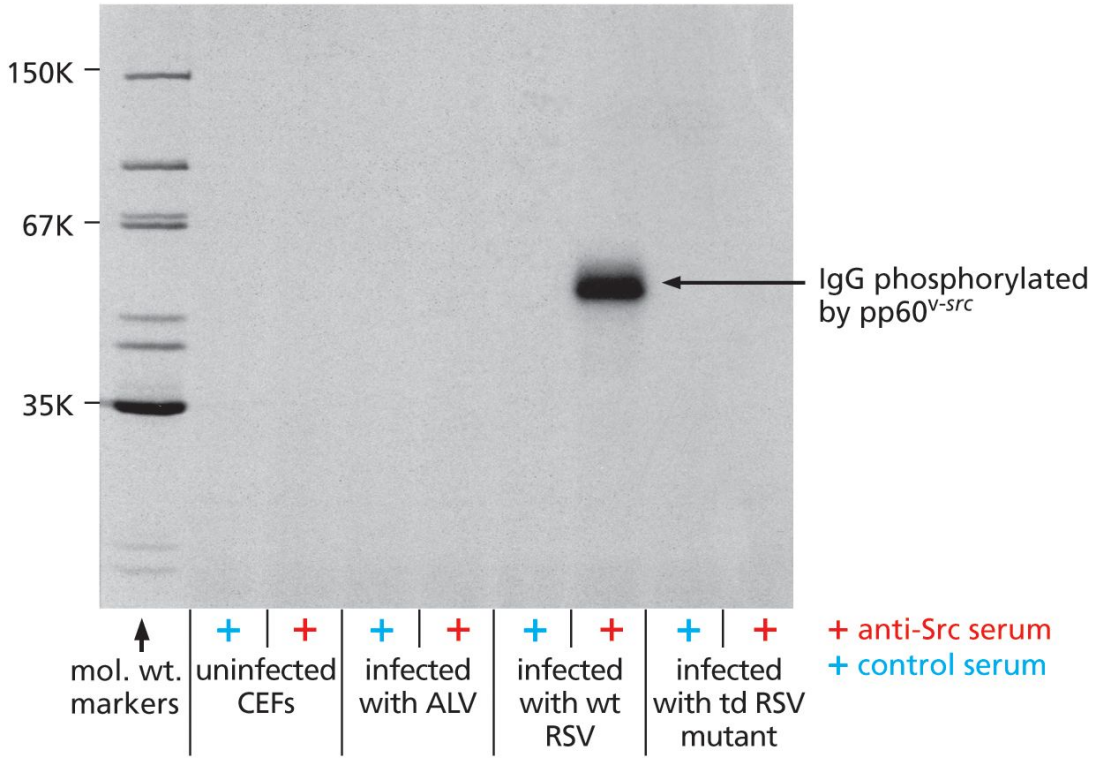
The amino acid sequence of Src provided few clues as to how this oncoprotein functions to promote cell proliferation and transformation. Avian and mammalian cells transformed by the v-*src* oncogene were known to exhibit a radically altered shape, to pump in glucose from the surrounding medium more rapidly than normal cells, to grow in an anchorage-independent fashion, to lose contact inhibition, and to form tumors. Whatever the precise mechanisms of action, it was obvious that Src affected, directly or indirectly, a wide variety of intracellular targets.

Clever biochemical sleuthing in 1977–1978 solved the puzzle of how Src operates. Antibodies were produced that specifically recognized and bound Src (**Supplementary Sidebar 5.1**). The antibody molecules were found to become phosphorylated when they were incubated in solution with both Src and adenosine triphosphate (ATP), the universal phosphate donor of the cell. Phosphorylation was known to involve the covalent attachment of phosphate groups to the side chains of specific amino acid residues. Hence, it was clear that Src operates as a protein kinase —an enzyme that removes a high-energy phosphate group from ATP and transfers it to a suitable protein substrate, in this instance, an antibody molecule (**Figure 5.3**). While Src does not normally phosphorylate antibody molecules, its ability to do so in these early experiments suggested that its usual mode of action also involved the phosphorylation of certain protein substrates within cells.



A sequence that begins when the catalytic cleft on Sarc opens, in order to permit transfer of high-energy phosphate to a kinase within the cleft. This phosphate comes from an A T P molecule, reducing it to A D P. The phosphate is then transferred to the substrate of an anti-Sarc antibody (I g G).

(A)



The results of an experiment, in blot form. The left edge of the image shows a vertical series of blots used as molecular weight markers for calibration. The rest of the image has control serum and anti-Sarc serum bands for four different categories of chicken embryo fibroblast: uninfected, infected with A L V, infected with wild-type R S V, and infected with transformation-defective R S V mutant. The only blot is in the band for infected with wild-type R S V,

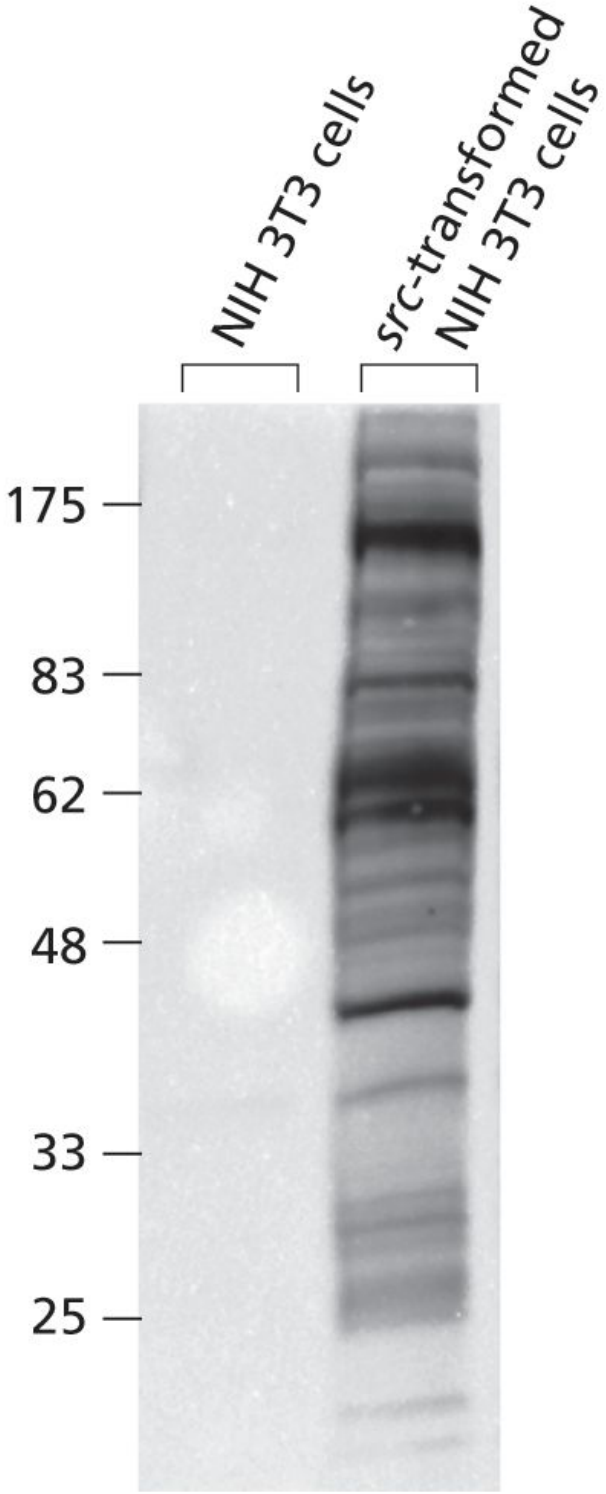
with anti-Sarc serum. The vertical position of this heavy blot suggests a molecular weight of about 50 k. The blot is labeled I g G phosphorylated by p p 60 v-Sarc.
(B)

Figure 5.3 Phosphorylation of a precipitating antibody molecule by Src
Protein kinases operate by removing the high-energy γ phosphate group from ATP and attaching it to the hydroxyl groups in the side chains of serine, threonine, or tyrosine residues of substrate proteins. (A) The antibody molecule that was used to immunoprecipitate Src molecules (see **Supplementary Sidebar 5.1**) also could serve as a substrate for phosphorylation by this kinase. In cells, Src phosphorylates a wide range of protein substrates. (B) This experiment revealed, for the first time, the biochemical activity associated with an oncoprotein. Normal rabbit serum (*blue* "=" *signs*) or serum from a rabbit bearing an RSV-induced, Src-expressing tumor (which contained antibodies against Src; *red* "=" *signs*) was used to immunoprecipitate cell lysates that were incubated with $^{32}PO_4$-radiolabeled ATP. Lysates were prepared from uninfected chicken embryo fibroblasts (CEFs); CEFs infected with avian leukosis virus (ALV), which lacks a *src* oncogene; CEFs infected with wild-type (wt) RSV; or CEFs infected with a transformation-defective (td) mutant of RSV, which lacks a functional *src* gene. Only the combination of tumor-bearing rabbit serum and a lysate from wt RSV–infected CEFs yielded a strongly ^{32}P-labeled protein that co-migrated with the precipitating antibody, indicating that the antibody molecule had become phosphorylated by the Src oncoprotein. (B, from M.S. Collett and R.L. Erikson, *Proc. Natl. Acad. Sci. USA* 75:2021–2024, 1978. With permission from the authors.)

Independent of this kinase activity, Src was itself a phosphoprotein, that is, it carried phosphate groups attached covalently to one or more of its amino acid side chains. This indicated that Src also served as a substrate for phosphorylation by a protein kinase—either phosphorylating itself (autophosphorylation) or serving as the substrate of yet another kinase. Its molecular weight and phosphoprotein status caused it initially to be called $pp60^{src}$, although hereafter we will refer to it simply as Src.

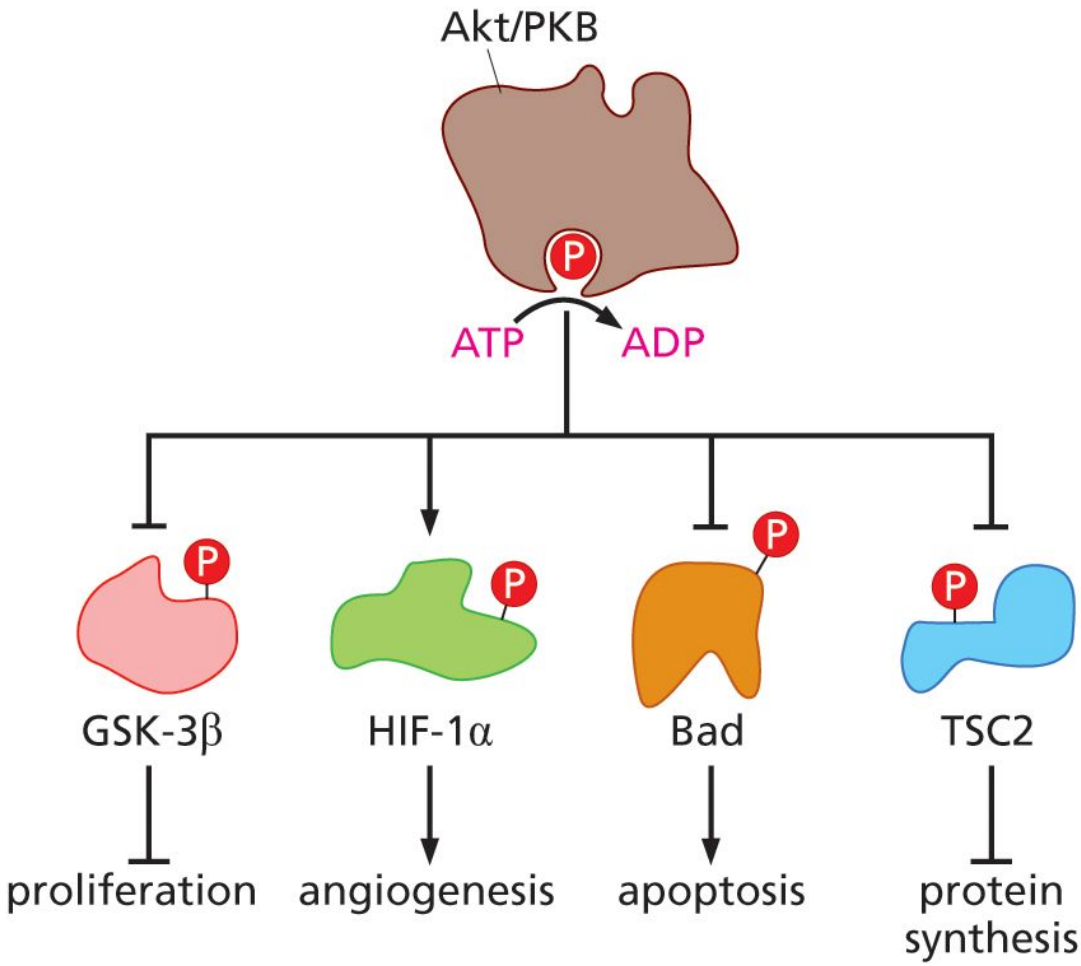
The fact that Src functions as a kinase was a major revelation. In principle, a protein kinase can phosphorylate multiple, distinct substrate proteins within a cell. In the case of Src, more than 50 distinct substrates have since been enumerated (**Figure 5.4A**). Once phosphorylated, each of these substrate proteins may be functionally altered and proceed, in turn, to alter the functions of its own set of downstream targets. This mode of action (Figure 5.4B and C) seemed to explain how a protein kinase could act pleiotropically to perturb multiple cell phenotypes. At the time of this discovery, other

protein kinases had already been found able to regulate complex circuits, notably those involved in carbohydrate metabolism.



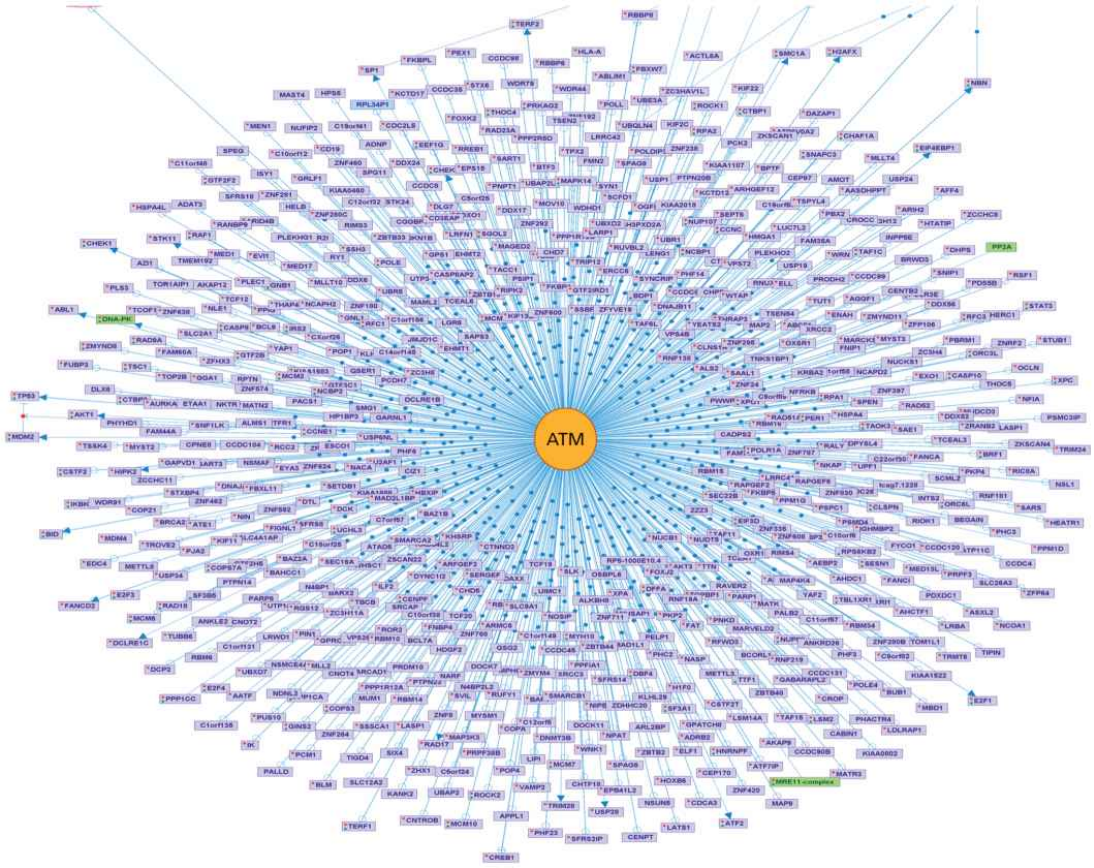
An autoradiograph with two lanes. There are numbers along the left edge, from 25 near the bottom to 175 near the top. The lane on the left, for untransformed N I H 3 T 3 cells, is essentially blank. The lane on the right, for Sarc-transformed N I H 3 T 3 cells, has a series of bands that are dark and pronounced from 25 on up.

(A)



A diagram illustrating the actions of the A k t / P K B kinase. After it receives a phosphate from A T P (which then becomes A D P), it can transfer the phosphate to one of four proteins shown. Phosphorylation of G S K-3 beta inactivates its power to inhibit proliferation, Phosphorylation of H I F 1 alpha activates its angiogenic powers, Phosphorylation of B a d inactivates its apoptotic powers, and Phosphorylation of T S C 2 inactives its power to block protein synthesis.

(B)



A sunburst-like figure with A T M at the center, surrounded by hundreds of protein substrate names. Lines connect A T M to the names.

(C)

Figure 5.4 Actions of protein kinases (A) This autoradiograph of proteins resolved by gel electrophoresis illustrates the fact that the phosphorylation state of a number of distinct protein species within a cell can be altered by the actions of the Src kinase expressed in cells by Rous sarcoma virus. This immunoblot analysis, using an anti-phosphotyrosine antibody, specifically detects proteins that carry phosphotyrosine residues, the known products of Src kinase action (see **Supplementary Sidebar 5.2**). The left channel contains proteins from a lysate of untransformed mouse NIH 3T3 fibroblasts and is essentially blank, indicating the relative absence of phosphotyrosine-containing proteins in cells that lack Src expression. The right channel shows the phosphorylated proteins in cells expressing an active Src kinase protein. (B) The pleiotropic actions of a protein kinase usually derive from its ability to phosphorylate and thereby modify the functional state of a number of distinct substrate proteins. Illustrated here are the actions of the Akt/PKB kinase, a serine/threonine kinase that can influence a wide variety of biological processes through phosphorylation of the indicated major

control proteins. (A number of other known substrates of this kinase are not shown here.) Thus, Akt/PKB can inactivate the antiproliferative actions of GSK-3β, the pro-apoptotic powers of Bad, and the translation-inhibiting actions of TSC2, and it can activate the angiogenic (blood vessel–inducing) powers of HIF-1α. In this diagram and throughout this book, arrowheads denote stimulatory signals, while lines at right angles (crossbars) denote an inhibitory signal. (C) A more typical behavior of a protein kinase is illustrated here. The ability of a serine/threonine kinase termed ATM, which evokes a highly complex set of biochemical changes in a cell in response to detected DNA damage (discussed in Chapter 12), has been associated with its phosphorylation of many hundreds of distinct protein substrates, most validated by direct biochemical analyses. (A, from S.M. Ulrich et al., *Biochemistry* 42:7915–7921, 2003. With permission from American Chemical Society. C, courtesy of Y. Shiloh.)

Src was soon found to be quite different from all other previously discovered protein kinases. These other kinases were known to attach phosphate groups to the side chains of serine and threonine amino acid residues. Src, in contrast, phosphorylated certain tyrosine residues of its protein substrates (**Supplementary Sidebar 5.2**). Careful quantification of the phosphorylated amino acid residues in cells revealed how unusual this enzymatic activity is. More than 99% of the phosphoamino acids in normal cells are phosphothreonine or phosphoserine; phosphotyrosine constitutes as little as 0.05 to 0.1% of these cells' total phosphoamino acids.

After transformation of cells by the v-*src* oncogene, the level of phosphotyrosine was found to rise dramatically, becoming as much as 1% of the total phosphoamino acids in these cells. (This helps to explain the dramatic differences between the two channels shown in Figure 5.4A.) When the same cells were transformed by other oncogenes, such as H-*ras*, their phosphoamino acid content hardly changed at all. Therefore, the creation of phosphotyrosine residues appeared to be a specific attribute of Src and was not associated with all mechanisms of cell transformation. The multiple bands of proteins phosphorylated by Src provided another insight: the ability of a protein kinase like Src to evoke multiple distinct biochemical changes in a cell (representing its ability to function in a pleiotropic fashion) is derived from its ability, and that of other kinases, to phosphorylate a multitude of functionally distinct protein substrates (see Figure 5.4B and C). Later studies yielded a second, related conclusion: signaling through tyrosine phosphorylation is a device that is used largely by mitogenic signaling pathways in mammalian cells, whereas the kinases that are involved in regulating thousands of other processes rely almost exclusively on serine and threonine phosphorylation to convey their messages.

Mutant forms of Src that had lost the ability to phosphorylate substrate proteins also lost their transforming powers. So the accumulating evidence converged on the idea

that Src succeeds in transforming cells through its ability to act as a tyrosine kinase (TK) and phosphorylate a still-uncharacterized group of substrate proteins within these cells. While an important initial clue, these advances only allowed a reformulation of the major question surrounding this research area. Now the problem could be restated as follows: How did the phosphorylation of tyrosine residues result in cell transformation?

OceanofPDF.com

Glossary

receptor
: Protein found on the plasma membrane or in the nucleus within a cell that is capable of specifically binding a signaling molecule (its cognate ligand). Most types of receptors emit signals, such as those inducing cell proliferation, in response to such binding. *See also* **ligand**.

kinase
: Enzyme that removes the γ phosphate from ATP and covalently attaches the phosphate moiety to substrate molecules, often but not exclusively proteins.

phosphoprotein
: A protein to which one or more phosphate groups have been covalently attached, usually to threonine, serine, or tyrosine residues.

autophosphorylation
: Phosphorylation of a protein molecule by its own associated kinase activity. *See also* **transphosphorylation**.

pleiotropy
: Ability of a gene or protein to concomitantly evoke multiple distinct downstream responses within a cell or organism.

5.3 The EGF receptor functions as a tyrosine kinase

After the cloning and sequencing of the v-*src* oncogene, the oncogenes of a number of other acutely transforming retroviruses were isolated by molecular cloning and subjected to DNA sequencing. Unfortunately, in the great majority of cases, the amino acid sequences of their protein products provided few clues about biochemical function. The next major insights came instead from another area of research. Cell biologists interested in how cells exchange signals with one another isolated a variety of proteins involved in cell-to-cell signaling and determined the amino acid sequences of these proteins. Quite unexpectedly, close connections were uncovered between these signaling proteins and the protein products of certain oncogenes.

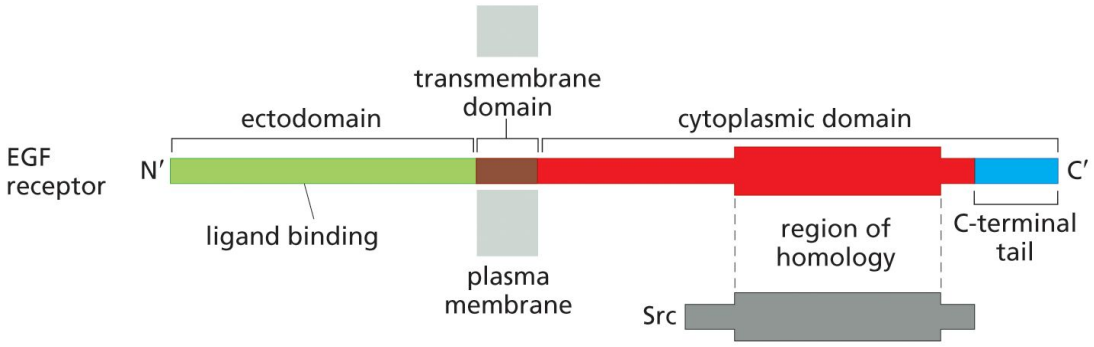
This line of research began with epidermal growth factor (EGF), the first of the growth factors to be discovered. EGF was initially characterized because of its ability to provoke premature eye opening in newborn mice. Soon after, EGF was found to have mitogenic effects when applied to a variety of epithelial cell types.

EGF was able to bind to the surfaces of the cells whose growth it stimulated; cells to which EGF was unable to bind were unresponsive to its mitogenic effects. Taken together, such observations suggested the involvement of a cell surface protein, an EGF *receptor* (EGF-R), that was able to specifically recognize EGF in the extracellular space, bind to it, and inform the cell interior that an encounter with EGF had occurred. In the language of biochemistry, EGF served as the ligand for its cognate receptor—the still-hypothetical EGF receptor.

Isolation of the EGF-R protein proved challenging because this receptor, like many others, is usually expressed at very low levels in cells. Researchers circumvented this problem by taking advantage of a human tumor cell line (an epidermoid carcinoma of the uterus) that expresses the EGF-R at elevated levels—as much as 100-fold higher than normal. These cells yielded an abundance of the receptor protein, which could then be purified biochemically and subjected to amino acid sequence analysis.

The sequence of the EGF-R protein provided important insights into its overall structural features and how this structure enables it to function (**Figure 5.5A**). Its large N-terminal domain of 621 amino acid residues, which protrudes into the extracellular space (and is therefore termed its ectodomain), was clearly involved in recognizing and binding the EGF ligand. The EGF receptor possessed a second distinctive domain that is common to many cell surface glycoproteins; this transmembrane domain of 23

amino acid residues threads its way from outside the cell through the lipid bilayer of the plasma membrane into the cytoplasm. The existence of this transmembrane domain could be deduced from the presence of a continuous stretch of hydrophobic amino acid residues located in the middle of the protein's sequence; this domain of EGF-R protein resides comfortably in the highly hydrophobic environment of the lipid bilayer that forms the plasma membrane. Finally, a third domain of 542 residues at the C-terminus (that is, the end of the chain synthesized last) of the EGF receptor was found to extend into the cytoplasm.



A schematic diagram of the receptor E G F receptor, with an N terminus on the left and a C terminus on the right. The segments, from left to right, are a ligand binding ectodomain, shown in green; a transmembrane domain, shown in brown, that spans the plasma membrane; and a cytoplasmic domain with a long red section followed by a shorter blue section. A widened part of the red section is the region of homology with a S r c protein, shown alongside. The blue section is the terminal tail.

(A)

A comparison of the amino acid sequences of the cytoplasmic domains of six proteins: S r c, A b l, F e S, Erb B, R a f, and M o s. Green highlighting indicates where S r c and E r b B match.

(B)

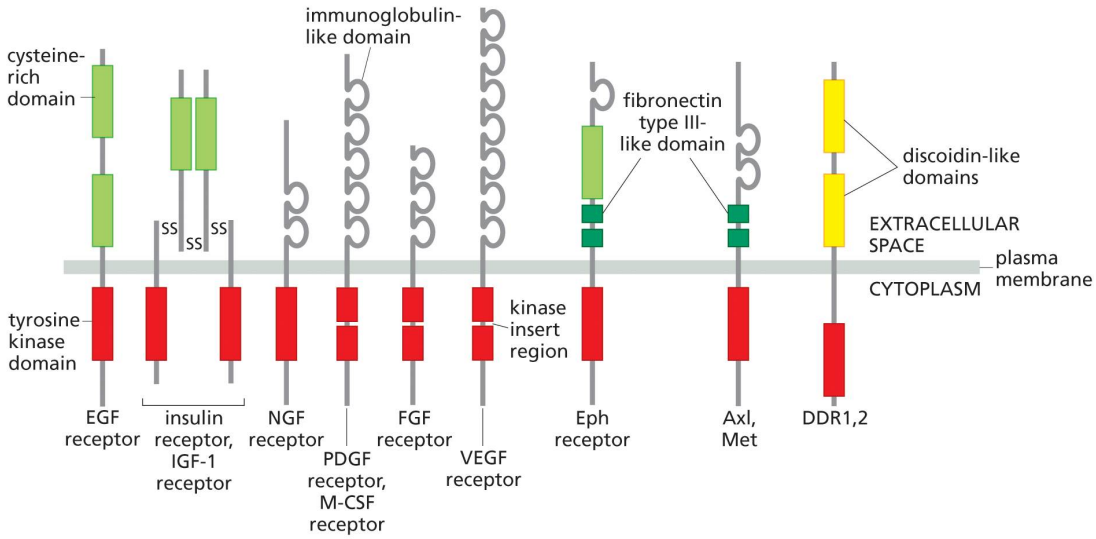
Figure 5.5 Structure of the EGF receptor (A) The receptor for epidermal growth factor (EGF-R) is a complex protein with an extracellular domain (ectodomain, *green*), a transmembrane domain that threads its way through the plasma membrane (*brown*), and a cytoplasmic domain (*red*, *blue*). The ligand-binding domain is responsible for binding EGF. Similarity in amino acid sequences (see panel B) demonstrates that one region of the cytoplasmic domain (*wide red rectangle*) is related to a region in the Src oncoprotein (*gray*). (B) Comparison of the amino acid sequences (using the single-letter code) of the cytoplasmic domains of the EGF-R (labeled “ErbB” here) and Src revealed areas of sequence identity (*green*), suggesting that the EGF-R, like Src, emits signals by functioning as a tyrosine kinase. While the sequence identities seem to be quite scattered, the shared residues nonetheless indicate clear evolutionary relatedness (homology)

between Src and ErbB; such homology of structure usually indicates analogous functions. Yet other viral oncoproteins, such as Abl and Fes, some of whose sequences are also shown here, were found to share some sequence similarity with these two. The viral oncoproteins specified by the *raf* and *mos* oncogenes, which function as serine/threonine kinases, are seen to be more distantly related, sharing even fewer sequences with Src and the EGF-R. The dashes indicate amino acid residues that are missing in one protein but are present in one or more of its homologs; these have been introduced to maximize the sequence alignment between homologs. (Adapted from G.M. Cooper, Oncogenes, 2nd ed. Sudbury, MA: Jones and Bartlett, 1995. www.jblearning.com. Reprinted with permission.)

The overall structure of the EGF receptor suggested in outline how it functions. After its ectodomain binds EGF, a signal is transmitted through the plasma membrane to activate the cytoplasmic domain of the receptor; once activated, the latter emits signals that induce a cell to grow and divide. Provocatively, examination of this cytoplasmic domain revealed a clear sequence similarity with the already-known sequence of the Src protein (Figure 5.5B). (Such shared structure indicates similar functions and a shared descent from a common precursor in the distant evolutionary past.)

Suddenly, it became clear how the EGF receptor emits signals in the cell interior: once its ectodomain binds EGF, somehow the Src-like kinase in its cytoplasmic domain becomes activated, proceeds to phosphorylate tyrosines on certain cytoplasmic proteins, and thereby causes a cell to proliferate. Subsequent sequencing efforts revealed overall sequence similarities among a variety of tyrosine kinases, many of which can function as oncoproteins (see Figure 5.5B).

Since these initial analyses of the EGF receptor structure, a large number of other, similarly structured receptors have been characterized (**Figure 5.6**). As discussed later, each of these receptors has its own growth factor ligand or set of ligands (**Table 5.1**). Depending on the particular growth factor–receptor pair, the binding of a ligand to its receptor can trigger multiple biological responses in the cell in addition to stimulating growth and division. Important among these are changes in cell shape, cell survival, cell metabolism, and cell motility.



An overview of different tyrosine kinase receptor structures, all shown embedded in a plasma membrane. The samples include an E G F receptor, an insulin receptor slash I G F-1 receptor, an N G F receptor, a P D G F receptor slash M-C S F receptor, an F G F receptor, a V E G F receptor, an E p h receptor, an A x l slash M e t, and a D D R 1,2. On the cytoplasm side, the tyrosine kinase domains are shown in red. Some have a break in the middle, a kinase insert region. On the extracellular side, the structures are more varied. There are long cysteine-rich domains shown as light green rectangles, shorter fibronectin type 3-like domains shown as dark green squares, long discoidin-like domains shown as yellow rectangles, and immunoglobulin like domains shown as series of connected loops.

Figure 5.6 Structure of tyrosine kinase receptors The EGF receptor (see Figure 5.5A) is only one of many similarly structured receptors that are encoded by the human genome. These tyrosine kinase receptors (RTKs) can be placed into distinct families, depending on the details of their structure. Representatives of most of these families are shown here. All have in common quite similar cytoplasmic tyrosine kinase domains (*red*), although in some cases (e.g., the VEGF receptor) these domains are interrupted by small “insert” regions. The RTK ectodomains (which protrude into the extracellular space; *green*, *gray*, *yellow*) have highly variable structures, reflecting the fact that they recognize and bind a wide variety of extracellular ligands. (From B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton, 2015.)

Table 5.1 Growth factors (GFs) and tyrosine kinase receptors that are often involved in tumor pathogenesis

Name of GF	Name of receptor	Cells responding to GF
PDGF[a]	PDGF-R	endothelial, VSMCs, fibroblasts, other mesenchymal cells, glial cells
EGF[b]	EGF-R[c]	many types of epithelial cells, some mesenchymal cells
NGF	Trk	neurons
FGF[d]	FGF-R[e]	endothelial, fibroblasts, other mesenchymal cells, VSMCs, neuroectodermal cells
HGF/SF	Met	various epithelial cells
VEGF[f]	VEGF-R[g]	endothelial cells in capillaries, lymph ducts
IGF[h]	IGF-R1	wide variety of cell types
GDNF	Ret	neuroectodermal cells
SCF	Kit	hematopoietic, mesenchymal cells

Abbreviation: VSMC, vascular smooth muscle cell.
Adapted in part from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton, 2015.

Interestingly, these receptors and their ligands represent relatively recent evolutionary inventions, and their antecedents cannot be found among the proteins made by almost all single-cell eukaryotes. Many were invented just before metazoan life first arose and have been retained in clearly recognizable form in all modern metazoa. This explains why research on the cell-to-cell communication systems of simpler metazoan

organisms, such as worms and flies, has so greatly enriched our understanding of growth factors and how they signal. Unexpectedly, recent research has revealed the presence of a tyrosine kinase receptor gene in the genome of at least one single-cell eukaryote; this organism, which may occasionally form multicellular aggregates, may be closely related to the common protozoan ancestor of all metazoa, and its receptor may be the prototype of many dozens of tyrosine kinase receptors present in modern metazoa including ourselves (**Supplementary Sidebar 5.3**).

Glossary

ligand
: Molecule that binds specifically to a receptor and thereby activates its signaling powers. *See also* **receptor**.

ectodomain
: Portion of a cell surface protein that protrudes from the plasma membrane into the extracellular space.

transmembrane
: Referring to the domain of a protein, usually composed of a stretch of 12 to 35 hydrophobic amino acids, that is threaded through a lipid bilayer membrane and therefore resides largely or entirely within the hydrophobic environment of the lipid bilayer.

hydrophobic
: Referring to a chemical moiety or environment that avoids direct interaction with water. *Compare* **hydrophilic**.

motility
: (adj., **motile**) Tendency for movement, such as that of individual cells, from one location to another.

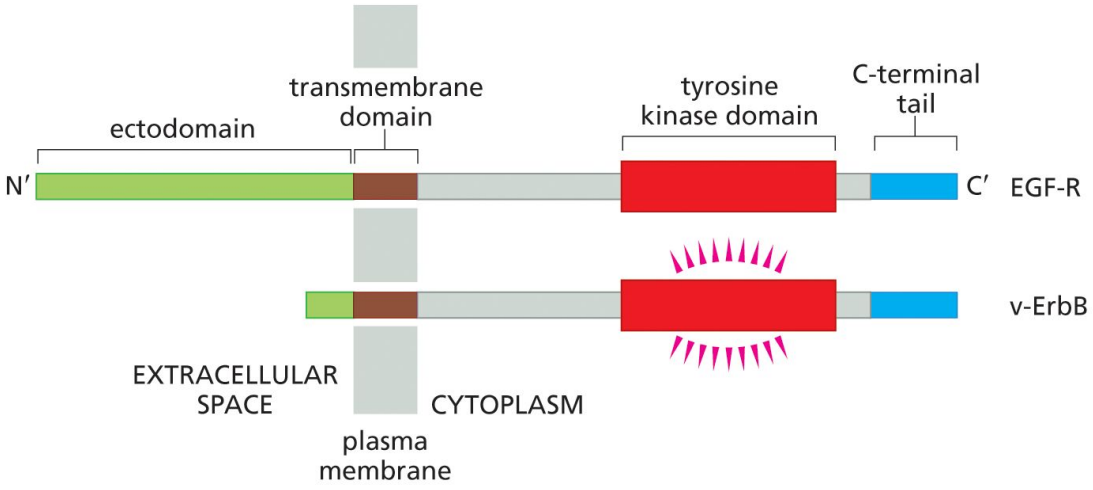
5.4 An altered growth factor receptor can function as an oncoprotein

A real bombshell fell in 1984 when the sequence of the EGF receptor was recognized to be closely related to the sequence of a known oncoprotein specified by the *erbB* oncogene. This oncogene had been discovered originally in the genome of avian erythroblastosis virus (AEV), a transforming retrovirus that rapidly induces a leukemia of the red blood cell precursors (an erythroleukemia). In one stroke, two areas of cell biology were united. A protein used by the cell to sense the presence of a growth factor in its surroundings had been appropriated (in its avian form) and converted into a potent retrovirus-encoded oncoprotein.

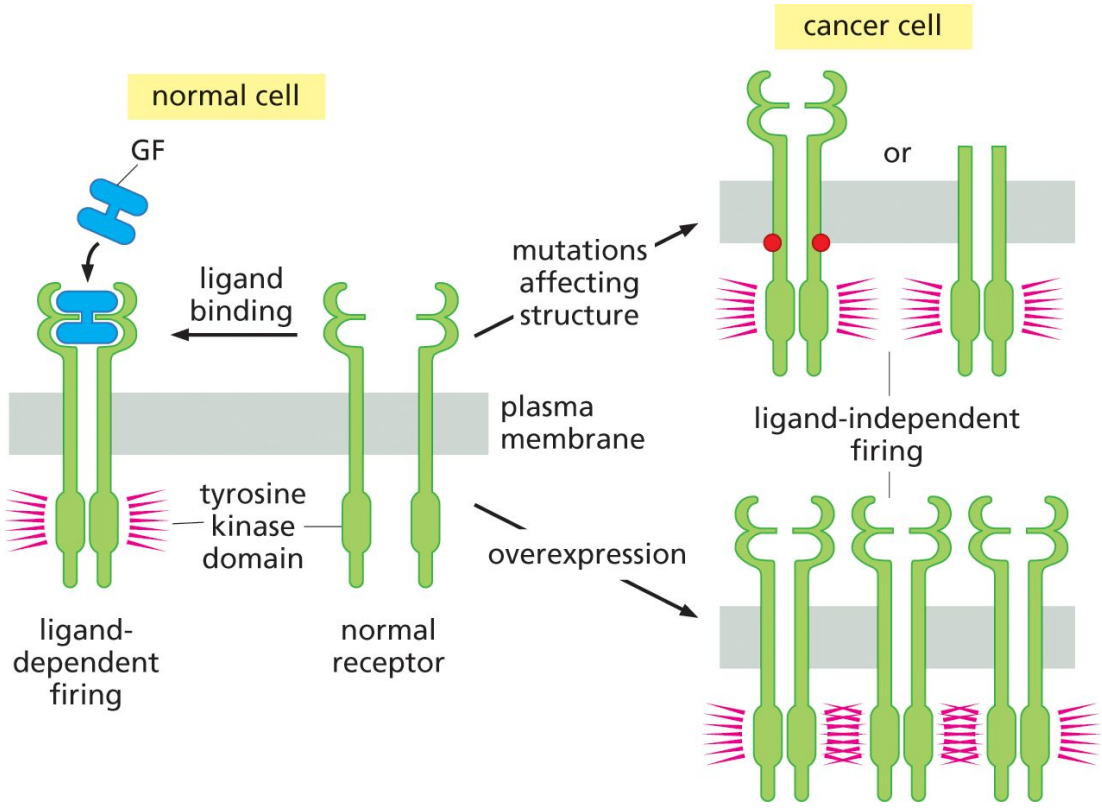
Once examined in detail, the oncoprotein specified by the *erbB* oncogene of avian erythroblastosis virus was found to lack sequences present in the N-terminal ectodomain of the EGF receptor (**Figure 5.7**). Without these N-terminal sequences, the ErbB oncoprotein clearly cannot recognize and bind EGF, and yet it functions as a potent stimulator of cell proliferation. This realization led to an interesting speculation that was soon validated: somehow, deletion of the ectodomain enables the resulting truncated EGF receptor protein to send growth-stimulating signals into cells in a constitutive fashion, fully independent of EGF. Years later, such truncated EGF receptors were discovered to be present in one-third of human glioblastomas and in smaller proportions of a variety of other human tumors. Still later, the presence in breast cancers of similarly truncated versions of ErbB/EGF-R's close cousin, termed variously ErbB2, HER2, or Neu, were found to be associated with particularly poor prognosis.



An E G F receptor and a v-Erb B oncoprotein shown schematically, side by side within the same plasma membrane. On the extracellular side, the E G F receptor has a long ectodomain, whereas the v-Erb B protein has much shorter one. On the cytoplasm side, the two proteins have the same structure: a long, gray domain with a widened tyrosine kinase domain shown in red, followed by a blue C-terminal tail. However, the v-Erb B protein's tyrosine kinase domain is signaling, where as the E G F receptor's is not.

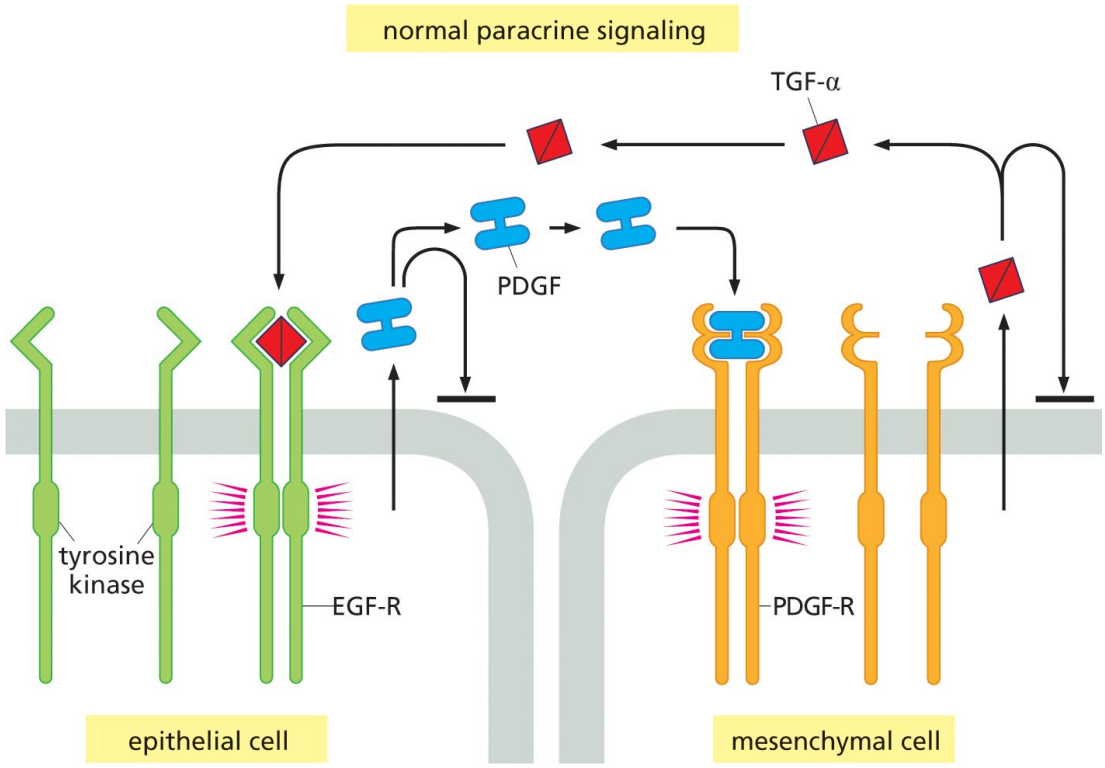
Figure 5.7 The EGF receptor and v-ErbB The EGF receptor and the v-ErbB oncoprotein of avian erythroblastosis virus are closely related. More specifically, the v-ErbB protein is specified by an altered version of the gene encoding the chicken EGF receptor, which encodes a truncated form of EGF-R that lacks most of the normally present ectodomain (*green*). In the absence of ligand, signaling by the intact receptor molecule is silent, whereas the truncated receptor can emit mitogenic signals constitutively, i.e., without stimulation by EGF ligand.

As indicated schematically in **Figure 5.8A**, mutations in the genes encoding growth factor receptors, including those specifying truncated receptors, may trigger ligand-independent firing by these receptors. Indeed, a variety of mutations, including those creating amino acid substitutions in the transmembrane domain (shown), or in the ectodomain and cytoplasmic domains (not shown), of some receptors can provoke ligand-independent firing. (In fact, Figure 5.8 introduces yet another idea that we will explore in detail shortly: growth factors often activate receptors by triggering receptor dimerization.) In Chapter 17, we will see how structurally altered growth factor receptors influence the responsiveness of human tumors to anti-cancer therapeutic drugs.



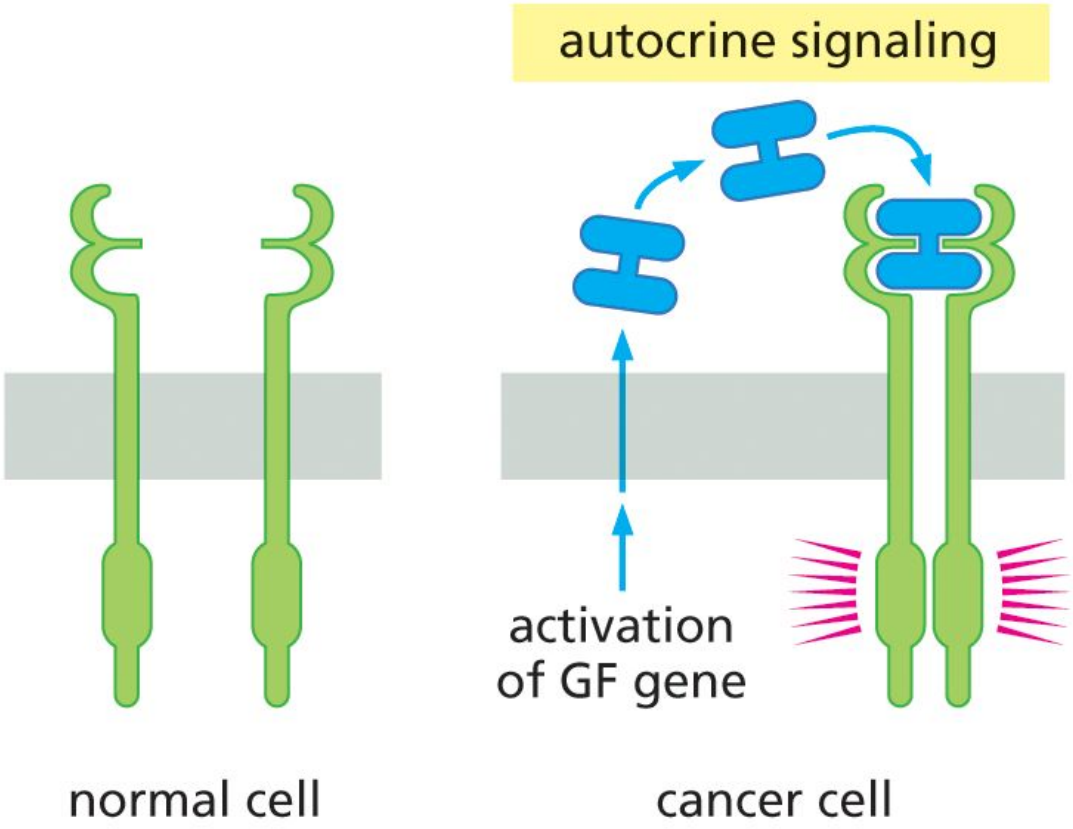
Two normal growth factor (G F) receptors with extracellular ectodomains and cytoplasmic tyrosine kinase domains. As one of them binds with a G F, the two subunits move together and the cytoplasmic domains begin signaling. This is ligand-dependent firing. Also shown are two cancer cell abnormalities that lead to ligand-independent firing. In mutations affecting structure, abnormalities in the receptors cause firing in the absence of any ligand. In overexpression, the crowding together of too many receptors causes subunits to connect and begin firing even in the absence of any ligand.

(A)



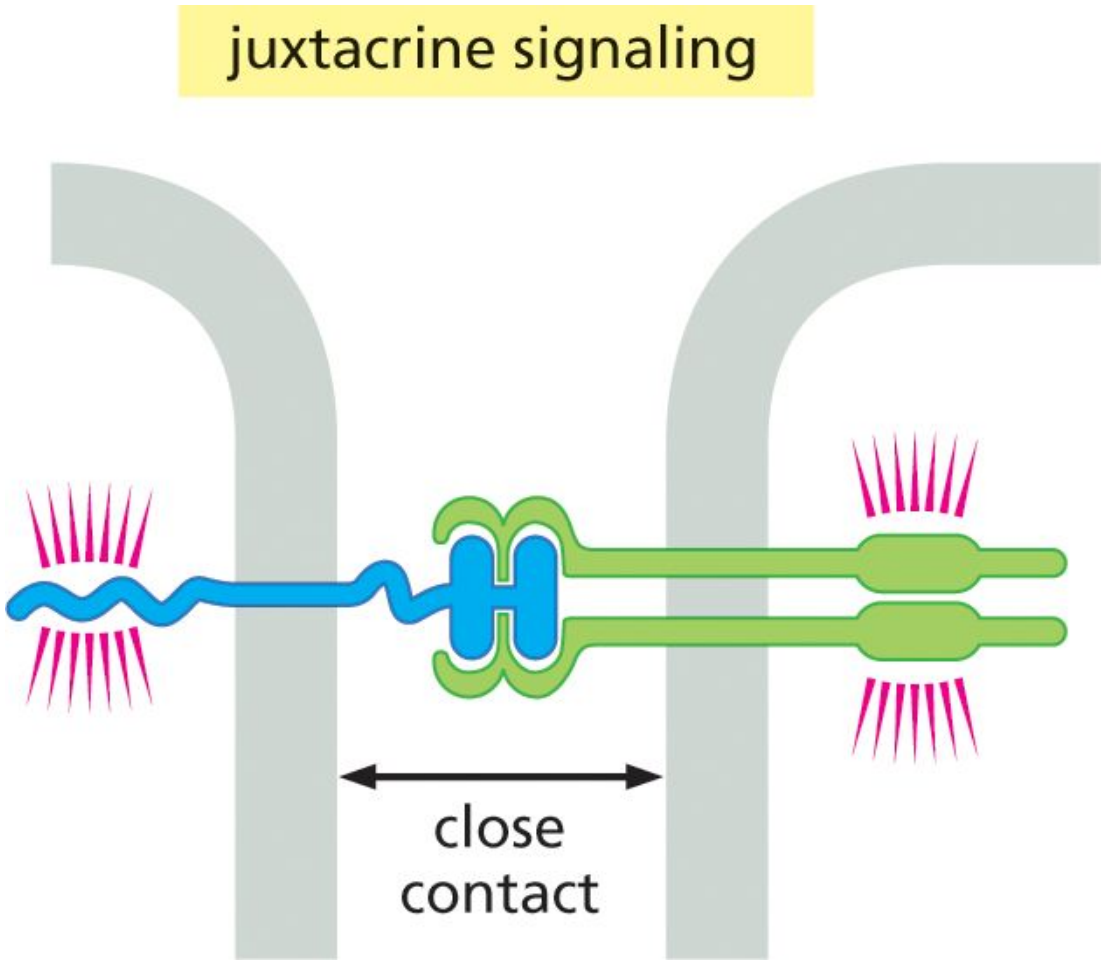
Normal paracrine signaling between an epithelial cell that produces P G D F and an adjacent mesenchymal cell that produces T G F alpha. Each ligand finds no receptors on the cell of origin but binds to receptors on the other cell, causing signaling by both sets of receptors.

(B)



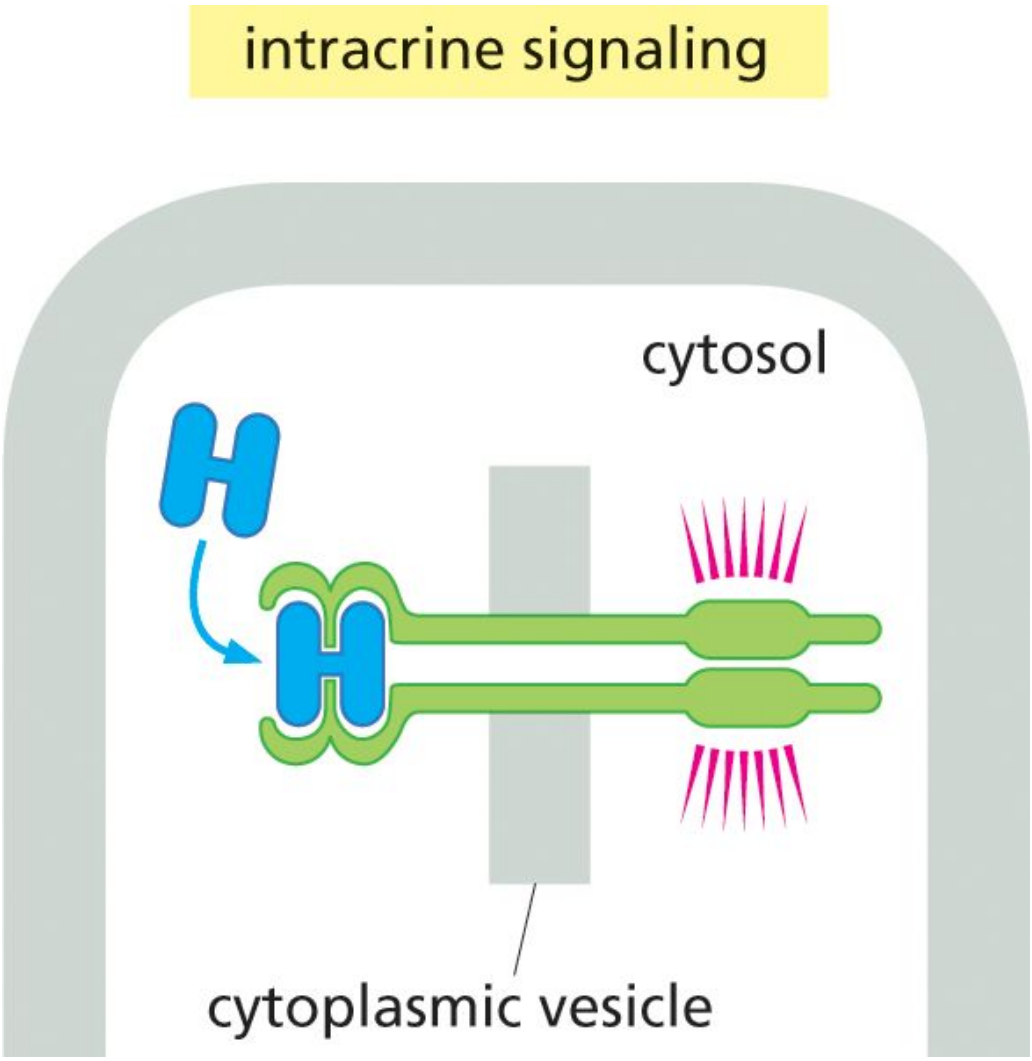
Autocrine signaling in a cancer cell. After activation of the G F gene, G F produced by the cell binds to G F receptors on the same cell.

(C)



Juxtacrine signaling. A ligand with a tail that remains within the cytoplasm of the cell of origin binds to a receptor on another cell that is in physical contact with the first. Both cytoplasmic ends emit signals.

(D)



Intracrine signaling. A G F ligand in the cytosol binds to a receptor embedded in the wall of a cytoplasmic vesicle.

(E)

Figure 5.8 Regulation of growth factor signaling (A) Normally functioning growth factor receptors emit cytoplasmic signals (*red spikes*) in response to binding soluble ligand (*blue*, *left*). However, mutations in the genes encoding the receptor molecules (*upper right*) can cause subtle alterations in protein structure, such as amino acid substitutions (*red dots*), that cause ligand-independent firing. More drastic alterations in receptor structure, including truncation of the ectodomain (see, for example, Figure 5.7) may also yield such deregulated signaling. In many human tumors, receptor proteins are overexpressed (*lower right*). Excessive numbers of normally structured receptor molecules can also drive ligand-independent receptor firing, apparently by causing these molecules to

frequently collide and thereby spontaneously dimerize and release signals (*red spikes*). (B) In general, in the context of paracrine signaling, normal cells do not synthesize and release a growth factor ligand whose cognate receptor they also display. Shown here is the tendency of epithelial cells to make PDGF (*blue*), the ligand for the PDGF-R displayed by mesenchymal cells; conversely, mesenchymal cells often make TGF-α, an EGF-related ligand (*red*), which binds the EGF-R displayed by epithelial cells. However, the PDGF made by an epithelial cell fails to find its cognate receptor on the surface of that cell (*horizontal bar*), preventing inadvertent activation of autocrine signaling. Similarly, the mesenchymal cells releasing TGF-α fail to express the cognate EGF-R that could bind and respond to this ligand. (C) In contrast, in many types of cancer, tumor cells acquire the ability to make a ligand for a growth factor receptor that they also naturally display (*right*). This creates an auto-stimulatory or autocrine signaling loop. (*continued*)

These insights into receptor function provided one solution to a long-standing problem in cancer cell biology. As mentioned earlier, normal cells had long been known to require growth factors in their culture medium in order to grow. In contrast, cancer cells propagated in tissue culture were known to have a greatly reduced dependence on growth factors for their proliferation and survival. The discovery of the ErbB–EGF-R connection yielded a simple, neat explanation of this particular trait of cancer cells: the ErbB oncoprotein releases signals very similar to those emitted by a ligand-activated, wild-type EGF receptor. However, unlike the EGF receptor, the ErbB oncoprotein can send a constant, unrelenting stream of growth-stimulating signals into the cell, thereby persuading the cell that substantial amounts of EGF are present in its surroundings when none might be there at all. Stated differently, in the presence of such an oncoprotein, a cell is liberated from dependence on GFs present in its surrounding. More generally, a variety of growth factor receptors that are configured much like the EGF-R have been found to be overexpressed in human tumors or synthesized in structurally altered form (**Table 5.2**).

Table 5.2 Examples of tyrosine kinase GF receptors altered in human tumors[a]

Name of receptor	**Main ligand**	**Type of alteration**	**Types of tumor**
EGF-R/ErbB1	EGF, TGFα	overexpression	non-small cell lung cancer; breast, head and neck, stomach, colorectal, esophageal, prostate,

Name of receptor	Main ligand	Type of alteration	Types of tumor
			bladder, renal, pancreatic, and ovarian carcinomas; glioblastoma
EGF-R/ErbB1		truncation of ectodomain	glioblastoma; lung and breast carcinomas
ErbB2/HER2/Neu	NRG, EGF	overexpression	30% of breast adenocarcinomas, ~20% of gastric carcinomas, other carcinomas
ErbB3, 4	various	overexpression	oral squamous cell carcinoma
Flt-3	FL	tandem duplication	acute myelogenous leukemia
Kit	SCF	amino acid substitutions	gastrointestinal stromal tumor
Ret	GFL	fusion with other proteins; point mutations	papillary thyroid carcinomas; multiple endocrine neoplasias 2A and 2B
FGF-R2	FGF	amino acid substitutions	breast, gastric, endometrial carcinomas
FGF-R3	FGF	overexpression; amino acid	multiple myeloma; bladder and cervical carcinomas;

Name of receptor	Main ligand	Type of alteration	Types of tumor
		substitutions; translocations	acute myelogenous leukemia
FGF-R4	FGF-4,5,6	overexpression	rhabdomyosarcoma, hepatocellular carcinoma
IR	IGF-2	overexpression	osteosarcoma
PDGF-Rβ	PDGF	translocations	chronic myelomonocytic leukemia

5.5 A growth factor gene can become an oncogene: the case of *sis*

The notion that oncoproteins can activate mitogenic signaling pathways received another big boost when the platelet-derived growth factor (PDGF) protein was isolated and its amino acid sequence determined. In 1983, the B chain of PDGF was found to be closely related in sequence to the oncoprotein encoded by the v-*sis* oncogene of simian sarcoma virus. Once again, study of the oncogenes carried by rapidly transforming retroviruses paid off handsomely.

The PDGF protein was discovered to be unrelated in structure to EGF and to stimulate proliferation of a different set of cells. PDGF stimulates largely mesenchymal cells, such as fibroblasts, adipocytes, and smooth muscle cells; in the brain, it can also stimulate the growth and survival of glial cells. By contrast, the mitogenic activities of EGF and related GF ligands are focused largely (but not entirely) on epithelial cells (for example, see Figure 5.8B). This specificity of action could be understood once the PDGF receptor was isolated: the PDGF-R was found to be expressed on the surfaces of mesenchymal cells and is not usually displayed by epithelial cells, while the EGF-R largely shows the opposite pattern of expression. (Like the EGF receptor, the PDGF-R uses a tyrosine kinase in its cytoplasmic domain to broadcast signals into the cell.)

The connection between PDGF and the *sis*-encoded oncoprotein suggested another important mechanism by which oncoproteins could transform cells: when simian sarcoma virus infects a cell, its *sis* oncogene causes the infected cell to release copious amounts of the PDGF-like Sis protein into the surrounding extracellular space. Once there, the PDGF-like molecules can attach to the PDGF-R displayed by the same cell that just synthesized and released them (Figure 5.8C). The result is strong activation of this cell’s

PDGF receptors and, in turn, a flooding of the cell with an unrelenting flux of the growth-stimulating signals released by the ligand-activated PDGF-R.

These discoveries also resolved a long-standing puzzle. Most types of acutely transforming retroviruses are able to transform a variety of infected cell types. Simian sarcoma virus, however, was known to be able to transform fibroblasts, but it failed to transform epithelial cells. The cell type–specific display of the PDGF-R explained precisely why this virus could transform some cells but not others.

Once again, a close connection had been forged between a protein involved in mitogenic signaling and a viral oncoprotein. In this instance, a virus-infected cell was forced to make and release a growth factor to which it could also respond. Rather than a growth factor signal sent from one type of cell to another cell type located nearby (often termed paracrine signaling; Figure 5.8B), or sent via the circulation from cells in one tissue in the body to others in a distant tissue (endocrine signaling), this represented an auto-stimulatory, or autocrine, signaling loop in which a cell manufactured its own mitogens (see Figure 5.8C and **Supplementary Sidebar 5.4**).

In fact, a variety of human tumor cells are known to produce and release substantial amounts of growth factors to which these cells can also respond (**Table 5.3**). Some human cancers, such as certain lung cancers, produce at least three distinct growth factors, specifically, transforming growth factor-α (TGF-α), stem cell factor (SCF), and insulin-like growth factor-1 (IGF-1); at the same time, the tumors express the receptors for these three ligands, thereby establishing three autocrine signaling loops simultaneously. Such autocrine signaling loops seem to be functionally important for the clinical behavior of tumors. Melanoma cells that develop resistance to therapeutic drugs designed to inhibit signaling pathways downstream of growth factor receptors often express elevated levels of the EGF-R, PDGF-R, IGF1-R, and AXL receptors (**Sidebar 5.2**) as well as their respective ligands.

Table 5.3 Examples of human tumors making autocrine growth factors

Ligand	Receptor	Tumor type(s)
CSF1	CSF1R	breast cancer
HGF	Met	miscellaneous endocrinal tumors, invasive breast and lung cancers, osteosarcoma
IGF-2	IGF-1R	colorectal
IL-6	IL-6R	myeloma, HNSCC
IL-8	IL-8R A	bladder cancer
NRG	ErbB2[a]/ErbB3	ovarian carcinoma
PDGF-BB	PDGF-Rα/β	osteosarcoma, glioma
PDGF-C	PDGF-Rα/β	Ewing’s sarcoma
PRL	PRL-R	breast carcinoma
SCF	Kit	Ewing’s sarcoma, SCLC

Ligand	Receptor	Tumor type(s)
VEGF-A	VEGF-R 1(Flt-1)	neuroblastoma, prostate cancer, Kaposi's sarcoma, osteosarcoma
TGFα	EGF-R	squamous cell lung, breast and prostate adenocarcinoma, pancreatic, mesothelioma
GRP	GRP-R	small-cell lung cancer

Abbreviations: HNSCC, head and neck squamous cell carcinoma; SCLC, small cell lung cancer.

Sidebar 5.2 Receptor overexpression results from a variety of molecular mechanisms

Receptor overexpression may cause a cell to become hyper-responsive to low concentrations of growth factor in the extracellular space; alternatively, overexpression may cause ligand-independent receptor firing, simply because mass-action effects may drive spontaneous receptor dimerization (see Figure 5.8A), much like the ligand-stimulated receptor dimerization described in the next section (see Figure 5.11).

In some cancer cells, receptors are overexpressed at the cell surface because the encoding gene is transcribed at an elevated rate, resulting in correspondingly increased levels of mRNA and protein. Alternatively, in a number of types of human cancers, these receptor genes are often amplified, leading to increased copy number of the involved genes and, once again, to proportionately increased levels of the corresponding mRNA transcript and receptor protein.

Yet other, more subtle mechanisms may also be responsible for increased numbers of receptor molecules being displayed at the cell surface. Some of these derive from the mechanisms that govern the *lifetime* of receptor molecules at the cell surface. Many receptor molecules are displayed at the surface for only a brief period of time before they are internalized via endocytosis, in which a patch of plasma membrane together with associated proteins is pulled into the cytoplasm, where it forms a vesicle. Thereafter, the contents of this vesicle may be dispatched to lysosomes, in which they are degraded, or alternatively they may be recycled back to the cell surface.

One protein, termed huntingtin-interacting protein-1 (HIP1), is part of a complex of proteins that facilitate endocytosis. HIP1 has been found to be overexpressed in a variety of human carcinomas. For reasons that are poorly understood, overexpression of HIP1 prevents the normal endocytosis of a number of cell surface proteins, including the EGF receptor (EGF-R). As a consequence, cells overexpressing HIP1 accumulate excessive numbers of EGF-R molecules at the cell surface and, in the case of NIH 3T3 mouse fibroblasts, become hyper-responsive to EGF. This explains why such cells can grow vigorously in the presence of very low levels of growth factor–containing serum (0.1%) that would otherwise cause normal NIH 3T3 cells to retreat into a nongrowing, quiescent state. Moreover, these cells behave like transformed cells in the presence of 10% serum in the tissue culture medium—the serum concentration that is routinely used to propagate untransformed NIH 3T3 cells; both behaviors demonstrate the hyper-responsiveness to GFs resulting from receptor overexpression.

Another protein, called cyclin G–associated kinase (GAK), is a strong promoter of EGF-R endocytosis. When its expression is suppressed, levels of cell surface EGF-R increase by as much as fiftyfold. A third protein, called c-Cbl, is responsible for tagging ligand-activated EGF-R, doing so via a covalent modification termed mono-ubiquitylation (which contrasts with the poly-ubiquitylation that causes degradation of a protein in proteasomes; see **Supplementary Sidebar 7.5**). This tagging causes the endocytosis of the EGF-R and its subsequent degradation in lysosomes. The v-Cbl viral oncoprotein, as well as several cellular proteins (Sts-1, Sts-2), can block this endocytosis, resulting, once again, in accumulation of elevated levels of EGF-R at the cell surface. In a more general sense, the

spontaneous receptor dimerization or hyper-responsiveness to growth factors resulting from receptor overexpression is likely to drive the proliferation of a variety of human cancer cell types *in vivo*.

Possibly the champion autocrine tumor is Kaposi's sarcoma, a tumor of cells closely related to the endothelial cells that form lymph ducts (see also **Supplementary Sidebar 3.5**). To date, Kaposi's tumors have been documented to produce VEGFs, Ang-1, Ang-2, bFGF, IL-6, IL-8, GRO-α, TNF-β, and ephrin B2—all ligands of cellular origin—as well as the receptors for these ligands. At the same time, the causal agent of this disease, the human herpesvirus-8 (HHV-8) genome that is present in Kaposi's tumor cells, encodes and thus produces two additional ligands—vIL6 and vMIP—whose cognate receptors are also expressed by the endothelial cell precursors that generate these tumors.

Such autocrine signaling loops seem to represent potential perils for tissues and organisms. In normal tissues, the proliferation of individual cells almost always depends on signals received from other cells; such interdependence ensures the stability of cell populations and the constancy of tissue architecture. A cell that has gained the ability to control its own proliferation (by making its own mitogens) therefore creates an imminent danger, since self-reinforcing, positive-feedback loops often lead to gross physiologic imbalances. (Nonetheless, autocrine signaling loops are clearly used in certain normal biological situations, such as those that operate to stably maintain the unique properties of stem cells including cancer stem cells, as we will see in Chapter 11. Accordingly, it seems that some autocrine loops operate normally to maintain specific states of differentiation, whereas others conveying mitogenic signals are confined largely to neoplastic cells.)

We should note that the activation of autocrine mitogenic signaling loops yields an outcome very similar to that occurring when a structurally altered receptor protein such as ErbB/EGF-R is expressed by a cell. In both cases, the cell generates its own mitogenic signals and its dependence upon exogenous mitogens is greatly reduced. Interestingly, these dynamics also have important implications for the development of anti-cancer drugs (**Sidebar 5.3**).

Sidebar 5.3 Autocrine signaling influences the development of anti-cancer therapies

Testing of the efficacy of a novel anti-cancer drug usually begins with analyses of the drug's ability to affect the growth and/or survival of cancer cells grown in culture (*in vitro*), as we will see later in Chapter 17. These tests are then followed up by the seeding of such cancer cells in host mice, where they are allowed to form tumors (*in vivo*). The responsiveness of these tumor grafts to drug treatment of the tumor-bearing mice is often used to predict whether the drug under study will have clinical efficacy, that is, an ability to shrink a tumor or stop its further growth in patients.

On some occasions, the *in vitro* drug responsiveness of a tumor cell population may predict its behavior *in vivo*; in other cases, it will not. The experience of certain drug developers indicates that these contrasting behaviors correlate with the production of autocrine growth factors by tumor cell lines. Those cancer cells that produce abundant autocrine growth factors usually respond to drug treatment similarly *in vitro* and *in vivo*, while those that do not secrete growth factors behave very differently under these two conditions. It seems that the tumor cells that secrete autocrine factors create their own growth factor environment both *in vitro* and *in vivo*. Conversely, those that do not secrete these factors depend on serum-associated mitogens *in vitro* and on the growth factors supplied by nearby host cells *in vivo*; the latter may differ dramatically from the spectrum of mitogens present in serum, providing a plausible explanation of the observed differences in responses.

- aAlso known as HER2 or Neu receptor.Return to reference a

OceanofPDF.com

Glossary

paracrine
: Referring to the signaling path of a hormone or factor that is released by one cell and acts on a nearby cell, ostensibly after transport through the interstitial fluid of a tissue. *Compare* **autocrine**, **endocrine, exocrine, intracrine**, **juxtacrine**.

endocrine
: (1) Referring to a gland that secretes substances into the general circulation and thus to the rest of the body. (2) Referring to the signaling path of a hormone or factor that is made by cells in a tissue, passes through the circulation, and affects the behavior of cells in another tissue at a distant anatomical site. *Compare* **autocrine**, **exocrine, intracrine**, **juxtacrine**, **paracrine**.

autocrine
: Referring to the signaling path of a hormone or factor that is released by a cell and proceeds to act upon the same cell (or same cell type) that has released it. *Compare* **endocrine**, **exocrine**, **intracrine**, **juxtacrine**, **paracrine**.

endocytosis
: Uptake by a cell of extracellular material together with associated extracellular fluid that is achieved through the invagination of a patch of plasma membrane, thereby yielding membrane-bound vesicles termed endosomes within the cytoplasm. Pinocytosis and phagocytosis are forms of endocytosis. *See also* **exocytosis**, **endosome**, **phagocytosis**, **pinocytosis**.

lysosome
: A cytoplasmic vesicle that contains in its lumen degradative enzymes in a solution of low pH, allowing it to degrade various molecules that are introduced into it; in addition, cells may sense nutrient availability by gauging the concentrations of certain amino acids in the lumina of their lysosomes.

mass action
: Referring to a situation in which the rate of a chemical or biochemical reaction is governed by the concentration of one or more of its reactants.

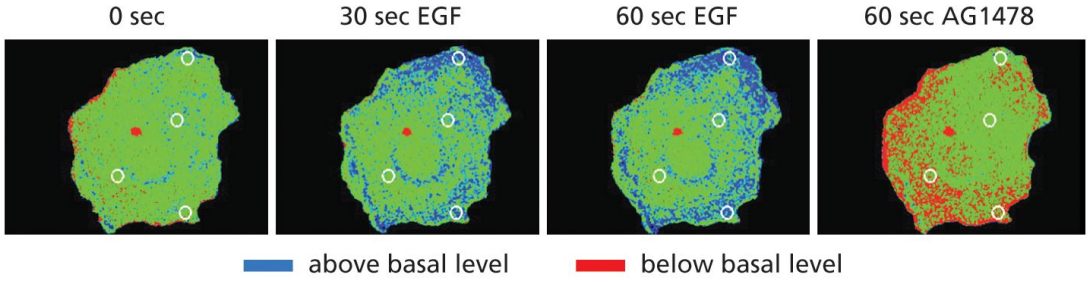
5.6 Transphosphorylation underlies the operations of many receptor tyrosine kinases

The actions of oncogenes such as *sis* and *erbB* provide a satisfying biological explanation of how a cell can become transformed. By supplying cells with a continuous flux of growth-stimulatory signals, oncoproteins are able to drive the repeated rounds of cell growth and division that are needed in order for large populations of cancer cells to accumulate and for tumors to form. Still, this biological explanation sidesteps an important biochemical question lying at the heart of mitogenic signaling: How do growth factor receptors containing tyrosine kinases (often called receptor tyrosine kinases or RTKs) succeed in transducing signals from the extracellular space into the cytoplasm of cells?

Knowing the presence of the tyrosine kinase enzymatic activity borne by the cytoplasmic domains of these proteins allows us to rephrase this question: How do growth factor receptors use their tyrosine kinase domains to emit intracellular signals in response to ligand binding?

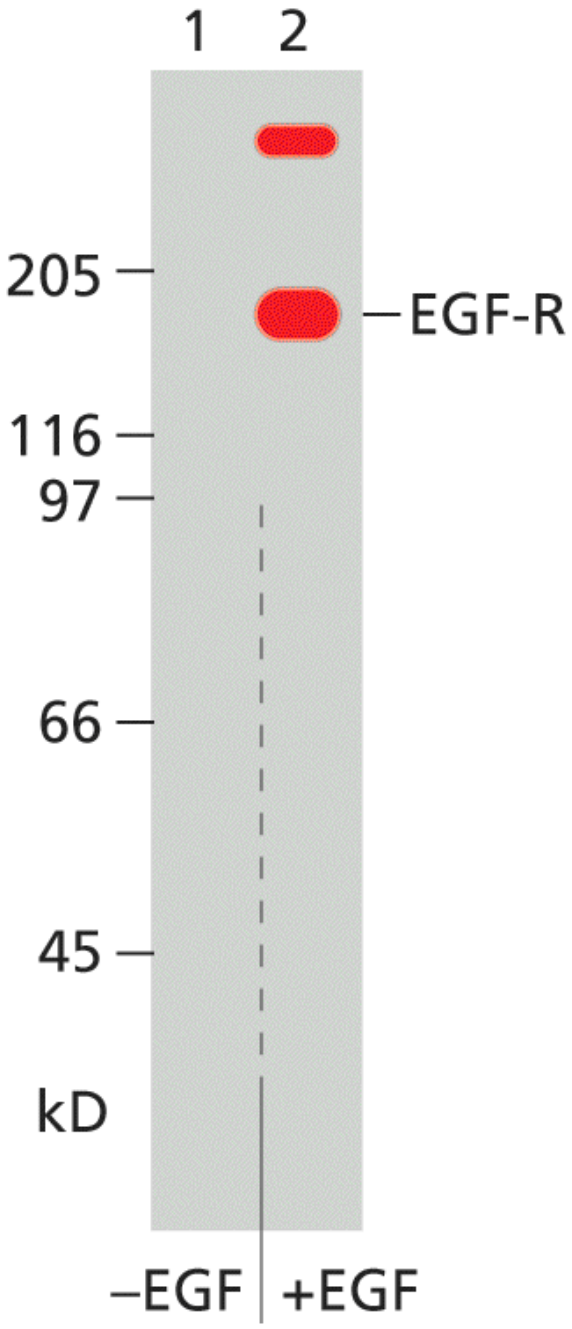
The solution to this problem came from a detailed examination of the proteins that become phosphorylated within seconds after a growth factor such as EGF is applied to cells expressing its cognate receptor, in this case the EGF-R (**Figure 5.9**). It would seem reasonable that a variety of cytoplasmic proteins become phosphorylated on their tyrosine residues following ligand binding to a growth factor receptor. Indeed, there are a number of such proteins. But the most prominent among these phosphotyrosine-bearing proteins is often the receptor molecule itself (**Figure 5.10**)! Hence, these receptors seem to be capable of autophosphorylation.



A four-image sequence, showing changes in a single cell. The first three images, show an irregular green shape with a red dot in the middle. At zero seconds, the

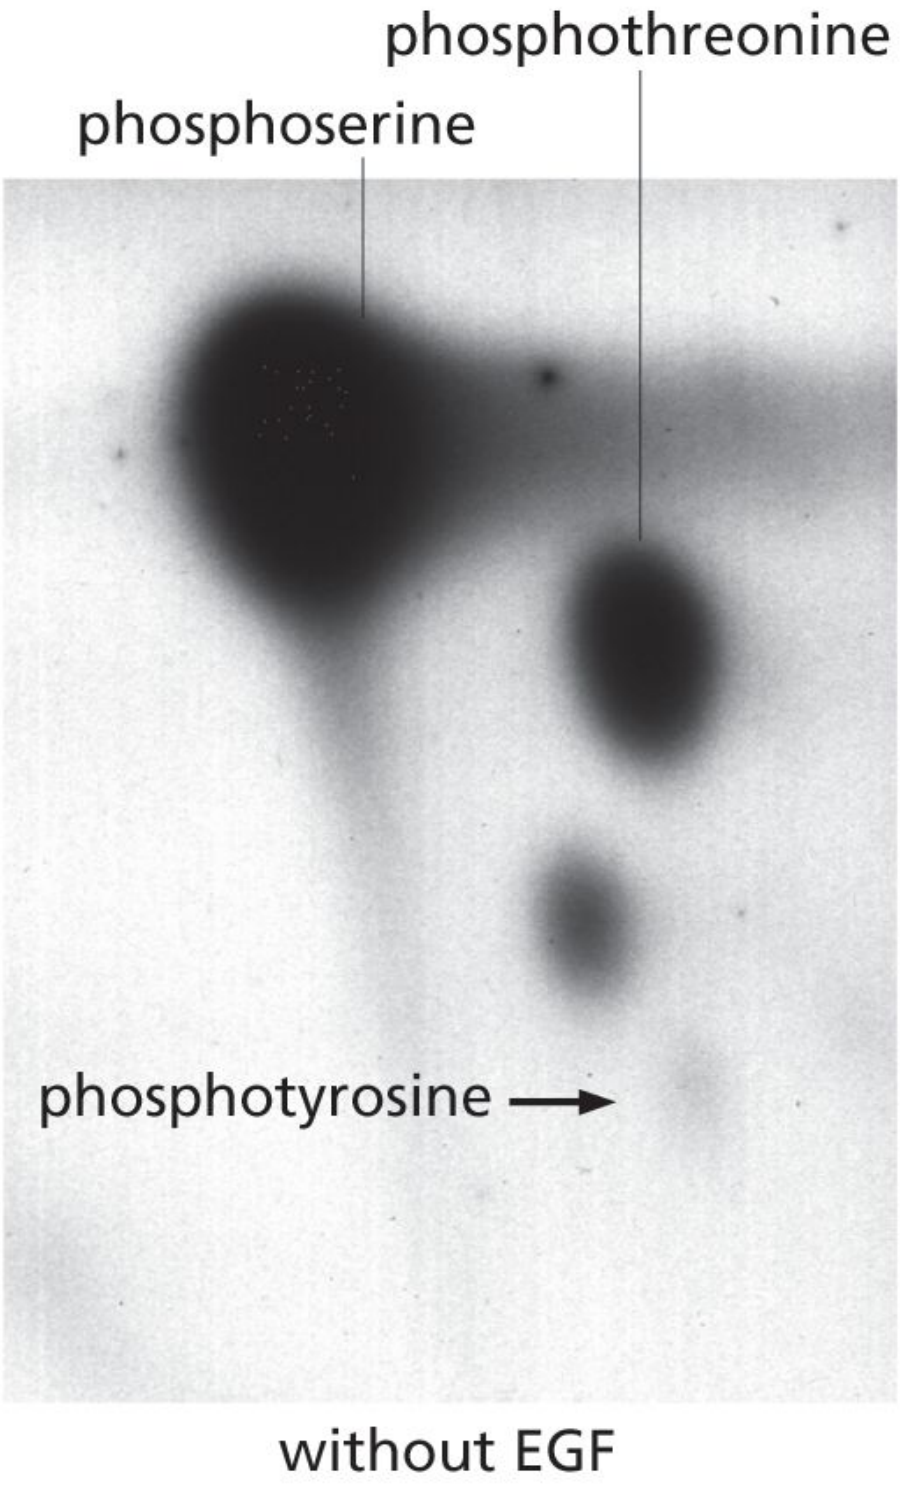
shape is more or less uniformly green except for the red dot. At 30 seconds, there are a lot of blue dots, and at 60 seconds, there are slightly more blue dots. The last image shows the same cell after 60 seconds of treatment with 60 A G 14 78. All the blue dots are gone, and there are red ones instead.

Figure 5.9 Formation of phosphotyrosine on the EGF-R following ligand addition The use of a fluorescent reagent that binds specifically to a phosphotyrosine residue on the EGF-R enables the visualization of receptor activation following ligand binding. Here, receptor activation is measured on a monkey kidney cell at a basal level (0 sec), as well as 30 and 60 sec after EGF addition. In addition, following a 2-minute stimulation by EGF, the effects of a 60-sec treatment by a chemical inhibitor of the EGF-R kinase (AG1478) are shown (*right*), indicating that the EGF-induced activation of the EGF-R can be rapidly reversed. Receptor activity above the basal level is indicated in *blue*, while activity below the basal level is indicated in *red*. The response to AG1478 treatment indicates that a significant basal level of EGF-R activity was present (at 0 sec) even before EGF addition. (From M. Offterdinger et al., *J. Biol. Chem.* 279:36972–36981, 2004. Copyright © 2004 ASBMB. This article is distributed under a Creative Commons Attribution 4.0 International license.)



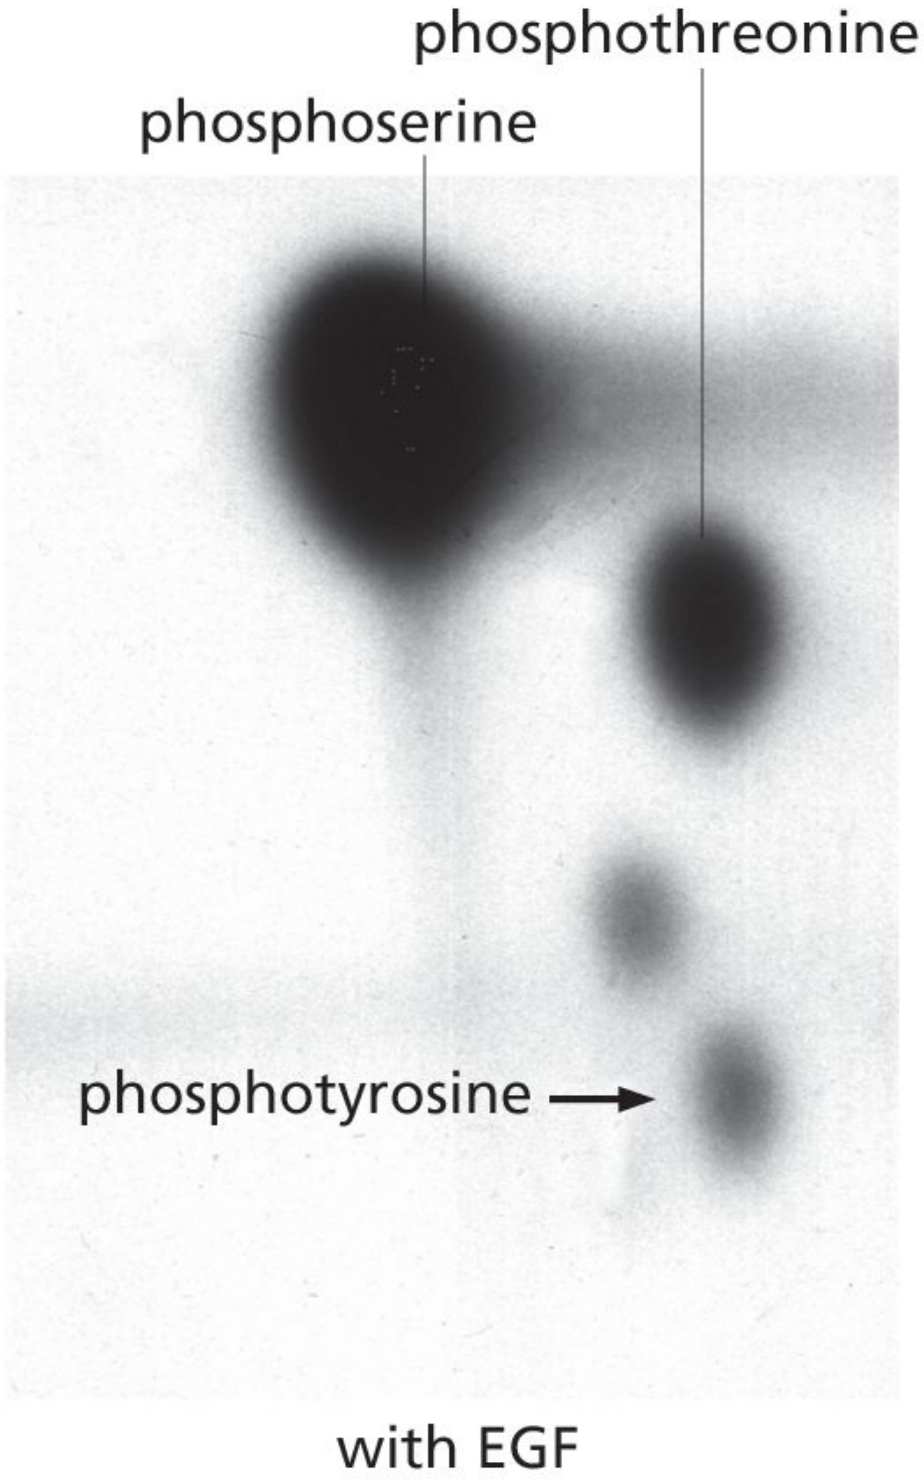
The results of immunoprecipitation with and without E G F treatment. The without E G F lane contains no blots. The with E G F lane contains two. A larger one between 116 and 205 kilo Daltons and a smaller one near the top.

(A)



An image produced using electrophoresis without E G F treatment. It contains a large, dark blot corresponding to phosphoserine, a smaller dark blot representing phosphothreonine, and a very faint blot representing phosphotyrosine.

(B)



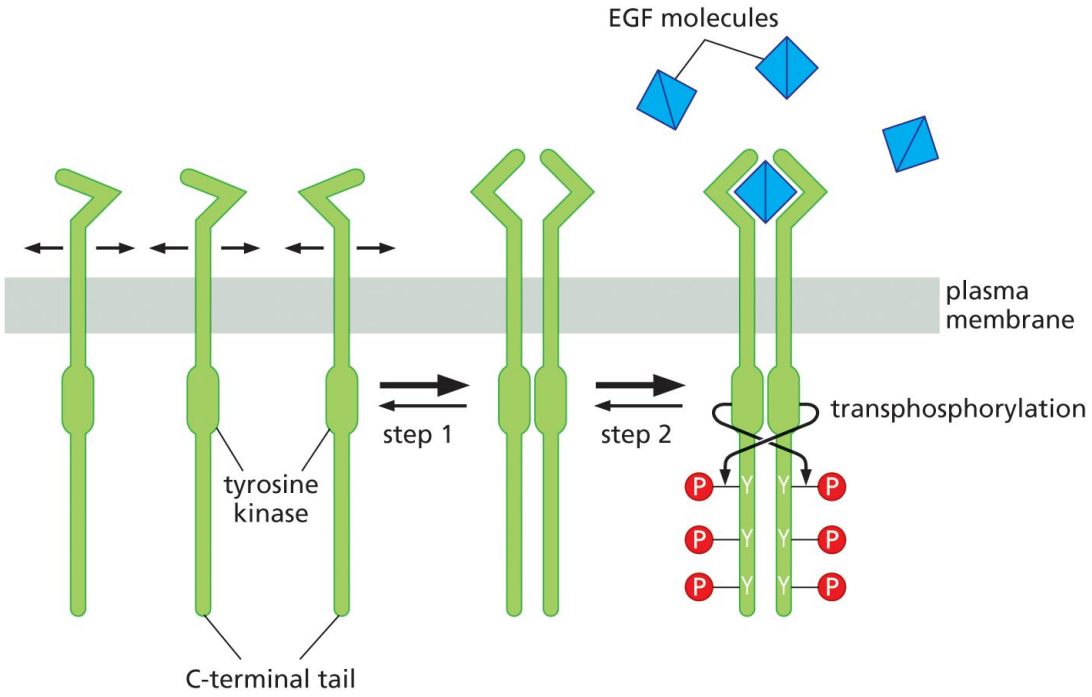
An image produced using electrophoresis with E G F treatment. It contains a large, dark blot corresponding to phosphoserine, a smaller dark blot

representing phosphothreonine, and another small, dark blot representing phosphotyrosine.
(C)

Figure 5.10 Apparent autophosphorylation of the EGF receptor (A) When human A431 epidermoid carcinoma cells, which greatly overexpress the EGF-R, are incubated in $^{32}PO_4$-containing medium and then exposed to EGF, a radiolabeled protein can be immunoprecipitated with an anti-phosphotyrosine antiserum (*lane 2*); this protein co-migrates upon gel electrophoresis with the EGF-R and is not detectable in the absence of prior EGF treatment (*lane 1*). (B) The $^{32}PO_4$-labeled phosphoamino acids borne by the proteins in such cells in the absence of EGF (as resolved by electrophoresis; see **Supplementary Sidebar 5.2**) are seen here. (C) Following the addition of EGF to A431 cells, a spot in the lower right becomes darker; internal markers indicate that this is phosphotyrosine. (A, from A.B. Sorokin et al., *FEBS Lett.* 268:121–124, 1990. With permission from John Wiley and Sons. B and C, courtesy of A.R. Frackelton Jr.)

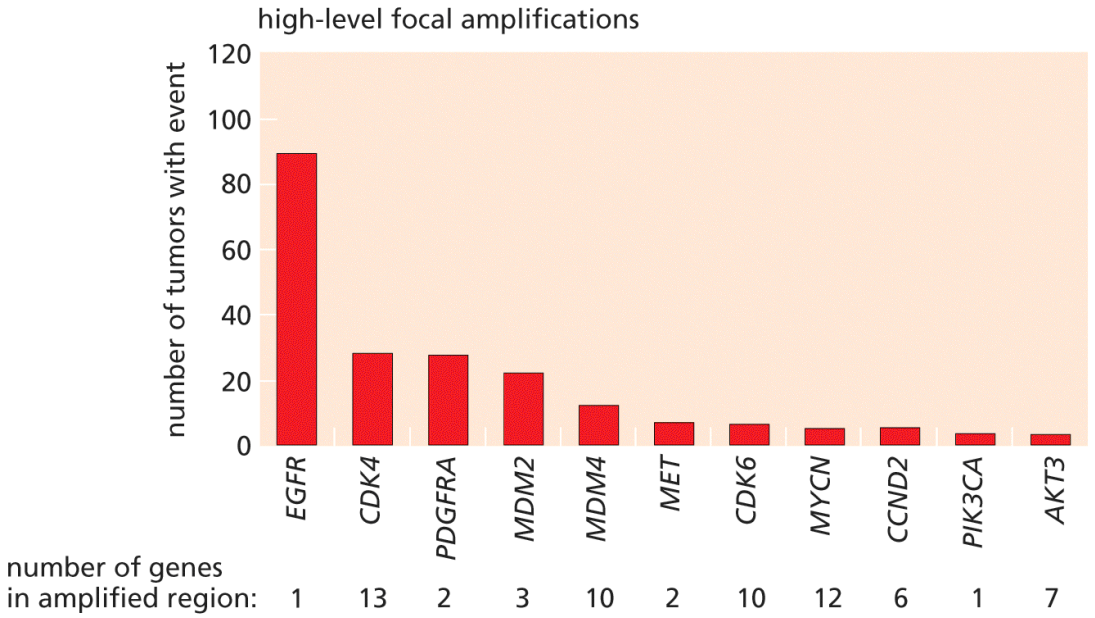
Another clue came from the structure of many growth factor ligands; they were often found to be dimeric, being composed either of two identical protein subunits (homodimers) or of very similar but nonidentical subunits (heterodimers) (see also **Supplementary Sidebar 5.5**). A third clue derived from observations that many transmembrane proteins constructed like the EGF and PDGF receptors have lateral mobility in the plane of the plasma membrane. That is, as long as the hydrophobic transmembrane domains of these receptor proteins remain embedded within the lipid bilayer of this membrane, they are relatively free to wander back and forth across the surface of the cell.

Taken together, these facts led to a simple model (**Figure 5.11A**). In the absence of ligand, a growth factor receptor exists in a monomeric (single subunit) form, embedded as always in the plasma membrane. It may wander laterally in the plasma membrane and encounter another identical RTK, with which it forms an unstable homodimeric complex. However, when presented with the appropriate growth factor ligand, the homodimeric receptor complex will be stabilized. Alternatively, a receptor molecule will bind to one of the two subunits of its dimeric ligand. Thereafter, the ligand–receptor complex will wander around the plasma membrane until it encounters another receptor molecule, to which the second, still-unengaged subunit of the ligand can bind. The result is, once again, the noncovalent cross-linking of the two receptor molecules achieved by the dimeric ligand that forms a bridge between them. (In all of these cases, the identity of the particular RTKs that are recruited into these complexes will be dictated by the binding specificities of the GF ligand.)



Several receptor subunits, each with a receptor ectodomain and a cytoplasmic domain containing a tyrosine kinase segment and a C-terminal tail. These subunits move left and right while embedded within a plasma membrane. Step 1, which is reversible, involves two subunits coming together in dimerization. Step 2, also reversible, involves the receptor ectodomains binding to an E G F molecule and phosphates being added to the two cytoplasmic domains during transphosphorylation.

(A)



A bar chart captioned high-level focal amplifications. It has number of tumors with event from 0 to 120 on the vertical axis. On the horizontal axis it lists eleven receptor types and for each also gives the number of genes in the amplified region. The data are as follows: E G F R, 1 gene in the amplified region, about 90 tumors with events. C D K 4, 13 genes in the amplified region, about 30 tumors with events. P D G F R A, 2 genes in the amplified region, about 30 tumors with events. M D M 2, 3 genes in the amplified region, about 20 tumors with events. M D M 4, 10 genes in the amplified region, about 10 tumors with events. M E T, 2 genes in the amplified region, about 5 tumors with events. C D K 6, 10 genes in the amplified region, about 5 tumors with events. M Y C N, 12 genes in the amplified region, about 5 tumors with events. C C N D 2, 6 genes in the amplified region, about 5 tumors with events. P I K 3 C A, 1 gene in the amplified region, about 3 tumors with events. A K T 3, 7 genes in the amplified region, about 3 tumors with events.

(B)

Figure 5.11 Receptor dimerization, ligand binding, transphosphorylation, and glioblastoma pathogenesis (A) In the absence of ligand, many growth factor receptor molecules (*left*, *green*) are free to move laterally (*diverging arrows*) in the plane of the plasma membrane. The consequences of these lateral migrations have been studied in the greatest detail in the case of the EGF receptor depicted here. When two receptor molecules encounter one another, they form a homodimer that persists for a brief period; at the same time, the ectodomains of these receptors change conformation and acquire increased affinity for binding growth factor

ligands (step 1). Subsequent binding of EGF ligand molecules results in further stabilization of the dimer and activation of the linked tyrosine kinase (TK) domains (step 2). Thus, the TK domain of each receptor subunit phosphorylates the C′-terminal cytoplasmic tail of the other subunit—the process of transphosphorylation (*arrows*). Other GF receptors, not yet studied in such detail, seem to behave in a similar fashion. (While the initial receptor–ligand interactions may occur while receptors such as the EGF-R are displayed on the cell surface, the bulk of subsequent signaling events may operate after the receptor–ligand complexes are internalized by endocytosis and are associated, at least transiently, with endosomes. In addition, as shown in **Supplementary Sidebar 5.5**, the EGF-related ligand TGF-α binds as monomers to opposite-facing domains of the EGF-R ectodomains.) (B) The dynamics of receptor function depicted in panel A shed light on how amplification of *EGFR* genes and resulting EGF-R protein overexpression confers proliferative advantage on glioblastoma cells. Sequence analysis of 206 human glioblastomas has revealed chromosomal regions that are repeatedly amplified (yielding focal amplifications), resulting in copy number alterations (CNAs) of the genes embedded in these chromosomal regions. As seen here, the chromosomal region harboring the *EGFR* gene is amplified in ∼90 of these tumors out of the total cohort of 206 tumors analyzed; in contrast, chromosomal regions harboring other growth factor receptors (*PDGFRA*, *MET*) and oncogenes are found to be amplified far less frequently. (The majority of the amplified *EGFR* genes encode wild-type protein, indicating that any effects of receptor amplification must derive from the increased number of receptor molecules expressed at the cell surface rather than the deregulated firing of structurally altered receptor molecules.) The excessive numbers of EGF-R molecules that are displayed on the surfaces of many of these brain tumor cells appear to drive an increased frequency of random collisions between these molecules and thus dimerization (step 1 of panel A). The number given below each receptor indicates the number of genes that are co-amplified with the receptor gene in the particular amplicon in which this gene resides. (B, from The Cancer Genome Atlas Research Network, *Nature* 455:1061–1068, 2008. With permission from Nature.)

X-ray crystallographic studies of growth factors bound to the ectodomains of their cognate receptors have revealed a variety of mechanisms by which these ligands are able to induce receptor dimerization (**Supplementary Sidebar 5.5**). In fact, certain GF ligands don’t naturally form dimers. For example, in the case of the EGF-R–related receptors, individual monomeric ligand molecules bind separately to the ectodomains of monomeric receptors. These GF-bound ectodomains respond by undergoing a steric shift that allows them to dimerize with one another via sites quite distant from the sites of ligand binding (see **Supplementary Sidebar 5.5**).

Once dimerization of the ectodomains of two receptor molecules has been achieved by ligand binding, the cytoplasmic portions are also pulled together. Now each kinase domain phosphorylates tyrosine residues present in the cytoplasmic domain of the other receptor. So the term “autophosphorylation” is actually a misnomer. This bidirectional, reciprocal phosphorylation is best described as a process of transphosphorylation (see Figure 5.11A). (Indeed, it is unclear whether a single isolated kinase molecule is ever able to phosphorylate itself.)

The phosphorylation of these tyrosine residues can have at least two consequences. The catalytic cleft of a kinase—the region of the protein where its enzymatic function operates—may normally be partially obstructed by a loop of the protein, preventing the kinase from interacting effectively with its substrates. In many RTKs, transphosphorylation of a critical tyrosine in the obstructing “activation loop” causes the loop to swing out of the way, thereby providing the catalytic cleft with direct access to substrate molecules (see **Supplementary Sidebar 5.6**). In addition, receptor transphosphorylation results in the phosphorylation of an array of tyrosine residues present in C-terminal, cytoplasmic portions of the growth factor receptor outside the kinase domain, as indicated in Figure 5.11A. As we will learn in the next chapter, these phosphorylation events enable the receptor to activate a diverse array of downstream signaling pathways.

As mentioned above, some receptor molecules may heterodimerize with others. For example, the HER2/ErbB2/Neu receptor, which is overexpressed in human breast cancers (see Figure 4.3), often forms heterodimers with its cousins, either the HER1/EGF-R or the HER3 receptor. Since HER2 lacks its own identified ligand, it may be that a single ligand molecule binding either HER1 (= EGF-R) or HER3 suffices to trigger ligand-activated heterodimerization with HER2 and activation of downstream signaling. HER3 actually has a defective kinase domain, but its C-terminal tail can nonetheless serve as a substrate for phosphorylation by the HER2-borne kinase. The resulting phosphotyrosines then enable HER3 to release signals into the cell.

Receptor heterodimerization is increasingly seen to play an important role in human cancer development. For example, the AXL receptor, which is a member of an RTK family distinct from that of HER1/2/3/4 (see Figure 5.6), can be expressed at significant levels and heterodimerize with the EGF-R in lung cancers being treated with drug inhibitors of EGF-R signaling. Signaling by the resulting heterodimers is relatively resistant to inhibition by these drugs because they inhibit only the EGF-R–associated tyrosine kinase, leaving the AXL-associated kinase unaffected, thereby enabling the outgrowth of drug-resistant cells and clinical relapse.

The receptor dimerization model explains how growth factor receptors can participate in the formation of cancers when the receptor molecules are overexpressed, that is,

displayed on the cell surface at levels that greatly exceed those seen in normal cells (see Figure 5.11B). Since these receptors are free to move laterally in the plane of the plasma membrane, their high numbers can cause them to collide frequently, and these chance encounters, like the dimerization events triggered by ligand binding, can result in transphosphorylation, receptor activation, and signal emission, as mentioned earlier. For instance, as Table 5.2 indicates, the EGF receptor is overexpressed in a wide variety of human tumors, mostly carcinomas. In such tumors, this overexpression may result in ligand-independent receptor dimerization and firing (**Sidebar 5.4**). In addition, overexpressed EGF-R may sensitize a cell to limiting amounts of ligand present in the extracellular space; this may place a cell in a hyper-responsive state, driving its proliferation under conditions where the low levels of ligand would fail to activate proliferation. [This touches on an issue that is almost unexplored in contemporary cancer research: how often is the frequently observed elevated receptor firing due to elevated levels of available ligands (**Sidebar 5.5**)?]

Sidebar 5.4 Clear evidence of ligand-independent receptor firing

Experiments with the Met receptor provide clear evidence of ligand-independent receptor dimerization and firing. In these experiments, the human Met receptor [whose ligand is hepatocyte growth factor (HGF), also known as scatter factor (SF)] was overexpressed in liver cells of a genetically altered mouse strain; this led, in turn, to the development of hepatocellular carcinomas (HCCs). Since the human Met receptor is incapable of binding the mouse HGF/SF ligand (the only ligand available in these mice), this dictated that the observed receptor activation, cell transformation, and tumor formation could only be ascribed to a ligand-independent process, specifically, spontaneous dimerization of overexpressed Met receptor molecules. Yet other indications of ligand-independent firing come from studies of structurally altered RTKs present in human tumors (**Supplementary Sidebar 5.7**).

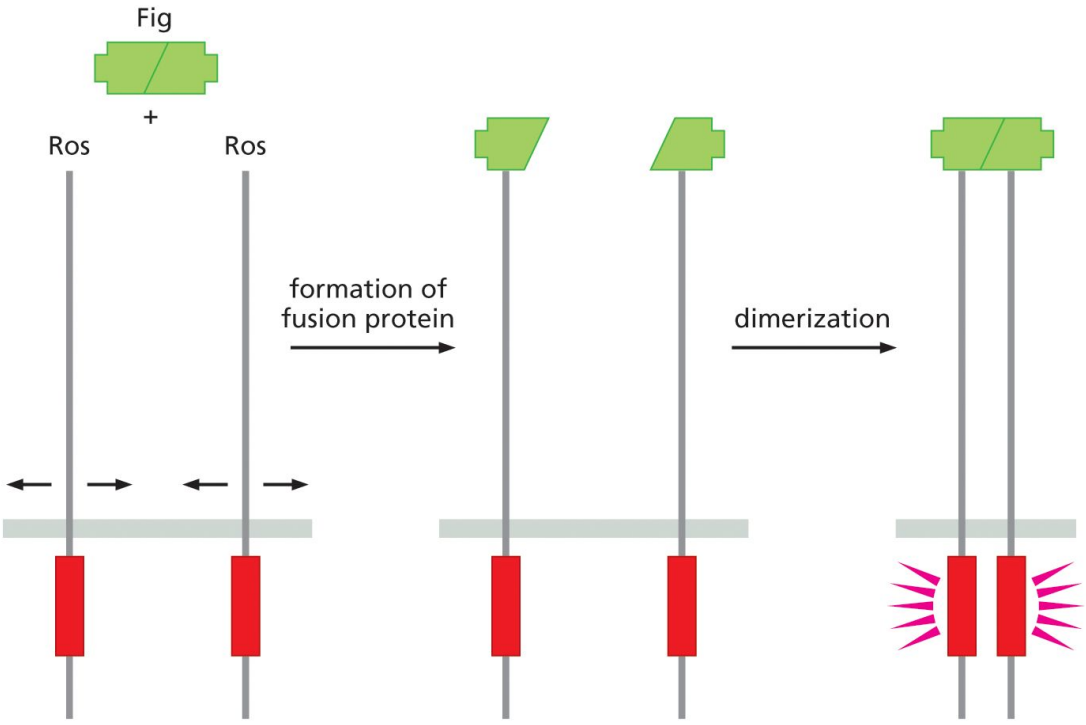
Sidebar 5.5 Regulation of ligand availability

A major unsolved problem in cell biology and therefore in cancer pathogenesis derives from the complex biochemical mechanisms that govern the availability of GF ligands and thus binding to their cognate receptors. As one example, in the case of the EGF-R, nine alternative ligand proteins have been identified that can all bind, via characteristic EGF-like domains, to this receptor; all of these EGF-like ligands are synthesized as transmembrane proteins that are initially displayed on the surface of ligand-producing cells and can thereafter be mobilized by certain proteases that liberate them from their plasma-membrane anchorage, thereby making them available for receptor binding. These proteolytic cleavage events are highly regulated and are clearly rate-limiting steps in ligand availability and thus receptor activation. In the case of the EGF-R,

proteolytic cleavage of EpCAM, a cell-surface epithelial adhesion molecule that is unrelated in structure to EGF itself, has been reported to generate a soluble ectodomain of this protein that is capable of activating EGF-R signaling, much like EGF itself.

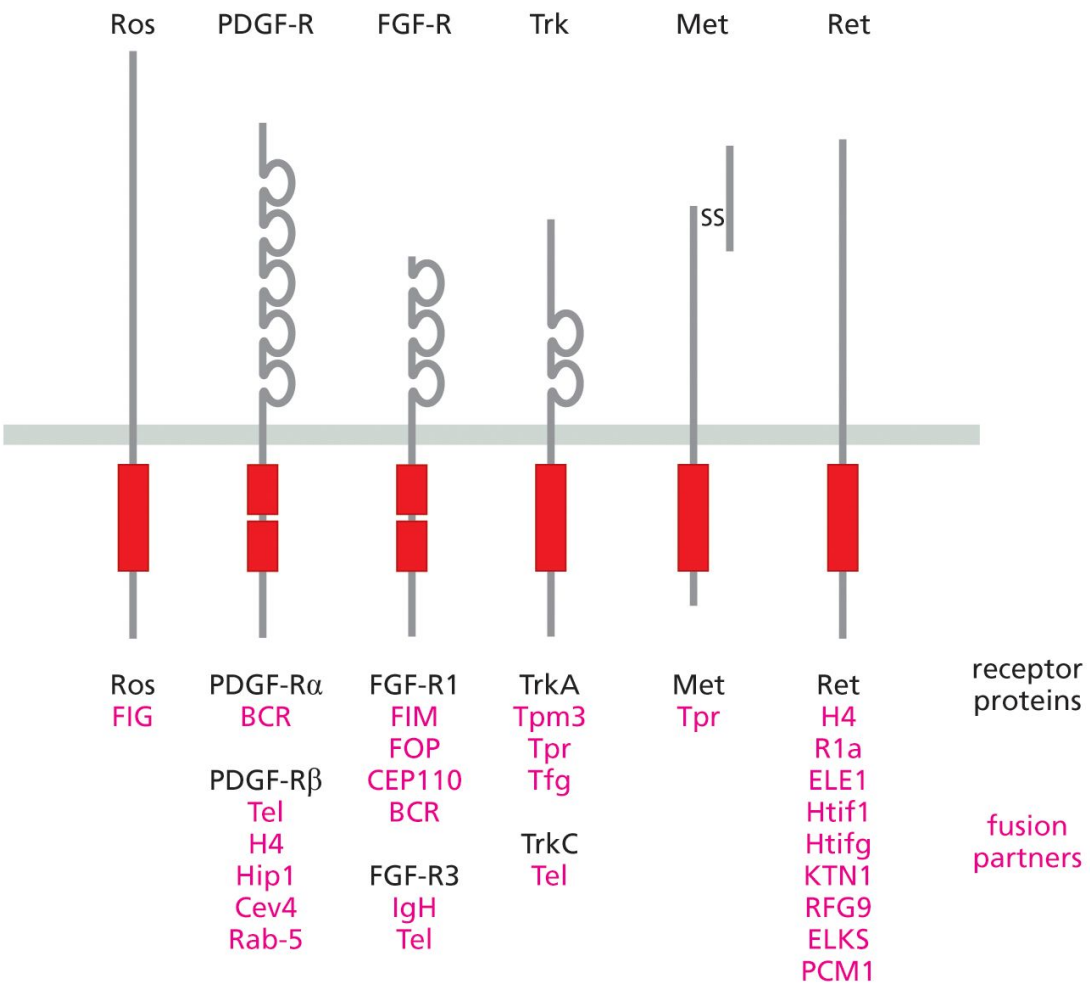
Members of the TGF-β family of GFs—there are 33 in all—are initially synthesized in inactive complexes that require regulated proteolytic activation, which liberates them from both inactivating subunits and sequestration in the extracellular matrix (ECM). Fibroblast growth factors (FGFs), of which there are 23 distinct species, operating with their cognate receptors (FGF-Rs), play a critical role in various types of morphogenesis and cancer pathogenesis. Their availability as ligands is governed by their binding to heparan proteoglycans in the ECM to which they bind with various affinities. A final example is provided by the process of lymphangiogenesis, which results in the formation of lymph ducts draining lymph from tissues throughout the body. In this case, a critical growth factor, VEGF-C, is required. Once secreted into the extracellular space, the precursor of mature VEGF-C must be cleaved by two distinct proteases that also regulate one another; the resulting cleavage is essential for the proper formation of lymphatic drainage of all tissues. Current research has not even begun to grapple with the complexity of signaling in the extracellular space.

Arguably, the most direct and compelling demonstration of the key role of receptor homodimerization comes from the mechanisms by which fusion proteins formed in many human cancers drive constitutive receptor signaling (**Figure 5.12**; see also **Supplementary Sidebar 5.7**). Nonetheless, it is important to know that the scheme of receptor dimerization oversimplifies the responses of certain receptors to binding of their cognate ligands: certain receptors are constitutively dimerized even in the absence of ligand binding, and some evidence suggests that higher-order clusters involving large numbers of receptor molecules may form on the surfaces of tumor cells in response to ligand binding. Conversely, some published reports indicate that certain ligand-bound monomeric receptors may also fire, ostensibly by associating with tyrosine kinases that are not covalently associated, like most RTKs, with ligand-binding ectodomains.



Two R o s receptors are free to move laterally side by side while embedded in a plasma membrane. An approaching F i g protein dimer separates into two parts, and each part binds to the end of an R o s receptor–but then the two parts of the F i g protein re-fuse, forcing dimerization of the two R o s receptors, resulting in signaling from the cytoplasmic domains.

(A)



Six different receptor types, shown schematically and with their receptor proteins and fusion partners listed. An R o s receptor has a long, straight ectodomain. Its receptor protein is R o s. Its fusion partner is F i g. A P D G F-R receptor has an ectodomain with many loops on it. One of its receptor proteins is P D G F R alpha. The corresponding fusion partner is B C G. The other receptor protein is P D G F R beta. The corresponding fusion partners are Tel, H 4, Hip 1, C e v 4, and Rab-5. An F G R-R receptor has an ectodomain with a shorter series of loops. One of its receptor proteins is F G F R 1. The corresponding fusion partners are F I M, F O P, C E P 110, and B C R. The other receptor protein is F G F R 3. The corresponding fusion partners are I g H and Tel. A T r k receptor's ectodomain has short series of loops and a short straight segment. One of its receptor proteins is T r k A. The corresponding fusion partners are T p m 3, T p r, and T f g. The other receptor protein is T r k C. The corresponding fusion partner is Tel. A Met receptor has an ectodomain consisting of two straight segments joined by a short lateral S S bridge. Its receptor protein is Met. Its fusion partner is T p r. Finally, a Ret receptor has a moderately long, straight ectodomain. Its receptor protein is

Ret. Its fusion partners are H 4, R 1 a, E L E 1, H t i f 1, H t i f g, K T N 1, R F
G 9, E L K S, and P C M 1.
(B)

Figure 5.12 Gene fusion causing constitutively dimerized receptors (A) The Ros receptor (*lower left*), like other RTKs, normally is free to move laterally in the plane of the plasma membrane and requires ligand binding for dimerization. However, in a glioblastoma, the reading frame specifying the ectodomain of the *ROS* gene has become fused to the reading frame of a second, unrelated neighboring gene, termed *FIG*, which encodes a protein that normally dimerizes spontaneously (*green*, *upper left*). In the resulting fusion protein (*right*), the dimerized Fig domain pulls two Ros receptors together, resulting in constitutive, ligand-independent dimerization and signaling. (B) Similarly, in a diverse array of malignant tumors, receptor dimerization occurs when the genes encoding growth factor receptors (*black type*) become fused to unrelated genes that happen to specify proteins that normally dimerize or form higher-order oligomers (*red type*), dragging together pairs of receptor monomers. Listed here are a number of such mutant, fused receptors found in human tumors; in certain cases, a given receptor may be found fused to multiple alternative oligomerizing proteins. (B, courtesy of A. Charest.)

A further source of complexity comes from the fact that not all ligands of RTKs are soluble GFs that are transported through intercellular space. Thus, the DDR receptors depicted in Figure 5.6 and **Supplementary Sidebar 5.5** bind various insoluble collagens that form key components of the extracellular matrix and basement membrane; loss of the DDR2 receptor function can compromise the ability of aggressive cancer cells to exhibit motility and invasiveness, key components of the cells of high-grade malignancies. Moreover, the Eph RTKs (see Figures 5.6 and 5.8D) bind ephrin ligands that are stably displayed on the surface of closely apposed neighboring cells, resulting in signals funneled into the cytoplasms of *both* the receptor- and ligand-displaying cells.

Finally, it is increasingly apparent that the strong mitogenic signals released by ligand-activated RTKs must be limited by opposing mechanisms that operate to constrain such signaling. As detailed in the next chapter, the phosphotyrosines created by actively signaling receptors are converted back to tyrosines by an array of phosphatases, thereby reversing the biochemical effects of RTK activation. Yet another critical negative-feedback mechanism depends on receptor internalization in which actively signaling RTKs are shunted via the process of endocytosis into the cytoplasmic vesicles termed endosomes, from which their signals continue to be emitted, and soon thereafter into cytoplasmic lysosomes, in which their GF ligands are released and the receptor molecules themselves are degraded. Interestingly, certain

ligand-activated RTKs, such as the EGF-R, seem to release the bulk of their signals not from their normal homes on the plasma membrane but instead while residing in endosomes prior to their eventual degradation in lysosomes.

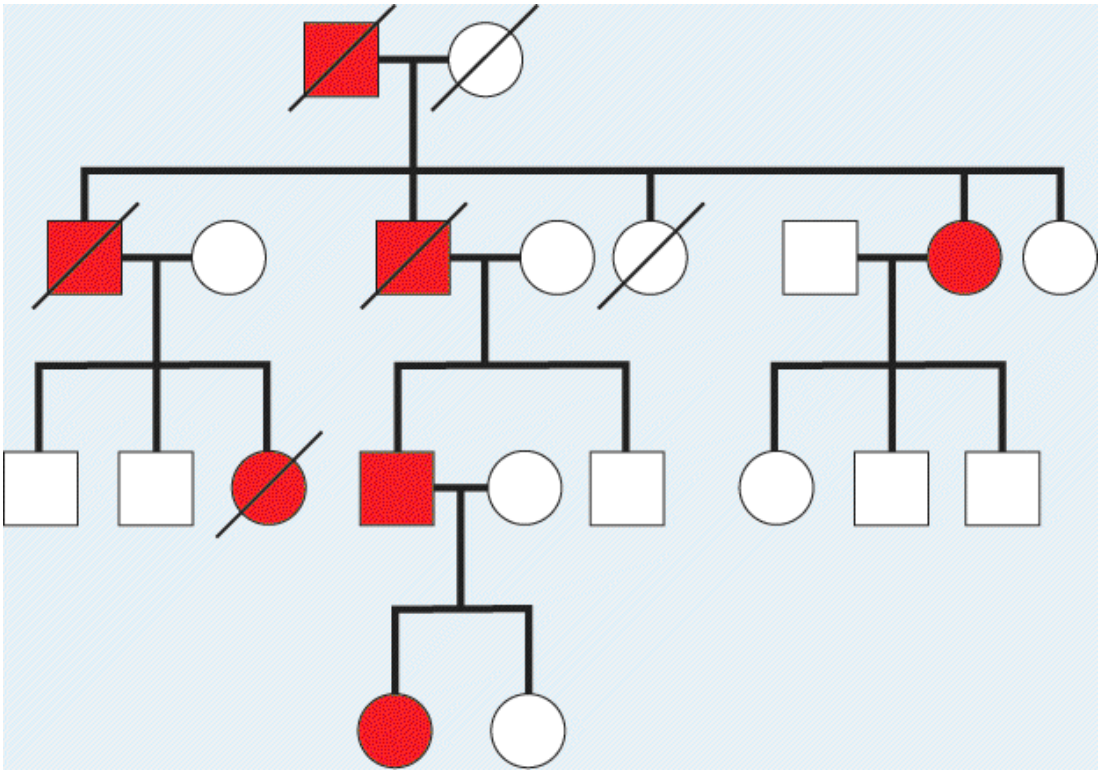
We can also note that of the approximately 20,000 protein-encoding genes in our genome, at least 58 specify protein products having the general structures of the EGF and PDGF receptors, that is, a ligand-binding ectodomain, a transmembrane domain, and a tyrosine kinase cytoplasmic domain. These receptors are further grouped into subclasses according to their structural similarities and differences (see Figure 5.6). Some of these receptors play seemingly unrelated roles in diverse tissues (**Supplementary Sidebar 5.8**). To date, only a minority of these receptors have been implicated as agents contributing to human cancer formation. It is likely that the involvement of other receptors of this class in human cancer will be uncovered in the future. Significantly, mutant alleles of certain tyrosine kinase receptor genes may also be transmitted in the human germ line. This explains the origins of a number of familial cancer syndromes, in which affected family members show greatly increased risks of contracting certain types of cancer (**Sidebar 5.6**).

Sidebar 5.6 Mutant receptor genes can be transmitted in the human germ line

Our discussions until now have focused on somatic mutations sustained in the genomes of cells as these cells advance toward neoplasia; for example, see Figure 4.5. However, certain mutant alleles of the genes encoding growth-promoting proteins, notably receptors, may also be passed through the germ line, resulting in familial cancer syndromes afflicting multiple members of a family; these represent our first exposure in this book to multi-generational cancer syndromes. The *ret* gene encodes an RTK; mutant alleles of this gene can be transmitted through the human germ line, where their transmission from one generation to the next causes the familial cancer syndromes known as multiple endocrine neoplasia (MEN) types 2A and 2B, as well as familial medullary thyroid carcinoma. Hereditary papillary renal cancer is due to inherited mutant alleles in the *met* gene, which encodes the receptor for hepatocyte growth factor (HGF). These mutant germ-line alleles of *met* usually carry point mutations that cause amino acid substitutions in the tyrosine kinase domain of Met that result in constitutive, ligand-independent firing by the receptor. (In the Rottweiler breed of dogs, a point mutation affecting the Met juxtamembrane region is transmitted through the germ line of ~70% of these pets and appears to contribute to their high risk of developing several types of cancer.)

Members of a Japanese family (**Figure 5.13**) have been reported to transmit a mutant allele of the Kit receptor in their germ line. Like the somatically mutated forms of *kit* (see **Supplementary Sidebar 5.8**), the mutant germ-line allele carries a mutation affecting the juxtamembrane domain of the Kit receptor and yields gastrointestinal

stromal tumors (GISTs). When this mutation is introduced into one of the two copies of the *kit* gene in the mouse germ line, mice inheriting this mutant allele develop tumors that are indistinguishable from GISTs seen in humans.



A pedigree chart showing three generations of offspring of two human parents, both now deceased. The original male parent carried a mutant gene, which was passed to both sons and one of three daughters. The affected daughter, who remains alive, did not pass the gene on to any of her three offspring. One of the sons, now deceased, passed the gene on to a daughter, also now deceased, but not to his two sons. The other son, also now deceased, passed the gene on to one of his two sons, who remains alive but in turn passed it on to a daughter, also still alive.

Figure 5.13 Familial gastrointestinal stromal tumors (GISTs) Gastrointestinal stromal tumors arise from the mesenchymal pacemaker cells of the lower gastrointestinal tract and contrast with the far more frequent colon carcinomas, which derive from the epithelial cell layer lining the lumen of the gut. In the case of the kindred depicted here, an allele encoding a mutant, constitutively active Kit tyrosine kinase receptor has been carried by at least four generations, afflicting them with GISTs and/or intestinal obstructions. The transmission of this mutant allele—which carries a deletion of a single amino acid residue in the juxtamembrane domain of the receptor protein (see Supplementary Sidebar 5.6)—through so many generations indicates that phenotypic expression of this mutant

germ-line allele is often delayed until relatively late in life after childbearing years. Affected individuals, *red*; males, *squares*; females, *circles*; deceased, *diagonal strikethroughs*. (From T. Nishida et al., *Nat. Genet.* 19:323–324, 1998. With permission from Nature.)

The familial syndromes described here are most unusual, because the great majority of human familial cancer syndromes involve germ-line mutations of genes that result, at the cellular level, in the formation of inactive, recessive alleles. Included among these are alleles of the tumor suppressor genes to be discussed in Chapter 7 and DNA repair genes to be described in Chapter 12. It seems likely that, in general, mutant alleles encoding constitutively active oncoproteins, such as mutant RTKs, cannot be tolerated in the germ line, because they usually function as dominant alleles in cells and are therefore highly disruptive of normal embryonic development. Recessive alleles present in single copy in the germ line can be tolerated, however, because their presence in cells becomes apparent only when the surviving wild-type dominant allele is lost. Because such loss is infrequent, expression of the cancer-inducing phenotype is delayed until late in development.

Nonetheless, the contrasting behaviors of the dominantly acting, oncogenic alleles of tyrosine kinase receptor genes listed above seem to be compatible with reasonably normal development because their expression (in the case of the *ret* and *kit* genes) is limited to a small set of tissues, and may even be delayed during embryogenesis, allowing embryos to develop normally without the disruptive effects of these growth-promoting alleles.

OceanofPDF.com

Glossary

homodimer
: Molecular complex composed of two identical subunits. *See also* **heterodimer**.

heterodimer
: Molecular complex composed of two distinct subunits. *See also* **homodimer**.

transphosphorylation
: Phosphorylation of one protein molecule by another, such as the phosphorylation of one receptor subunit by the kinase carried by another. *See also* **autophosphorylation**.

phosphatase
: An enzyme that removes phosphate groups from phosphorylated substrates, such as the phosphoamino acid residues in a protein or the phosphorylated inositol of a phospholipid.

endocytosis
: Uptake by a cell of extracellular material together with associated extracellular fluid that is achieved through the invagination of a patch of plasma membrane, thereby yielding membrane-bound vesicles termed endosomes within the cytoplasm. Pinocytosis and phagocytosis are forms of endocytosis. *See also* **exocytosis**, **endosome**, **phagocytosis**, **pinocytosis**.

endosome
: Membranous vesicle lying beneath the plasma membrane that is formed after a patch of the plasma membrane invaginates into the cytoplasm via the process of endocytosis and pinches off from the plasma membrane into the cytoplasm, carrying with it extracellular fluid and associated molecules. *See also* **endocytosis.**

juxtamembrane
: Located immediately adjacent to a membrane.

dimer
: Molecular complex composed of two subunits.

monomer
: Molecule composed of a single unit or a single subunit of a chemical entity that is capable of forming higher–molecular-weight polymeric

structures by association with or covalent linkage to other identical or similar units.

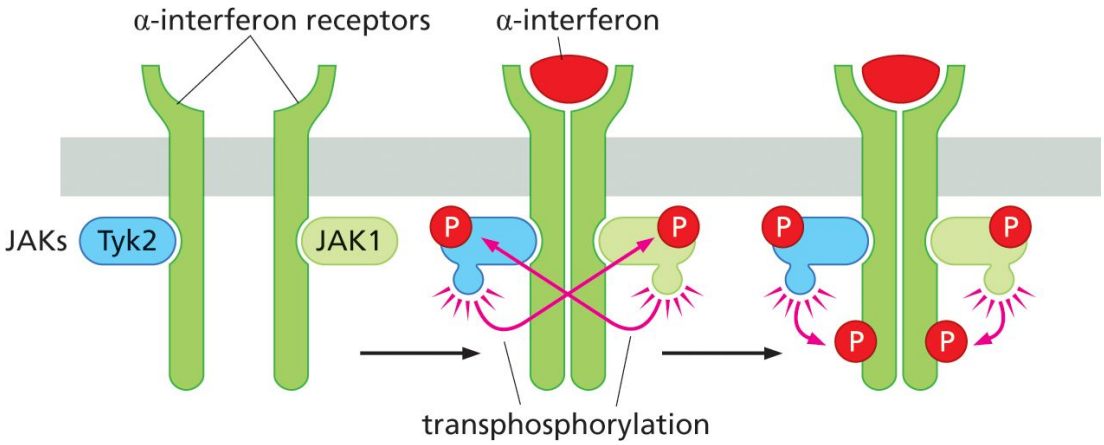
5.7 Yet other types of receptors enable mammalian cells to communicate with their environment

The cytokine receptors are especially important in receiving signals controlling the development of various hematopoietic cell types. This class of receptors also uses tyrosine kinases. However, in this case, the responsible kinases, termed JAKs (Janus kinases), are separate polypeptides that associate with the cytoplasmic domains of the cytokine receptors through noncovalent links. Indeed, as early as the 1980s, the discovery of a number of other structurally unrelated types of metazoan receptors made it clear that the tyrosine kinase receptors (RTKs) described above represent only one class of receptors among a far larger group of cell-surface molecules belonging to various structural and functional classes. As is the case with RTKs, each of these other receptor types is specialized to detect the presence of specific extracellular ligands or groups of related ligands and to respond to this encounter by transducing signals through the plasma membrane into the cell.

One class of receptors that is especially important in receiving signals controlling the development of various hematopoietic cell types also uses tyrosine kinases. In this case, however, the responsible kinases, termed JAKs (Janus kinases), are separate polypeptides that associate with the cytoplasmic domains of these receptors through noncovalent links. Included here are the receptor for erythropoietin (EPO), which regulates the development of erythrocytes (red blood cells), and the thrombopoietin (TPO) receptor, which controls the development of the precursors of blood platelets, called megakaryocytes. The receptors for the important immune regulator interferon are also members of this class, as is the large group of interleukin receptors that regulate diverse immune responses. When these various cytokine receptor molecules dimerize in response to ligand binding, the associated JAKs phosphorylate and activate each other (**Figure 5.14**); the activated JAKs then proceed to phosphorylate the C-terminal tails of the receptor molecules, thereby creating receptors that are activated to emit signals, much like the RTKs described in the previous section. We will return to the details of JAK intracellular signaling in the next chapter.

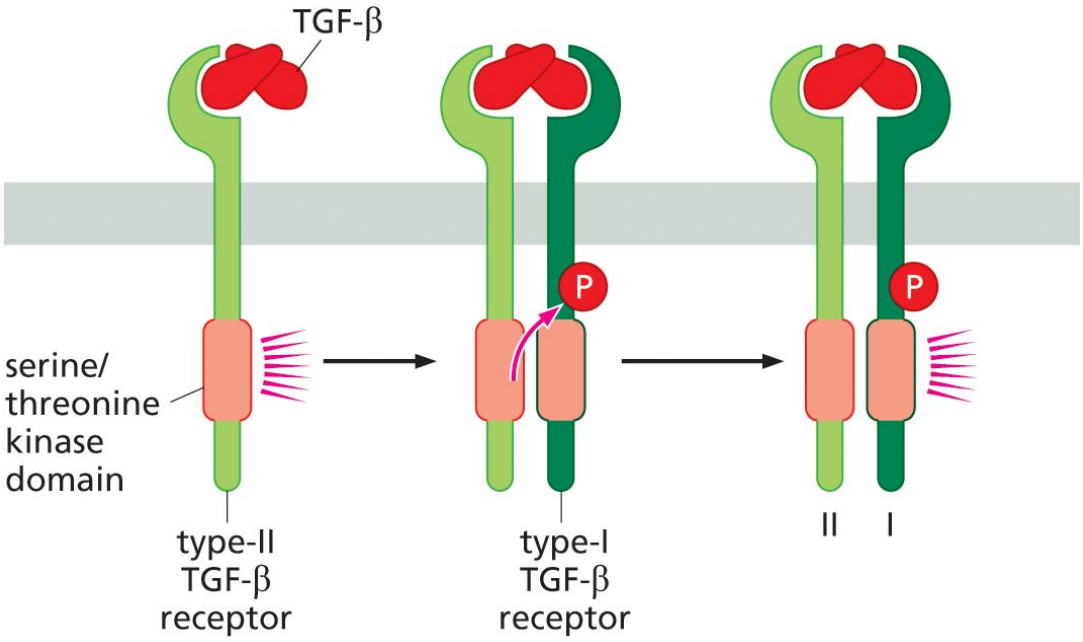


The structure and functioning of a cytokine receptor consisting of two subunits. On the extracellular side of a plasma membrane, each subunit has a cuplike alpha interferon receptor ectodomain. The cytoplasmic domain of each subunit has a J A K attached. One is a T y k 2, and the other is a J A K 1. When alpha interferon binds to the ectodomains, the two subunits move together. The J A Kays phosphorylate each other and thereupon each become active. The J A Kays then each phosphorylate the C-terminal tail of their own subunit, and the entire receptor begins actively signaling.

Figure 5.14 Structure of cytokine receptors The interferon receptor (IFN-R, *darker green*), like the receptors for erythropoietin and thrombopoietin, carries noncovalently attached tyrosine kinases (TKs) of the JAK family (in this case, Tyk2 and Jak1). Upon ligand binding (in this case α-interferon), the two TKs transphosphorylate and thereby activate one another. Subsequently, they phosphorylate the C-terminal tails of the receptor subunits, placing the receptor in an actively signaling configuration, much like the receptor tyrosine kinases described in Section 5.6.

Transforming growth factor-β (TGF-β) and related ligands have receptors that are superficially similar to the tyrosine kinase receptors, in that they have an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic kinase domain. However, these receptors invariably function as heterodimers, such as the complex of the type I and type II TGF-β receptors (**Figure 5.15**). Importantly, their kinase domains phosphorylate serine and threonine rather than tyrosine residues. TGF-β ligands play centrally important roles in cancer pathogenesis, since they suppress the proliferation of normal epithelial cells while promoting the acquisition of malignant properties by already-transformed cells. Upon ligand binding, the type II TGF-β receptor subunit, which carries a constitutively active serine/threonine kinase, is brought into close proximity with the type I TGF-β receptor subunit, which it then phosphorylates. The kinase belonging to the type I TGF-β receptor subunit becomes

activated as a consequence, and proceeds to phosphorylate cytosolic proteins that subsequently migrate to the nucleus, where they trigger expression of certain target genes. (A series of TGF-β-related factors, including activin and bone morphogenetic proteins, or BMPs, use similar receptors for signaling; they are not discussed further here, as their role in cancer development has not been as extensively documented.) We postpone more detailed discussion of the effects of the TGF-β signaling system on proliferation (until Chapter 8) and on carcinoma cell aggressiveness (until Chapter 14).

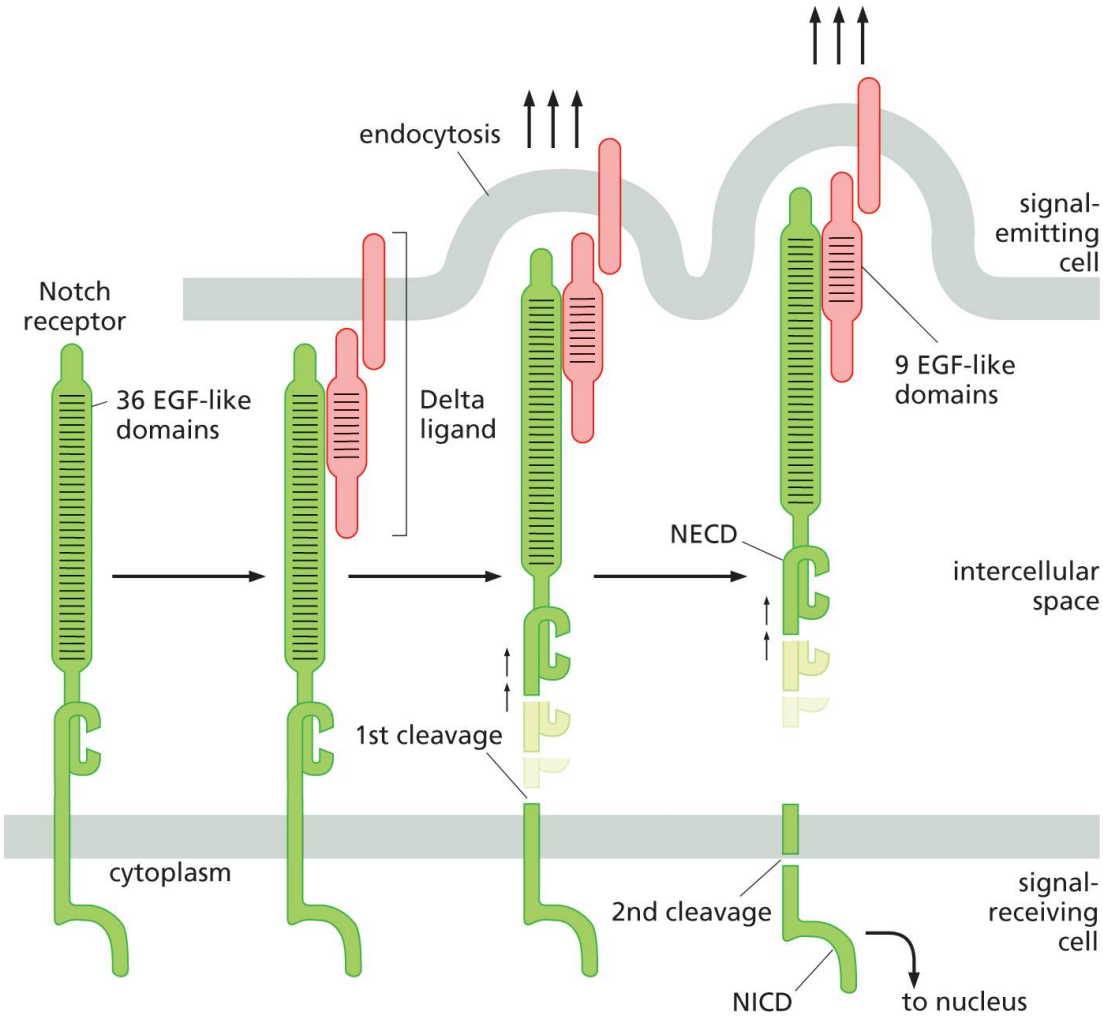


The structure and functioning of T G F beta receptors. On the extracellular side of a plasma membrane, a Type 2 T G F beta receptor has a cuplike receptor ectodomain. The cytoplasmic domain has a serine slash threonine kinase domain. When T G F beta binds to the ectodomain, the serine slash threonine kinase domain begins signaling. A Type 1 T G F beta receptor, structurally the mirror of the Type 2, attaches to the type 1, and the serine slash threonine kinase on the Type 2 phosphorylates the serine slash threonine kinase on the Type 1. The kinase on the Type 1 then begin signaling.

Figure 5.15 Structure of the TGF-β receptor The structure of the TGF-β receptor is superficially similar to that of tyrosine kinase receptors (RTKs), in that both types of receptors signal through cytoplasmic kinase domains. However, the kinase domains of TGF-β receptors specifically phosphorylate serine and threonine, rather than tyrosine residues. After the type II receptor (TGF-βRII) is brought into contact with the type I receptor (TGF-βRI) through the binding of TGF-β ligand, it phosphorylates and activates the kinase carried by the type I

receptor. The activated type I receptor kinase then emits signals by phosphorylating certain cytoplasmic substrates.

A far more primitive form of a transmembrane signaling system is embodied in the Notch receptor (termed simply Notch) and its multiple alternative ligands (NotchL, Delta, Jagged; **Figure 5.16**). Importantly, these ligands are immobilized cell-surface proteins that are displayed by the signal-emitting cell. Hence, ligand–receptor interactions require close physical association between the signal-emitting and signal-receiving cells, similar to the Ephrin-Eph receptors depicted in Figure 5.8D and unlike other examples of receptor–ligand interactions, where the ligands are secreted as soluble proteins into the extracellular space by a cell that may be located at some distance from the cell destined to respond to this ligand. Hence, the interactions of Notch with its ligands conform to the signaling pattern between closely apposed cells that we have termed juxtacrine signaling (Figure 5.8D).



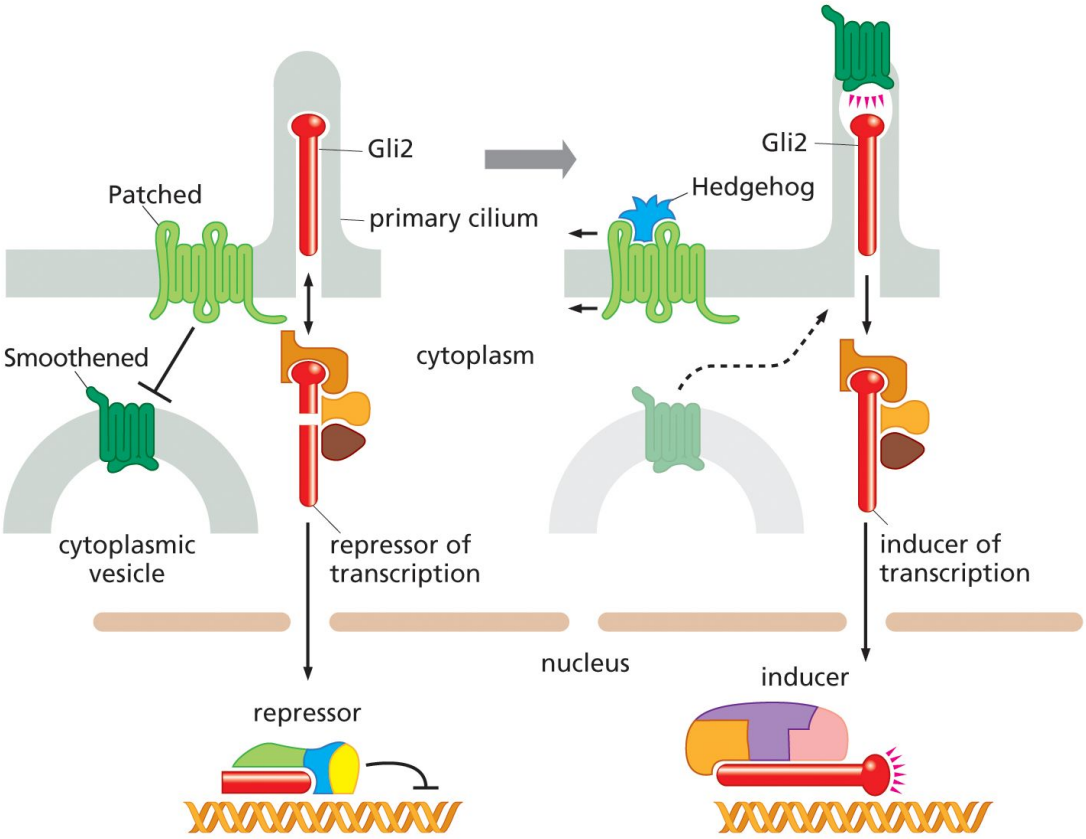
The structure and functioning of the Notch receptor. The receptor's ectodomain has a C-shaped structure near the transmembrane domain, and it ends in a series of 36 E G F like domains. The cytoplasmic domain is short and hook shaped. After the ectodomain binds to a delta ligand attached to a signal-emitting cell, the ligand is drawn back into a fold of that cell's membrane. The Notch receptor separates at the ectodomain-transmembrane domain junction. It then separates at the transmembrane domain-cytoplasmic domain junction, and the hooklike cytodomain fragment begins migrating toward the nucleus of the signal-receiving cell.

Figure 5.16 Structure of the Notch receptor The Notch receptor (*green*) appears to embody a very primitive type of signaling. The extracellular domain (NECD) of Notch displayed by the recipient cell is composed of two polypeptides that are associated via noncovalent interactions. After it has bound a ligand (for example, NotchL or, as shown here, Delta, *pink*) that is being displayed on the surface of an adjacent signal-emitting cell, the bound ligand (here, Delta) undergoes endocytosis into the ligand-presenting cell. This ligand binding also triggers two successive proteolytic cleavages of the Notch receptor. The resulting C-terminal cytoplasmic fragment (NICD) of the Notch receptor is thereby liberated, allowing it to migrate to the cell nucleus, where it alters the expression of certain genes. Mammals have five distinct Notch ligands and four distinct Notch receptors.

Interestingly, considerable evidence points to a mechanism in which the Notch ligand–presenting cell must attach its ligand to the Notch receptor and then use mechanical force to tear the Notch ectodomain away from the signal-receiving cell. (This mechanical force is generated by the endocytosis of the ligand, which pulls it into the cytoplasm of the ligand-presenting cell!) The mechanical tension initially created by ligand binding seems to stretch in some fashion the Notch (receptor) ectodomain, making it vulnerable to cleavage by a protease; this cleavage is followed by a second proteolytic cleavage that releases a fragment from the Notch receptor cytoplasmic domain. The released fragment then migrates to the nucleus, where it functions as part of a complex of transcription factors that activate expression of a cohort of responder genes. Mutant, constitutively active forms of Notch, which fire in a ligand-independent fashion, have been found in half of adult T-cell leukemias. Of note, Notch signaling seems often to direct cell fate, that is, the choice of which specific differentiation pathway a stem cell chooses to enter, rather than providing mitogenic signals.

Yet another receptor, termed Patched, is constructed from multiple transmembrane domains that weave their way back and forth through the plasma membrane (**Figure 5.17**); receptors configured in this way are often termed serpentine receptors. Curiously, the Patched–Smoothened signaling system depends on a cellular structure that was once dismissed as nothing more than an evolutionary relict, a vestige of our

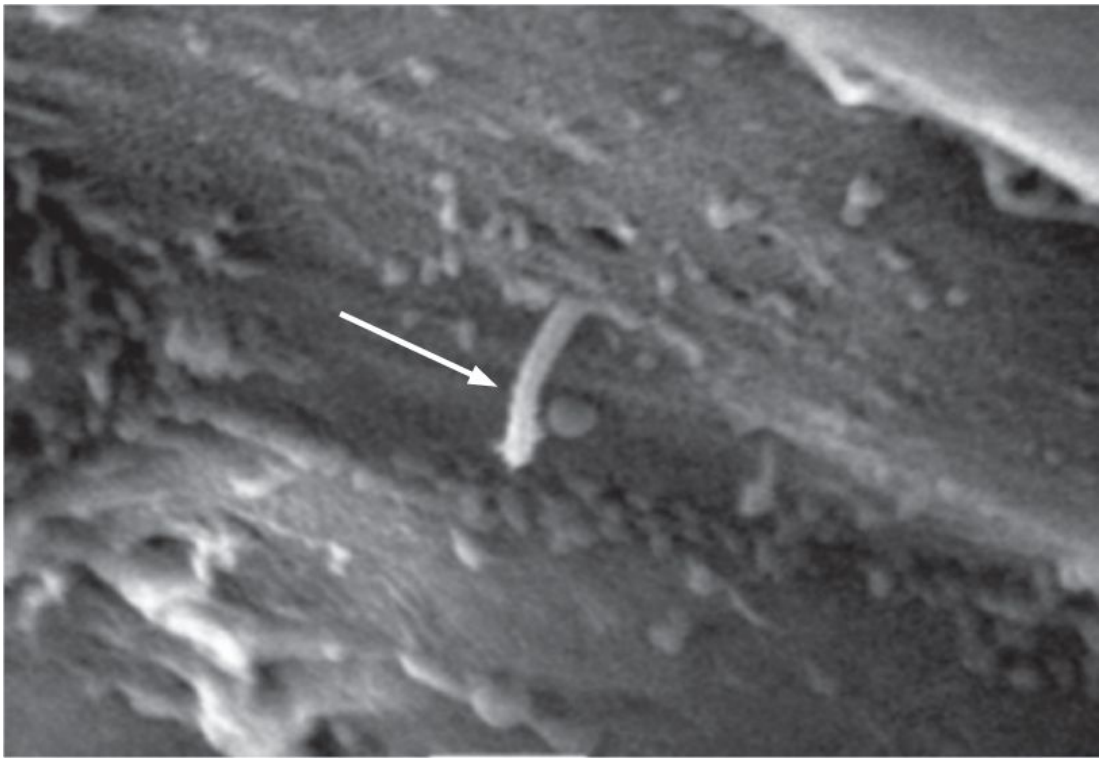
early origins as ciliated or flagellated single-cell eukaryotes. A primary cilium protrudes from the surfaces of cells belonging to almost all mammalian cell types, often being deployed by these cells for various forms of sensory input (see Figure 5.17B). Normally, Smoothened (Smo), which is associated with cytoplasmic membranous vesicles, and the Gli2 transcription factor cycle back and forth in and out of the primary cilium (Figure 5.17A and C). However, when a Hedgehog (Hh) ligand binds its Patched receptor in the plasma membrane, Smoothened and Gli2 are permitted to accumulate in the primary cilium, where Gli2 is converted into an inducer of transcription and is dispatched to the nucleus. (The related Gli1 and Gli3 behave in slightly different ways.)



Two diagrams show variations in the functioning of the Patched-Smoothened signaling system. In both versions, Patched is a folded protein within a plasma membrane near a primary cilium that has a Gli 2 protein through its core, and Smoothed is a folded protein within the wall of a cytoplasmic vesicle. Normally, Smoothened remains where it is, under the influence of Patched. The Gli2 cilium core moves down into the cytoplasm, a portion that acts as a repressor of transcription breaks off and moves into the cell nucleus, where it becomes part of a complex that inhibits transcription. In an alternate process, a Hedgehog ligand binds to Patched and blocks its influence on Smoothened.

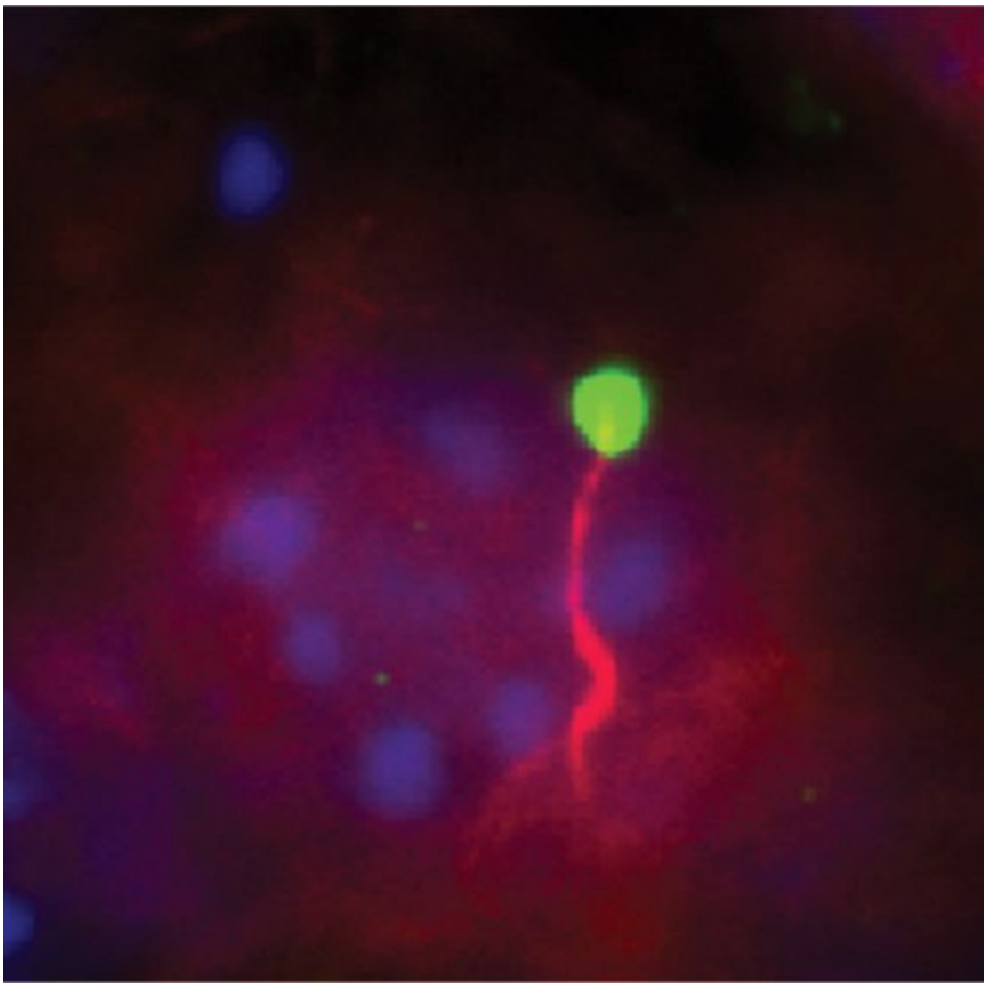
Smoothened moves up into the tip of the cilium, and under its influence the entire Gli2 cilium core moves into the cytoplasm, and from there, unbroken, into the cell nucleus, where it becomes part of a complex that induces transcription. Part B is a scanning electron micrograph of a cilium protruding from the surface of an epithelial cell. Part C shows a bright yellow green blob perched on the tip of a purplish-red filament that extends up from a red surface.

(A)



A scanning electron micrograph of a cilium protruding from the surface of an epithelial cell.

(B)



A bright yellow green blob perched on the tip of a purplish-red filament that extends up from a red surface.

(C)

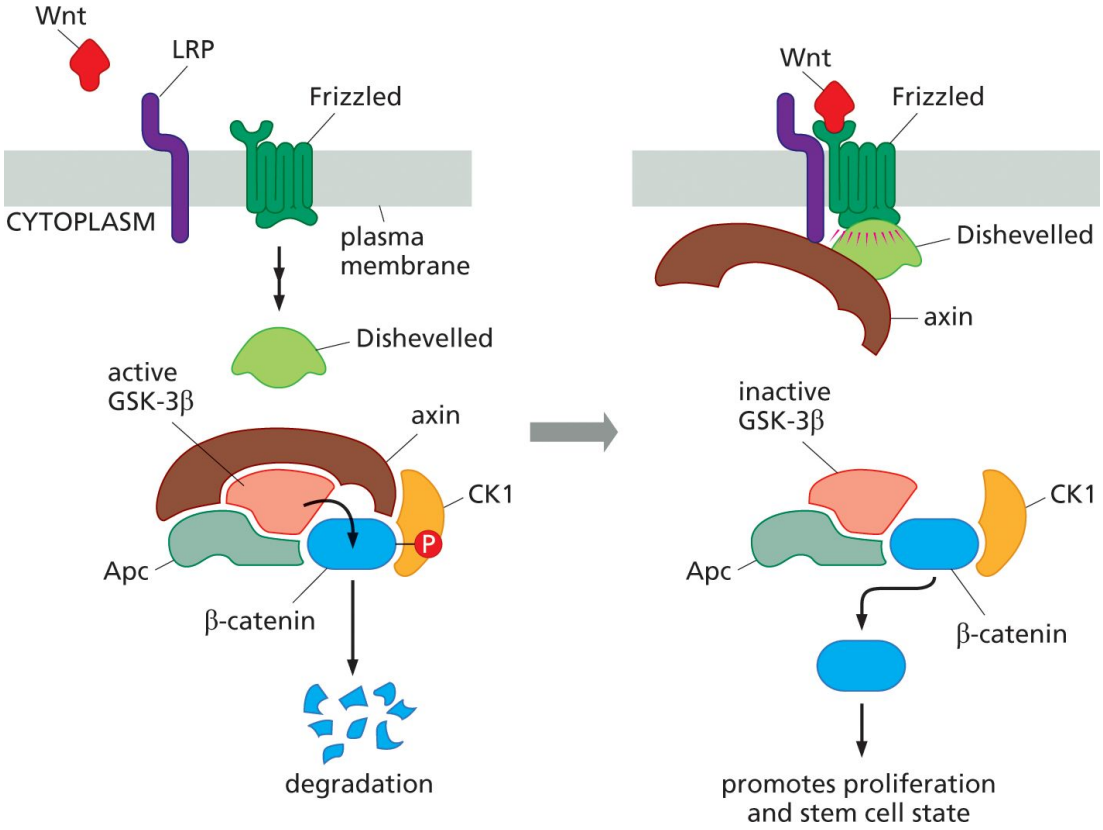
Figure 5.17 The Patched–Smoothened signaling system The Hedgehog pathway utilizes its own, unique signaling system. (A) Normally (*left*), Smoothened (Smo), a seven-membrane-spanning protein structurally related to the Frizzled receptors of the Wnt signaling family (*dark green*; see Figure 5.18), is functionally inert, being confined in cytoplasmic vesicles by the actions of Patched (Ptc; *light green*), which contains 12 membrane-spanning domains (*top left*). This sequestration seems to depend on the catalytic actions of Patched on Smoothened, which prevents Smoothened from moving into primary cilia. Recent research suggests that Ptc acts to control the access of Smo to cholesterol molecules (*not shown*). However, when a Hedgehog (Hh) ligand (*right, blue*) binds to Patched, the latter releases Smoothened from its site of sequestration in the cytoplasm, and Smoothened moves onto the surface of a primary cilium and

proceeds, in some unknown fashion, to protect Gli2 from cleavage, enabling Gli2 to move into the nucleus, where it can act with yet other protein partners as an inducer of transcription. (According to an alternative version, Smoothened routinely cycles in and out of the primary cilium. In the absence of Hh binding, Patched, which is associated closely with the primary cilium, prevents Smoothened accumulation in the cilium; in the presence of Hh, however, Patched is inactivated, thereby allowing the accumulation of Smoothened in the cilium.) Two other Gli proteins—not pictured here—operate in slightly different ways. (B) While most discussions of cell surface receptors imply that such receptors are dispersed randomly across the surface of the plasma membrane, in fact many receptors are displayed only in localized, specialized domains of the cell surface. The Smoothened receptor (like the PDGF-α receptor) is displayed on the surface of primary cilia (*white arrow*), which protrude from the plasma membrane of many types of mammalian cells, as is seen here in a scanning electron micrograph of the surface of an epithelial cell. (C) The cycling of Gli back and forth between the cytosol and the tip of the primary cilium can be blocked experimentally, trapping Gli (*green*) at the tip of the primary cilium (*magenta stalk*) and revealing dramatically one phase of its biochemical cycle. (A, courtesy of D. Thomas and adapted from S. Goetz and K.V. Anderson, *Nat. Rev. Genet.* 11:331–344, 2010. B, from C.J. Haycraft et al., *PLoS Genet.* 1(4):e53, 2005. This article is distributed under the terms of the Creative Commons Public Domain declaration. C, from J. Kim, M. Kato and P.A. Beachy, *Proc. Natl. Acad. Sci. USA* 106:21666–21671, 2009. With permission from National Academy of Sciences, U.S.A.)

In fact, the primary cilium also hosts an RTK—the PDGF-Rα—that we discussed earlier, whose signaling is absolutely dependent on localization to this tiny organelle; thus, blockage of this localization precludes effective ligand-stimulated receptor firing. A similar association operates between primary cilia and the receptors for certain Wnts and GPCRs that are described below. The Hedgehog (Hh) ligands of mammals, specifically, Desert Hh, Indian Hh, and Sonic Hh, appear to function in normal development primarily as morphogens, that is, molecules that enable embryonic tissues to develop specific patterns and shapes.

The Wnt factors represent yet another, entirely independent signaling system. As described earlier, their discovery is traced back to a *Drosophila* mutant termed *Wingless* and a related gene termed *int-1* in mice; the latter was discovered because of insertional mutagenesis by mouse mammary tumor virus (see Sidebar 3.4). These Wnt proteins—humans make at least 19 distinct Wnt species—are tethered tightly to the extracellular matrix (ECM) and, through a lipid tail, to cell membranes, and thus do not appear to be freely diffusible like several of the growth factors that we encountered earlier. Growth factors of the Wnt class activate receptors of the Frizzled (Fzd/Frz) family, which, like Patched, are complex receptors that weave back and forth through

the plasma membrane multiple times (**Figure 5.18**). (Their name comes from the behavior of a *Drosophila* mutant allele encoding one of these receptors that creates disordered hairs growing in disorganized orientations from the cuticle of this fruit fly; mammals express ten distinct receptors belonging to this family.)



A diagram shows canonical W n t signaling via Frizzled receptors. A plasma membrane contains an L R P and a Frizzled receptor. When W n t floats freely, by itself, outside the cell, a Dishevelled protein remains floating freely, by itself, within the cytoplasm. Then beta catenin is phosphorylated by active G S K-3 when the two are joined in a complex that also includes A p c, axin, and C K 1. Subsequently the beta catenin is degraded into small pieces. On the other hand, when W n t binds to the Frizzled receptor, the Dishevelled protein binds to the receptor on the other side, and the axin binds to the Dishevelled protein and the L R P. Then the complex in which G S K-3 would phosphorylate beta catenin remains incomplete, and so the beta catenin remains unphosphorylated. Instead of being degraded, it proliferates and promotes stem cell state.

Figure 5.18 Canonical Wnt signaling via Frizzled receptors Receptors of the Wnt proteins are members of the Frizzled (Frz) family of transmembrane proteins. In the canonical Wnt signaling pathway, and in the absence of Wnt ligand binding (*left*), a complex of axin (*brown*) and Apc (*light blue-green*) allows glycogen

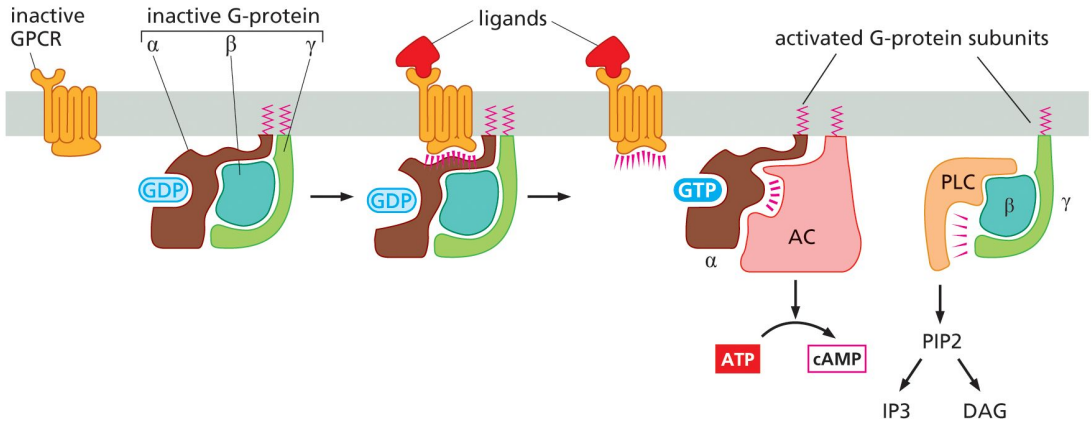
synthase kinase-3β (GSK-3β, *pink*) to phosphorylate β-catenin (*blue*). This marks β-catenin for rapid destruction by proteolysis. However, when a Wnt ligand binds to certain Frizzled receptors (*right*, *dark green*) and the LRP co-receptor (*purple*), the resulting activated Frizzled receptor, acting via the Dishevelled protein (*light green*) and axin (*dark brown*), causes inhibition of GSK-3β. This spares β-catenin, which may accumulate in the nucleus and promote cell proliferation. Two other Wnt-activated pathways, termed "non-canonical Wnt pathways," are not shown here.

In the absence of Wnt signaling, the cytoplasmic enzyme glycogen synthase kinase-3 β (GSK-3β) phosphorylates several key proliferation-promoting proteins, including β-catenin, tagging them for destruction. However, the binding of Wnts to Frizzled receptors triggers a cascade of steps that shut down GSK-3β firing, allowing these proteins to escape degradation and promote cell proliferation (see Figure 5.18). This pathway also plays a critical role in cancer pathogenesis, and we will discuss it in great detail later in this book.

The control of β -catenin levels by Wnts, often termed "canonical Wnt signaling," is only one of multiple ways by which Wnts and their Frizzled receptors affect cell behavior. Certain Wnts, acting together with a subset of the Frizzled receptors, signal through entirely different biochemical pathways that together constitute "non-canonical Wnt signaling." Two of these pathways, which play especially important roles in cancer development—termed Wnt-PCP and Wnt-Ca^2=—contribute in important ways to the formation of certain cancers and will be described in some detail in the next chapter. Recent research has revealed another four non-canonical Wnt signaling pathways whose respective contributions to cancer cell phenotypes are still being described.

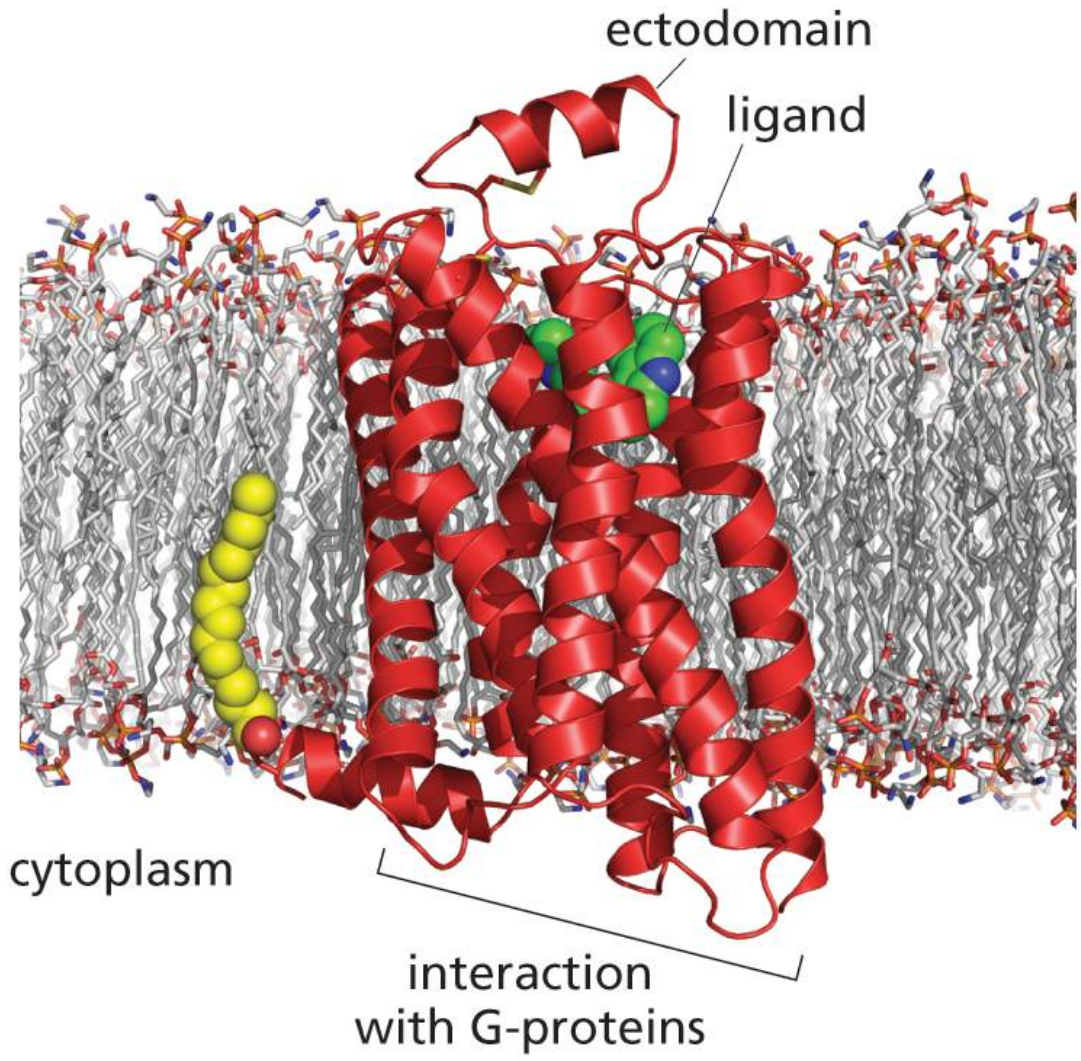
The. structure of Patched and the Frizzled receptors echoes that of a far larger family of 7 membrane-spanning, serpentine receptors that fall into the class of G-protein–coupled receptors (GPCRs). The latter are named because of their ability to activate guanosine nucleotide–binding proteins (G-proteins, for short), which function, much like Ras (see Section 5.10), as binary on–off switches that alternate between a GTP-bound active state and a GDP-bound inactive state (**Figure 5.19**). (The close structural resemblance of the Frizzled receptors with the GPCRs caused many, at one time, to speculate that Frizzled receptors also employ G-proteins for signaling, which is manifestly not the case.) In more detail, the G-proteins activated by ligand-bound GPCRs are structurally complex, being formed as heterotrimers composed of α, β, and γ subunits. As indicated in Figure 5.19A, once a GPCR binds its ligand, a poorly understood shift in the configuration of the receptor causes it to trigger the release of GDP by the α subunit of the G-protein, permitting the binding of GTP instead. The α subunit then dissociates from its β and γ partners, and both the α subunit and the

complexed β=γ subunits may then proceed to interact with their own respective effector proteins, that is, proteins that do the work of the the G-proteins by transmitting signals further into the cell interior. In the case of the GPCR depicted in Figure 5.19A, the effector of the activated α subunit is the adenylate cyclase (AC) enzyme, while the β=γ complex activates a distinct effector—phospholipase C-β (PLC-β). Eventually, an actively signaling α subunit turns itself off by hydrolyzing its bound GTP (converting it to GDP) and reassociates with its β and γ partners. These heterotrimeric complexes then retreat into their inactive, nonsignaling state, awaiting signals once again from a ligand-activated GPCR.



A diagram describing signaling by G P C Rs. A G P C R sits inactive within a plasma membrane, near to an inactive G-protein attached to the cytoplasmic side of the membrane. The protein has alpha, beta and gamma subunits. The alpha unit contains a G D P particle. After the G P C R binds with a ligand, it binds to the alpha subunit of the G protein. The alpha unit releases its G D P and acquires a G T P. Next, the alpha subunit separates from the beta-gamma complex, but both remain attached to the inner wall of the plasma membrane. The alpha unit binds to an A C complex and signals it to produce c A M P from A T P. Meanwhile, the beta-gamma complex binds to a P L C complex and signals it break P I P 2 into I P 3 and D A G.

(A)



The complicated coiled structure of G P C R shown as a ribbon diagram. Much of the protein is alpha helices that lie between the inner and outer layers of the plasma membrane, but the ectodomain protrudes on the extracellular side. Several portions also protrude on the cytoplasmic side and are the site of interaction with G proteins. The ligand bound to the protein on the extracellular side is also visible, but deeply embedded.

(B)

Figure 5.19 Signaling via the G-protein-coupled receptors (GPCRs) (A) In the absence of ligand binding to the GPCR, both the GPCR and its cognate heterotrimeric G-protein (which is composed of α, β, and γ subunits) are in inactive configurations. In response to ligand binding (usually a low molecular weight molecule), the receptor binds to and stimulates the α subunit of the G protein to release its GDP (guanosine diphosphate) and bind GTP (guanosine

triphosphate) instead (*light blue*). The α subunit then dissociates from the β=γ pair. Now, the α subunit (*brown*) can proceed to regulate key enzymes: in the case shown here, the α subunit activates an adenylate cyclase (AC) (*pink*), which generates cAMP, which in turn modulates the activity of several cellular proteins kinase A (PKA). In some cases the β=γ complexes can activate their own constituencies of downstream effectors, such as a phospholipase C (PLC) (*orange*) shown here. PLC cleaves phosphatidylinositol 2 (PIP2) embedded in the plasma membrane (*not shown*), yielding two products, that is IP_3 which increases intracellular calcium and diacylglycerol (DAG) which proceeds to activate one form of protein kinase C (PKC). By subsequently hydrolyzing its bound GTP to GDP, the α subunit of the G-protein eventually shuts down signaling, acting much like the Ras protein (see Figure 5.24), permitting the re-association of the α, β, and γ subunits with one another. (B) The structures of G-protein–coupled receptors (GPCRs) have been elusive because of difficulties in crystallizing them. A structure of rhodopsin produced in 2000 was followed in 2007 by the elucidation of the structure of the β2-adrenergic receptor, which is composed of seven α-helices (*red*). A low–molecular-weight ligand (*green*) is shown binding in the receptor's core, while a molecule of cholesterol (*yellow*) is shown embedded in the lipid bilayer of the surrounding plasma membrane. Some serpentine receptors, notably GPCRs, are specialized to bind low–molecular-weight ligands, whereas others, like Frizzled receptors, bind higher–molecular-weight polypeptide ligands. (B, from V. Cherezov et al., *Science* 318:1258–1265, 2007. With permission from AAAS.)

A recent survey of the human genome sequence indicates that it encodes, in addition to the tyrosine kinase receptors, eleven TGFβ-like receptors, four Notch receptors, two Patched receptors, and ten Frizzled receptors. The GPCRs vastly outnumber these. Altogether, there are more than 800 *GPCR* genes in the mammalian genome, constituting ∼4% of the coding genes in the genome; of these, 400 or so GPCRs function as olfactory receptors and most of the remainder appear to be nonfunctional pseudogenes. The functional versatility of these receptors is illustrated by their diverse functions beyond olfaction, as some underlie mechanisms of taste in the mouth, detection of photons in the retina, and signaling by dozens of distinct neurotransmitters in the brain. While vast in number, these receptors have to date been found to contribute directly to the formation of only a relatively small number of human cancers (described in Chapter 6). However, a subset of the GPCRs, termed chemokine receptors, play an important role in recruiting various immune cells into the tumor-associated stroma, which interact in various complex ways with cancer cells, as described in Chapters 13 and 15. Moreover, hyperactive signaling by certain chemokine receptors also contributes to mitogenic signals in a small subset of human tumors.

OceanofPDF.com

Glossary

cytokine
: (1) Secreted protein that operates like growth factors to stimulate or inhibit various cell types, notably those constituting various branches of the hematopoietic and immune systems. (2) Less commonly, secreted proteins that convey signals between cells, including mitogenic growth factors.

thrombopoietin
: A growth factor that stimulates the production of megakaryocytes and thus of derived blood platelets.

megakaryocyte
: Large cell of the hematopoietic system that produces platelets by pinching off fragments of its cytoplasm.

juxtacrine
: Type of cell–cell signaling in which the signal-emitting cell must be directly apposed to the signal-receiving cell in order for the signal to be properly transmitted. *Compare* **autocrine**, **endocrine**, **exocrine**, **intracrine**, **paracrine**.

cell fate
: The entrance of a less-differentiated cell into a specific differentiation lineage and eventual differentiated state, often determined by a cell long before such a cell manifests specific markers of such a state.

serpentine
: Referring to the class of membrane proteins, such as G protein-coupled receptors, that wend their way back and forth (in a snakelike pattern) through a membrane multiple times.

primary cilium
: Single nonmotile cilium displayed by many types of mammalian cells which bears a specific set of receptors that confer responsiveness to various cytokines. *See also* **cilium**.

morphogen
: Low–molecular-weight substance that induces cells to assemble and participate in the construction of a tissue of a certain shape and form.

G-protein

A signaling protein that actively emits signals when it has bound GTP and shuts itself off by hydrolyzing the GTP, yielding bound GDP and transition of the protein to its inactive, non-signaling state. *See also* **guanine nucleotide exchange factor**.

effector

An agent (such as a protein) that carries out the actual work of a biological process rather than simply regulating it.

pseudogene

A gene present in the genome that shares extensive sequence similarity with known functional genes but encodes a defective function, such as a catalytically inactive enzyme; such pseudogenes invariably derive evolutionarily from functional genes that have sustained inactivating mutations in the distant past but have nonetheless persisted in an organism's genome.

chemokine

(1) A polypeptide that serves as an attractant for motile cells, notably leukocytes, via chemotaxis. (2) More narrowly, a member of a family of low–molecular-weight (8–10 kD) secreted proteins, most of which contain four cysteine residues in evolutionarily conserved sites. *See also* **chemotaxis**.

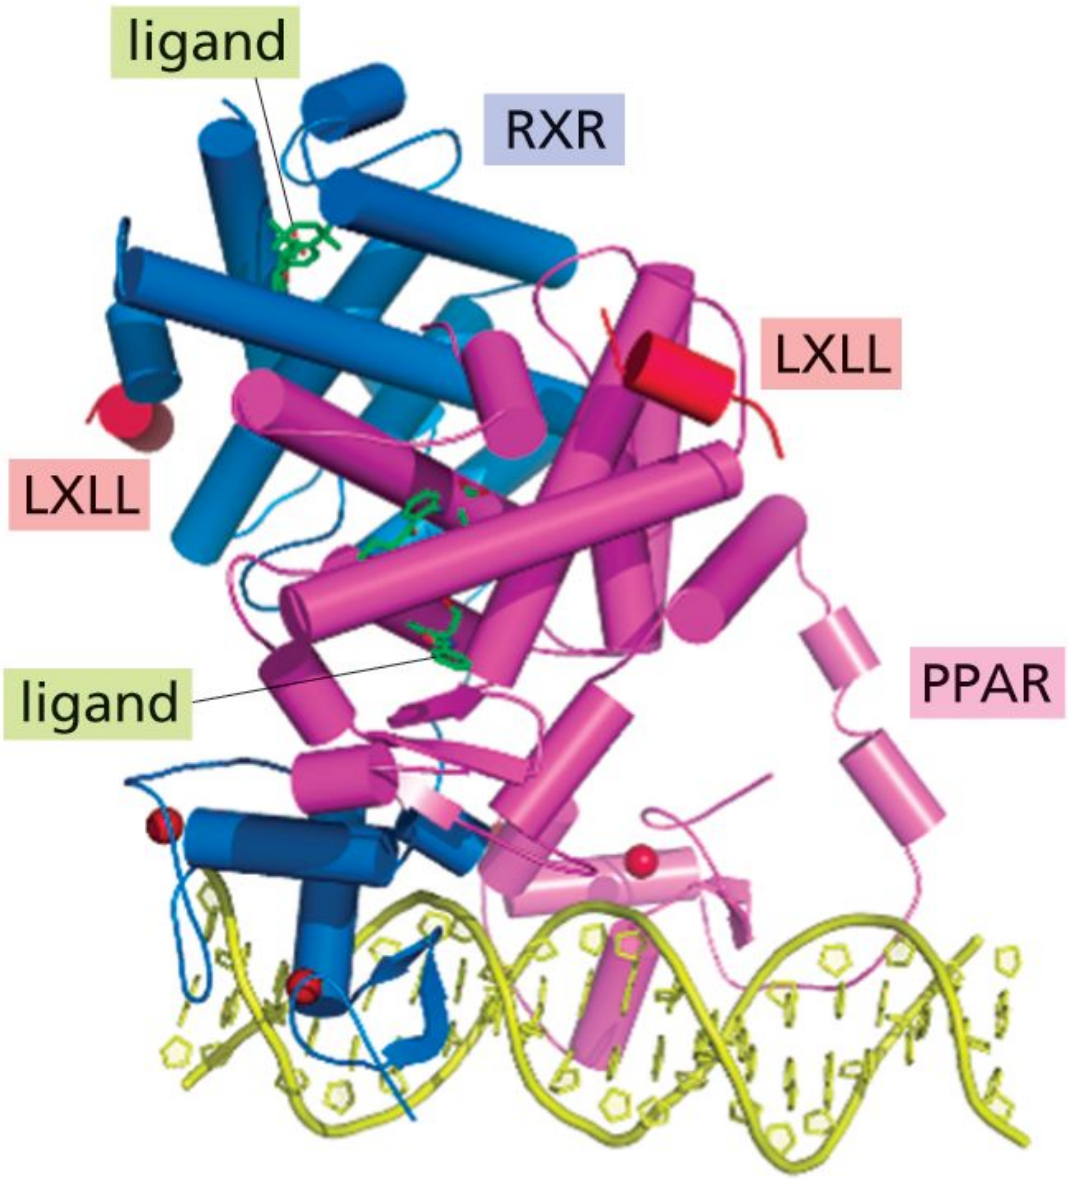
5.8 Nuclear receptors sense the presence of low–molecular-weight lipophilic ligands

The ability of cells to sense various extracellular signals is dictated by the chemical properties of signaling ligands and the impermeability of the plasma membrane to polar compounds, including almost all polypeptides. These conditions necessitated the development of two of the major classes of receptors that we have already encountered: because neither polypeptide GFs nor the low–molecular-weight polar ligands of GPCRs can penetrate the plasma membrane, their corresponding receptors display elaborate ligand-binding ectodomains to the extracellular environment.

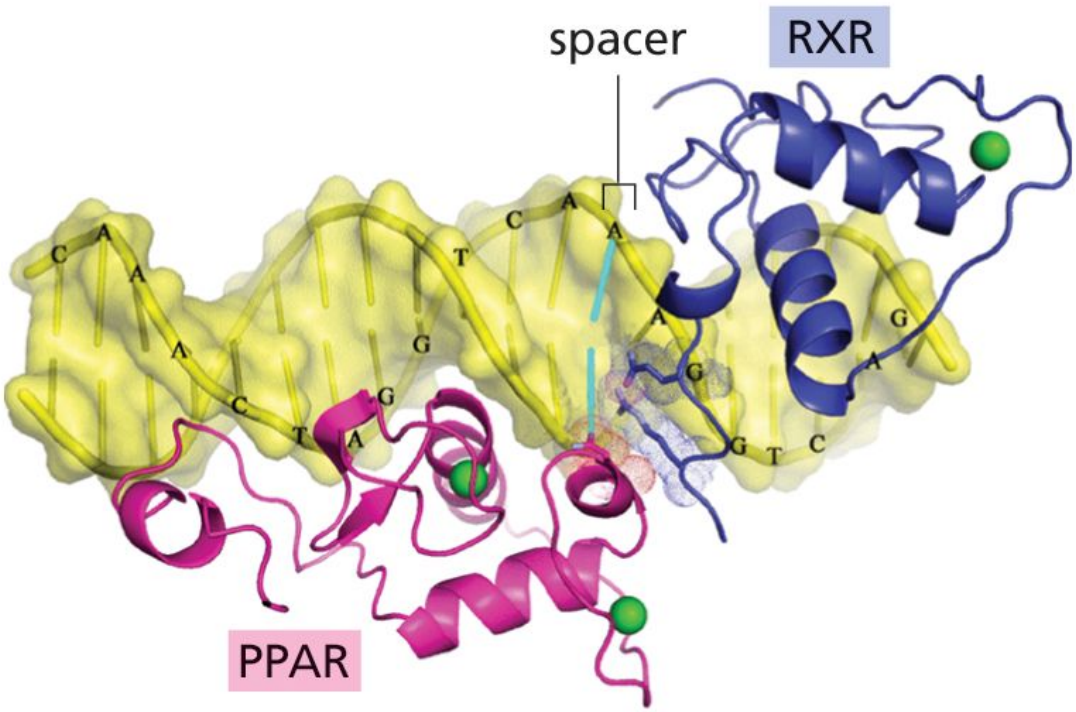
Another class of signaling ligands, however, consists of molecules that are both of low molecular weight and relatively hydrophobic; included among these are steroid sex hormones, retinoids, and vitamin D. Their hydrophobicity enables these ligands to readily penetrate the plasma membrane and advance further into the nucleus, where they may bind and activate a series of nuclear DNA-binding proteins that function as transcription factors. The complex cytoplasmic signaling cascades that have evolved to function as intermediaries between a diverse array of cell surface receptors and the nuclear transcription machinery are not needed here, since these "nuclear receptors" can bind their ligands and directly regulate the expression of target genes by binding to the promoters of these genes. Prominent among the 48 or so human nuclear receptors are those that bind the steroid hormones estrogen, progesterone, and androgens. These three receptors play key roles in the development of common human malignancies, in particular, breast, ovarian, and prostate carcinomas.

Nuclear receptor molecules contain a DNA-binding domain, a hinge region, and a conserved ligand-binding domain, these three being flanked by variable N′- and C′-terminal domains. Some nuclear receptors remain in the cytoplasm until ligand binding triggers their nuclear import, while others are constitutively bound to chromatin. Once associated with the chromatin, these receptors bind as homo- or heterodimers (**Figure 5.20A**) to a pair of recognition sequences in the DNA located within or near the promoters of genes whose expression they control; these recognition sequences are often termed hormone response elements (HREs) and are composed of a pair of hexanucleotides separated by a variable number of spacer sequences (Figure 5.20B).



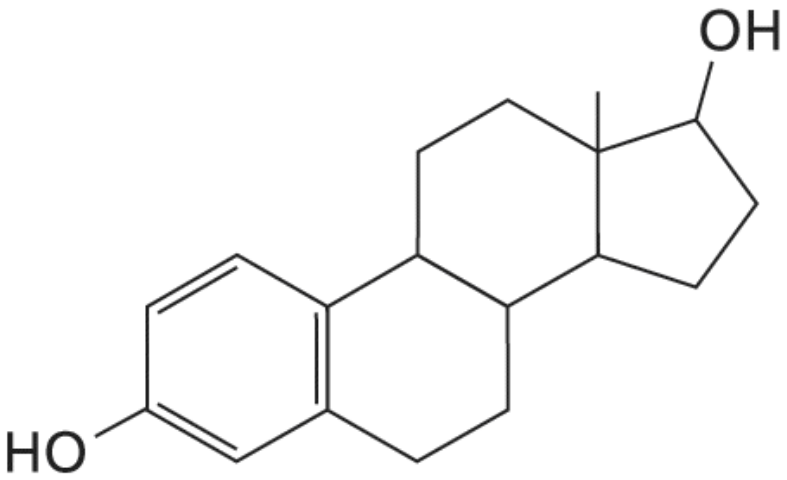
A three-dimensional rendering of a nuclear receptor complex, with dark blue segments labeled R X R, light purple segments labeled P P A R, and two short red segments labeled L X L L. Two thin green strands are labeled ligands. Also shown are three red dots. The entire structure is attached to a D N A molecule.

(A)

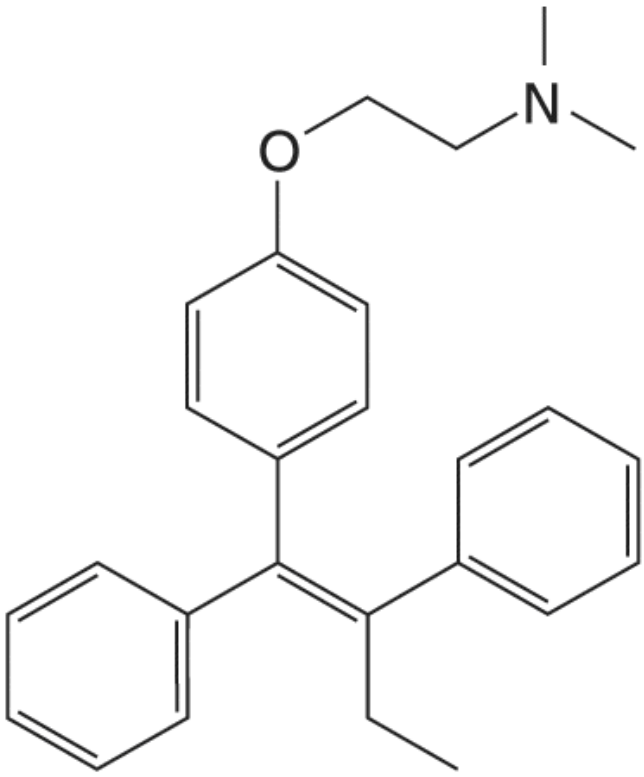


Details for the D N A attachment in Part A. A sequence of bases spirals around the D N A: C A A A C T A G G T C A A A G G T C A G. In this sequence, A G G T C A occurs twice, with an A between them labeled spacer. A P P A R domain binds to the first A G G T C A. An R X R domain binds to the second one.

(B)



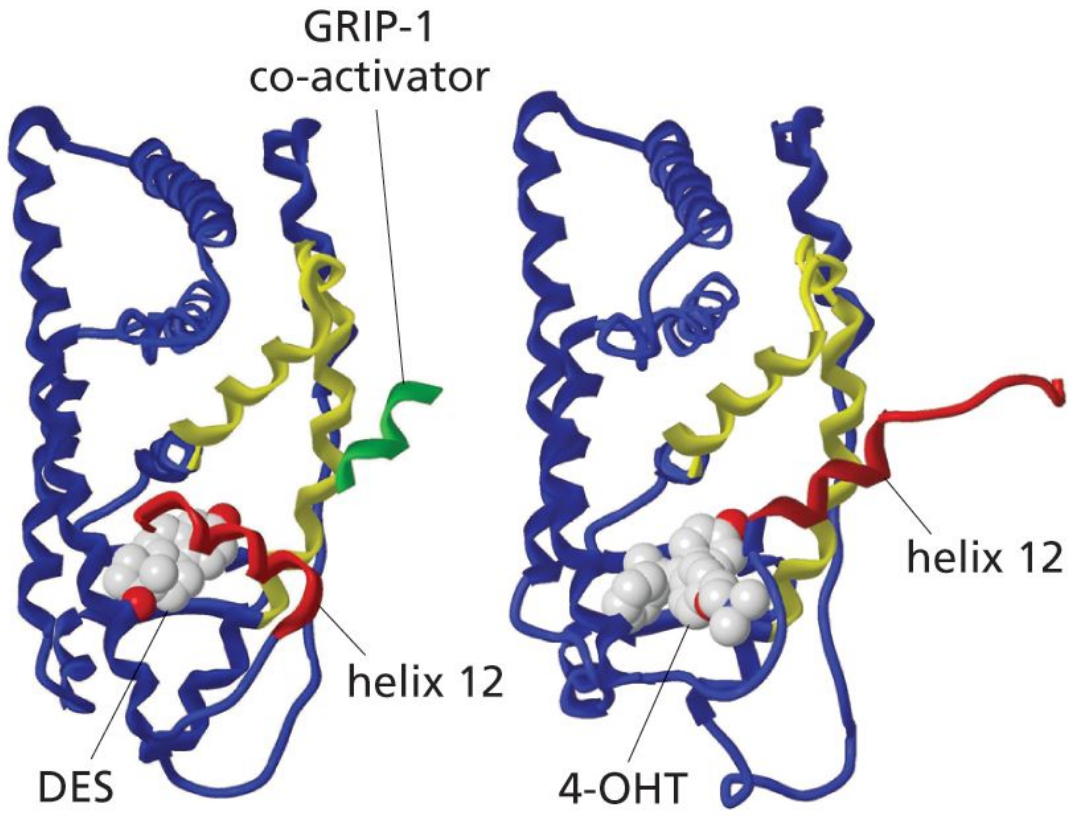
E2/estrogen



4-OHT/tamoxifen

Two molecular diagrams. One is E 2 slash estrogen, featuring 17 carbons joined as three six-carbon rings and a five-carbon ring. An O H group hangs off each end, and an 18th carbon attaches in the middle. The other molecule is 4-O H T slash tamoxifen, featuring three full, separate six carbon rings held

together by a 19th and 20 carbon that also have an attached ethyl group. One of the six-rings has an attached oxygen to which, in turn, is attached a two-carbon chain with a dimethyl amino group at the other end.
(C)



Two very similar structures, side by side. The left one has a cluster of spheres labeled D H S where the right one has a cluster labeled 4-O H T. The left one has a GRIP-1 co-activator, while the right one does not. Both have a section labeled helix 12, but on the right one this is in the position of the left one's GRIP-1 co-activator.

(D)

Figure 5.20 Nuclear receptors (A) While the estrogen receptor (ER) often functions as a homodimer, many other nuclear receptors function as heterodimers, with each monomer binding its own ligand and its own recognition site in the DNA. Seen here is the structure of a nuclear receptor complex that has been elucidated in its entirety—the heterodimeric complex of PPAR-γ (peroxisome proliferator-activated receptor-γ, *light purple*) and the RXR (retinoid X receptor, *blue*). The LXLL domain (where L = leucine and X = variable amino acid residue) of the co-activator of each receptor (*red*) enables the co-activator to bind directly

to the receptor; the bound co-activators then recruit chromatin-modifying enzymes to the nearby chromatin. The ligands (*green*) of the two receptors are rosiglitazone (bound by PPAR) and 9-*cis*-retinoic acid (bound by RXR). Zinc ions are seen as *red dots*. α-helices are depicted as cylinders. (B) The DNA-binding domains of the two subunits of the receptor shown in (A) are seen here in greater detail, in this case binding to two copies of the sequence AGGTCA (separated by a single base-pair spacer sequence, *light green lines*). Other nuclear receptors have paired DNA recognition sites with spacers of various lengths, and one class of these receptors bind DNA as monomers. Zinc ions are seen as *green dots*. (C) Like the ligands of other nuclear receptors, 17β-estradiol, otherwise called estrogen or simply E2, causes a conformation shift of the estrogen receptor (ER) that enables the receptor to associate physically with a co-activator, resulting in activation of transcription. Binding of pseudoligands, such as the synthetic drug 4-hydroxytamoxifen (4-OHT, *below*), causes an alternative stereochemical shift in the ER that results in the loss of contact with co-activators and the acquisition of contact with co-repressors; this explains why tamoxifen is often used therapeutically to antagonize estrogen signaling. (D) Analysis of the effects of the E2 mimic diethylstilbestrol (DES; *white, left*) versus 4-OHT (*white, right*) reveals a shift in the location of helix 12 of the ER (*red*). Following DES binding (*left*), the ER (*dark purple/blue*) is able to associate with a domain of the GRIP-1 (glucocorticoid receptor-interacting protein-1) transcriptional co-activator (*green*). However, if the E2 antagonist 4-OHT is bound (*right*), the shift in helix 12 of the ER (*red*) precludes the binding of the co-activator, blocking transcriptional activation. (A and B, from V. Chandra et al., *Nature* 456:350–356, 2008. With permission from Nature. D, adapted from A.K. Shiau et al., *Cell* 95:927–937, 1998. With permission from Elsevier.)

In the case of the estrogen receptor (ER), binding of its natural ligand—17β-estradiol, commonly called estrogen or simply E2 (see Figure 5.20C)—causes a conformational shift of α-helices near the ER ligand-binding pocket; these shifts allow the receptor to attract one of several receptor co-activators and release co-repressors, that is, proteins that relay signals from the ER to the general transcriptional machinery (see Figure 1.15). These intermediaries often act by modifying nearby histones or, alternatively, by recruiting histone-modifying enzymes (see Section 1.8). The resulting modified chromatin then either allows or prevents transcription of associated genes by RNA polymerase II. A selective estrogen receptor modulator (SERM), as represented here by tamoxifen, causes the ER to release co-activators (see Figure 5.20D) and to recruit co-repressors (not shown), resulting in effective blocking of E2 signaling; this shutdown, in turn, can confer great clinical benefit when this SERM is used to treat patients having ER-positive human breast carcinomas. For example, in one clinical trial, blocking E2 signaling with tamoxifen treatment resulted in an almost twofold

reduction in the breast cancer relapse rate of postmenopausal women whose ER-positive primary tumors had been surgically removed. Yet other nuclear receptors play key roles in cancer pathogenesis. For example, the vitamin D ligand molecule, acting via its cognate nuclear receptor, has strong effects in normalizing the otherwise highly abnormal stroma of pancreatic adenocarcinomas.

OceanofPDF.com

Glossary

nuclear receptor
: One of a family of nuclear DNA-binding proteins that bind lipid-soluble ligands and, in response, undergo a conformational shift that enables them to directly control the transcription of genes to which they are bound.

hormone response element
: An oligonucleotide sequence in genomic DNA to which hormone-activated nuclear receptors bind.

co-activator
: Protein that associates with a DNA-binding transcription factor and causes, directly or indirectly, the modification of nearby chromatin proteins and a resulting stimulatory effect on the transcription of an adjacent gene. *See also* **co-repressor**.

co-repressor
: Protein that associates with a DNA-binding transcription factor and causes, directly or indirectly, the modification of nearby chromatin proteins and a resulting inhibitory effect on the transcription of an adjacent gene. *See also* **co-activator**.

selective estrogen receptor modulator
: A pharmacological agent that binds as a pseudo-ligand to the estrogen receptor and perturbs its behavior in one way or another. *See* **pseudoligand**.

tamoxifen
: A synthetic pharmacological analog of estrogen which can bind the estrogen receptor and inhibit a subset of the normal signaling functions of this estrogen-activated receptor, thereby antagonizing the actions of estrogen.

5.9 Integrin receptors sense association between the cell and the extracellular matrix

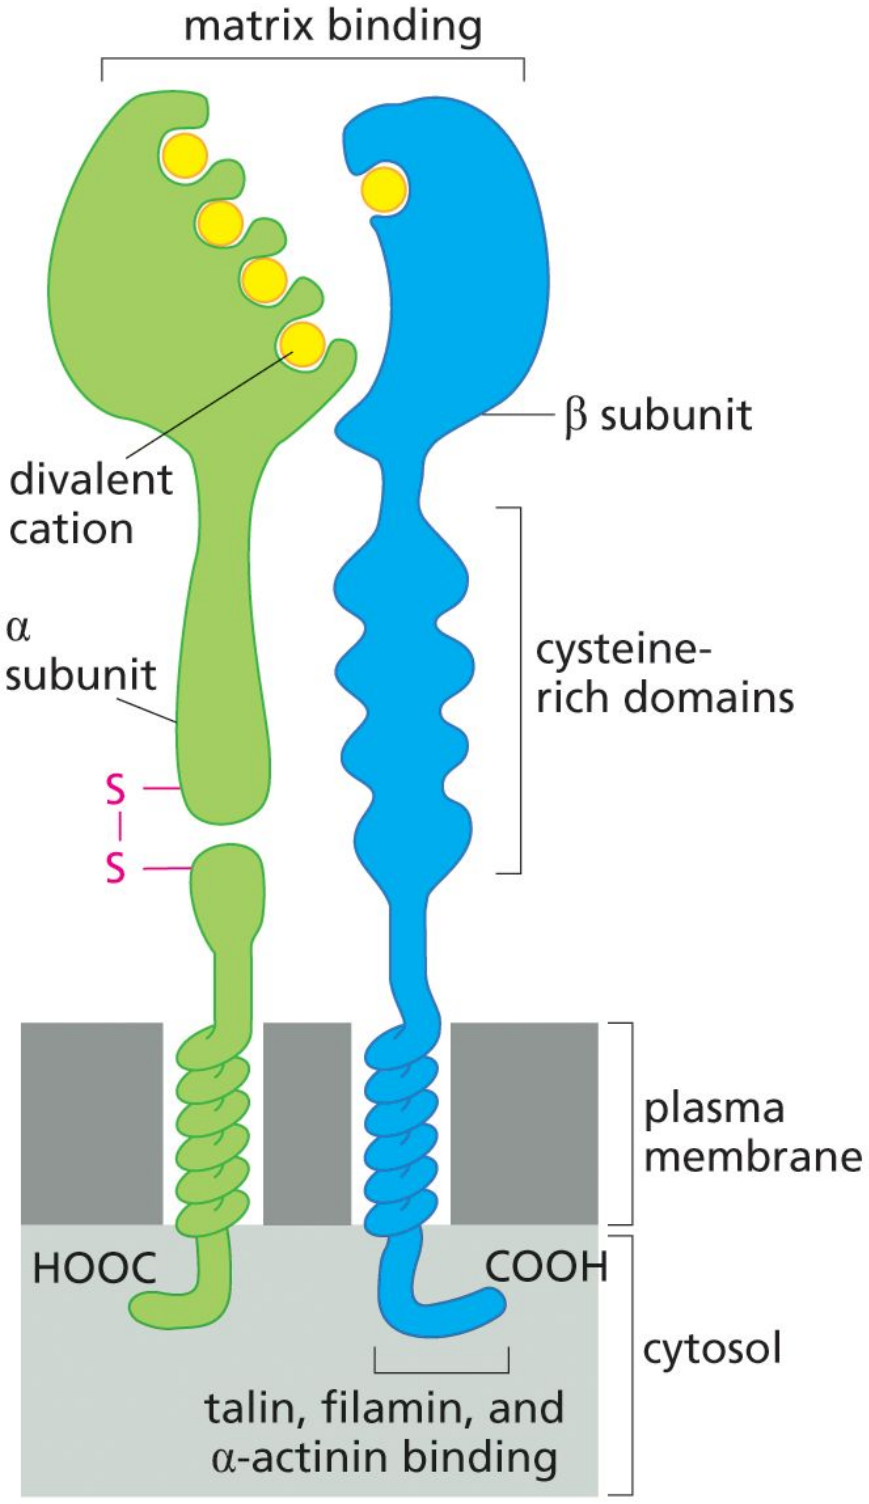
The biology of normal and transformed cells provides hints of yet another type of cell surface receptor, one dedicated to sensing a quite different class of molecules in the extracellular space. Recall that an important attribute of transformed cells is their ability to grow in an anchorage-independent fashion, that is, to proliferate without attachment to a solid substrate such as the one at the bottom of a Petri dish (see Section 3.5). This behavior contrasts with that of normal cells, which require attachment in order to proliferate. Indeed, in the absence of such attachment, many types of normal cells will activate a version of their death program (apoptosis) that is often termed anoikis. These cell death processes will be explored in detail in Chapter 9.

Biochemical analyses of the solid substrate to which cells adhere at the bottom of Petri dishes have revealed that, in very large part, cells are not anchored directly to the glass or plastic surface of these dishes. Instead, they attach to a complex network of molecules that closely resembles the extracellular matrix (ECM) usually found in the spaces between cells within most tissues (see Figure 1.11C). The ECM is composed of a series of glycoproteins, including collagens, laminins, proteoglycans, and fibronectin. After cells are introduced into a Petri dish, they secrete ECM components that adhere to the glass or plastic; once a provisional ECM is laid down in this way, the cells attach themselves to this matrix; this process of ECM assembly mirrors in some fashion the formation of ECM in living tissue. Consequently, the anchorage dependence observed *in vitro* reflects the need of normal cells to be tethered within living tissues to ECM components in order to survive and proliferate.

The trait of anchorage dependence makes it obvious that cells are able to sense whether or not they have successfully attached themselves to the ECM. As was learned in the mid-1980s, such sensing depends on specialized receptors that inform cells about the extent of tethering to the ECM and about the identities of specific molecular components of the ECM (for example, collagens, laminins, fibronectin) to which tethering has occurred. Sensing of the collagen fibers in the ECM can be accomplished by an unusual pair of RTKs, termed discoidin domain receptors (DDRs; see Figure 5.6). However, most sensing of ECM components is carried out by a specialized class of cell surface receptors termed integrins. In effect, the molecular components of the ECM serve as the ligands of the integrin receptors. At the same time, the integrins

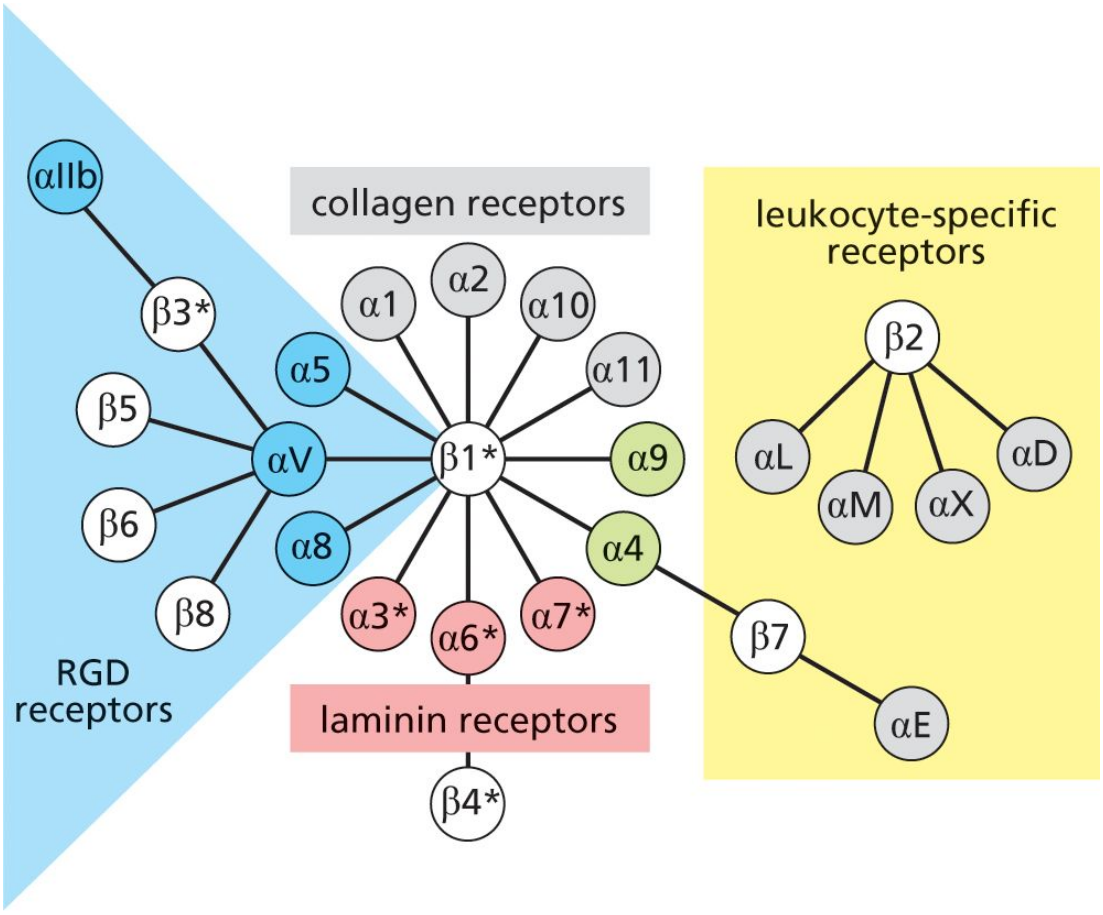
create mechanical stability in tissues by tethering cells to the scaffolding formed by the ECM.

Integrins constitute a large family of heterodimeric transmembrane cell surface receptors composed of α and β subunits (**Figure 5.21**). At least eighteen α and eight β subunits have been enumerated; together, 24 distinct heterodimers are known. **Table 5.4** indicates that the ectodomain of each integrin heterodimer shows specificity for binding a specific ECM molecule or a small subset of ECM components. The much studied α5β1 integrin, for example, is the main receptor for fibronectin, an important glycoprotein component of the ECM found in vertebrate tissues. Laminins, which are large, multidomain ECM molecules, have been reported to be bound by as many as 12 distinct integrin heterodimers.



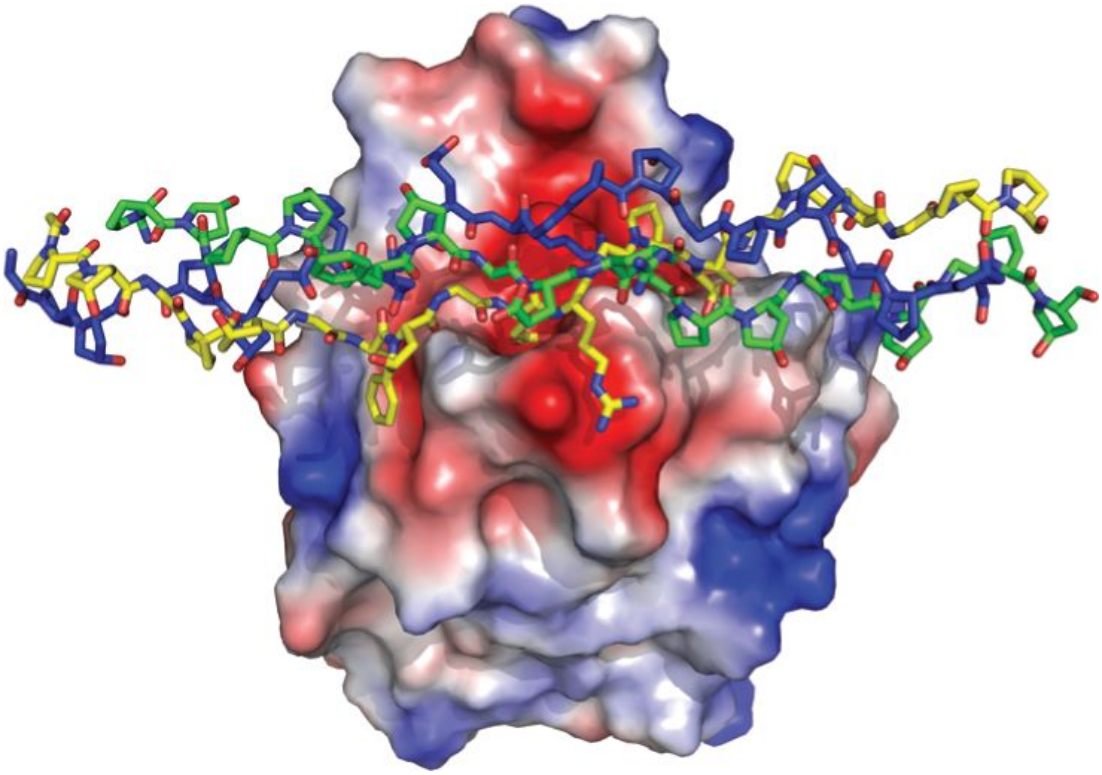
A diagram of an integrin, with a green alpha subunit on the left and a blue beta subunit on the right. At the top end is the matrix binding domain, with four divalent cations on the alpha subunit and one cation on the beta subunit. Below the matrix binding portion is a section that in the alpha subunit

contains an S S bond and in the beta subunit contains a series of cysteine-rich domains. The lower end of this section connects to transmembrane domain, which in each subunit is spiral-shaped. The domain that extends into the cytosol is hook-shaped, and the carboxyl group at the end is shown. On the beta subunit, this part is labeled talin, filamin, and alpha-actinin binding. (A)



A diagram showing the 24 ways different types of alpha and beta subunits normally combine. Alpha 2 b can combine with beta 3. Beta 3, along with betas 5, 6 and 8, can combine with alpha V. Alpha V, along with alphas 5 and 8, can combine with beta 1. All these combinations form R G D receptors. Beta 1 can also combine with alphas 1, 2 10 and 11 to form collagen receptors and with alphas 3, 6 and 7 to form laminin receptors. Alpha 6 can also combine with beta 4 to form a laminin receptor. Beta 1 can also combine with alphas 4 and 9, whose receptitivity is not specified. Beta 7 can combine with alpha 9 or alpha E to form a leukocyte-specific receptor. Finally, leukocyte-specific receptors can also be formed by combining beta 2 with alpha L, M, X or D. Asterisks appear on betas 1, 3 and 4 and alphas 3, 6 and 7.

(B)



A space-filling model of an alpha 2 beta 1 integrin, shown as a red, white and blue blob with a sort of stick-figure “crown” in many color that is collagen I.

(C)

Figure 5.21 Structure of integrins Integrin molecules function as heterodimeric cell surface receptors, each composed of an α plus a β subunit (*green*, *blue*). (A) The ectodomains of these receptors bind specific components of the extracellular matrix (ECM). Divalent cations (*yellow dots*), notably magnesium, manganese, and calcium, modulate this binding in various ways. At the same time, the cytoplasmic domain (largely that of the β subunit) is linked, via intermediary proteins, to the cytoskeleton (largely that constructed by actin fibers); in addition, the cytoplasmic domains may attract a variety of signal-transducing proteins that become activated when the ectodomain binds an ECM ligand. (B) The α and β integrin subunits associate with one another as heterodimers in various specific combinations to enable the binding of a variety of ECM ligands and to transduce multiple signals into the cell. As is apparent, the set of heterodimers actually found in cells is far less (24) than might be theoretically predicted through combinatorial interactions of each α subunit with each β subunit (144 in all). [The most promiscuous of the β subunits is β1 (*center*), which can associate with 12 alternative α subunits, resulting in many distinct integrin heterodimers.] RGD

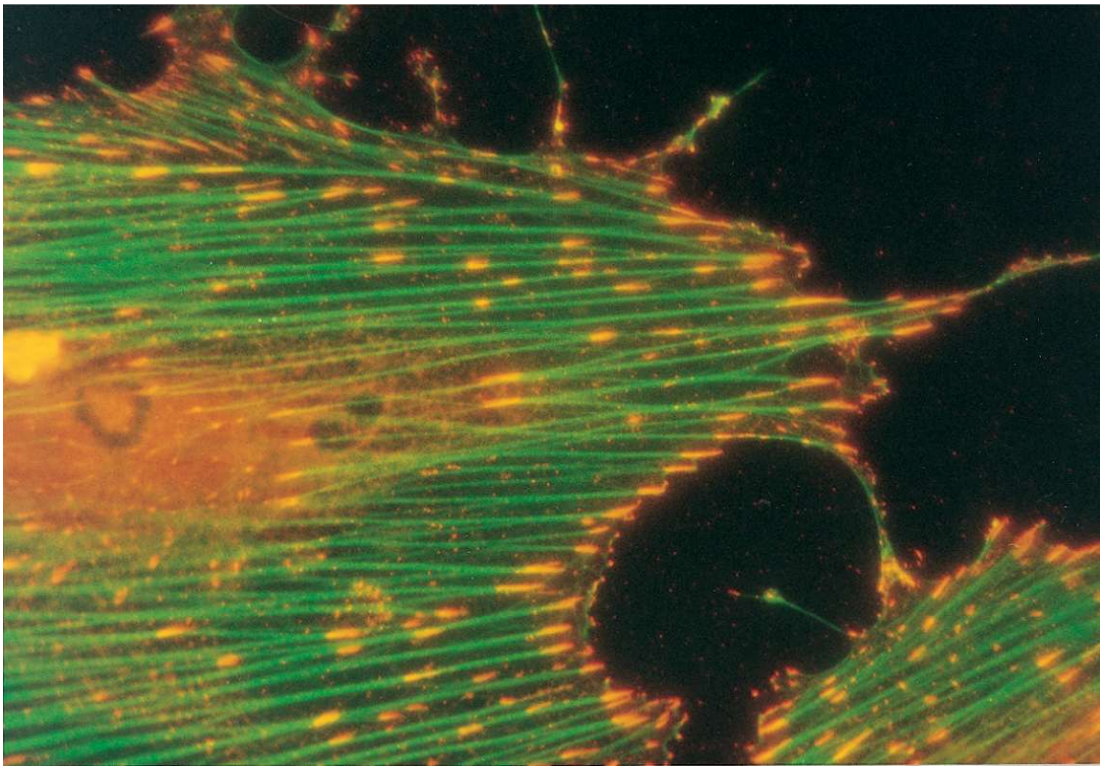
receptors recognize the arginine–glycine–aspartic acid tripeptide motif that is found in a number of distinct ECM proteins and represents the core sequences recognized by these integrins to initiate such binding. Laminin is a critical component of the basement membrane (see Figure 2.3). Asterisks denote alternatively spliced cytoplasmic domains. (C) One depiction of integrin–ECM binding comes from the crystallographic analysis of the ectodomain of the α2β1 integrin (*space-filling structure*) interacting with collagen I, a triple helix (*stick figures*). The *red* surface patches on the integrin ectodomain contain the more acidic side chains, while the *blue* surface patches contain basic amino acids. (B, from R.O. Hynes, *Cell* 110:673–687, 2002. C, from J. Emsley et al., *Cell* 101:47–56, 2000. Both with permission from Elsevier.)

Table 5.4 Examples of integrins and their extracellular matrix ligands

Integrin	**ECM ligand**
α1β1	collagens, laminin
αvβ3	vitronectin, fibrinogen, thrombospondin
α5β1	fibronectin
α6β1	laminin
α7β1	laminin
α2β3	fibrinogen
α6β4	laminin—epithelial hemidesmosomes

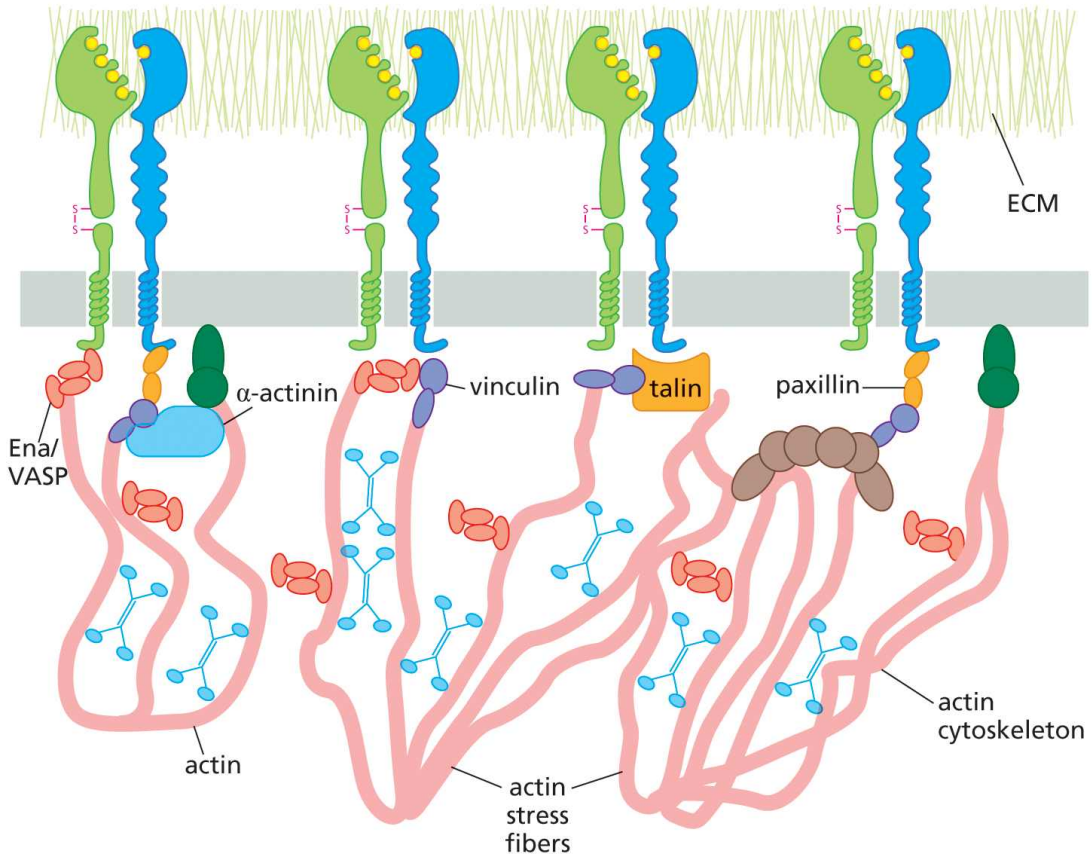
Having bound their ECM ligands through their ectodomains, integrins cluster to form *focal adhesions* (**Figure 5.22A**). This clustering affects the organization of the cytoskeleton underlying the plasma membrane, since some integrins are linked directly or indirectly via their cytoplasmic domains to important components of the

cytoskeleton, such as actin, vinculin, talin, and paxillin (Figure 5.22B and C). The formation of focal adhesions may also cause the cytoplasmic domains of integrins to activate signaling. As an example, by triggering the release of anti-apoptotic signals, integrins reduce the likelihood of anoikis. The functions of integrins continue to be critical during the development of many tumors, indicating that tumor cells usually do not evolve to a stage where they have completely outgrown their dependence on integrins and thus tethering to the ECM in order to acquire survival and proliferation signals (**Sidebar 5.7**).



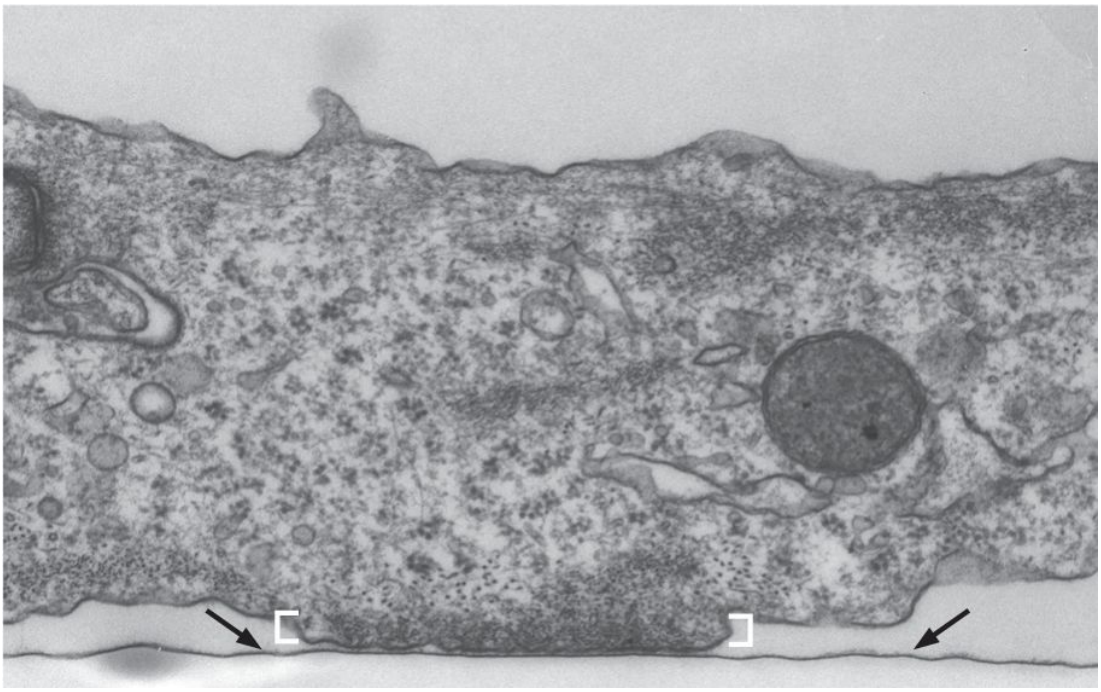
A fluorescence micrograph in which long green lines with yellow orange ends run horizontally across the image. They run between a cloudy orange structure on the left and a cluster of round black shapes on the right.

(A)



A schematic figure showing how integrins are organized. On the cytoplasmic side of a plasma membrane, pink actin fibers form a network of stress fibers and make up the cytoskeleton. Various other, small structures are present near the membrane, including pinkish globule clusters labeled E n a / V A S P, a light blue blob labeled alpha actinin, purple globules labeled vinculin, an orange box labeled talin, and orange globules labeled paxillin. Integrins, each composed of a green subunit and a blue one, lie on the extracellular side but with hooklike tails passed through the plasma membrane for attachment. The heads of the integrins are embedded in a layer of fibers that runs parallel to the plasma membrane. This is the extracellular matrix.

(B)



A black and white micrograph in which a portion of a cell membrane, indicated by brackets, is attached to an underlying surface defined by a dark line, indicated by arrows.

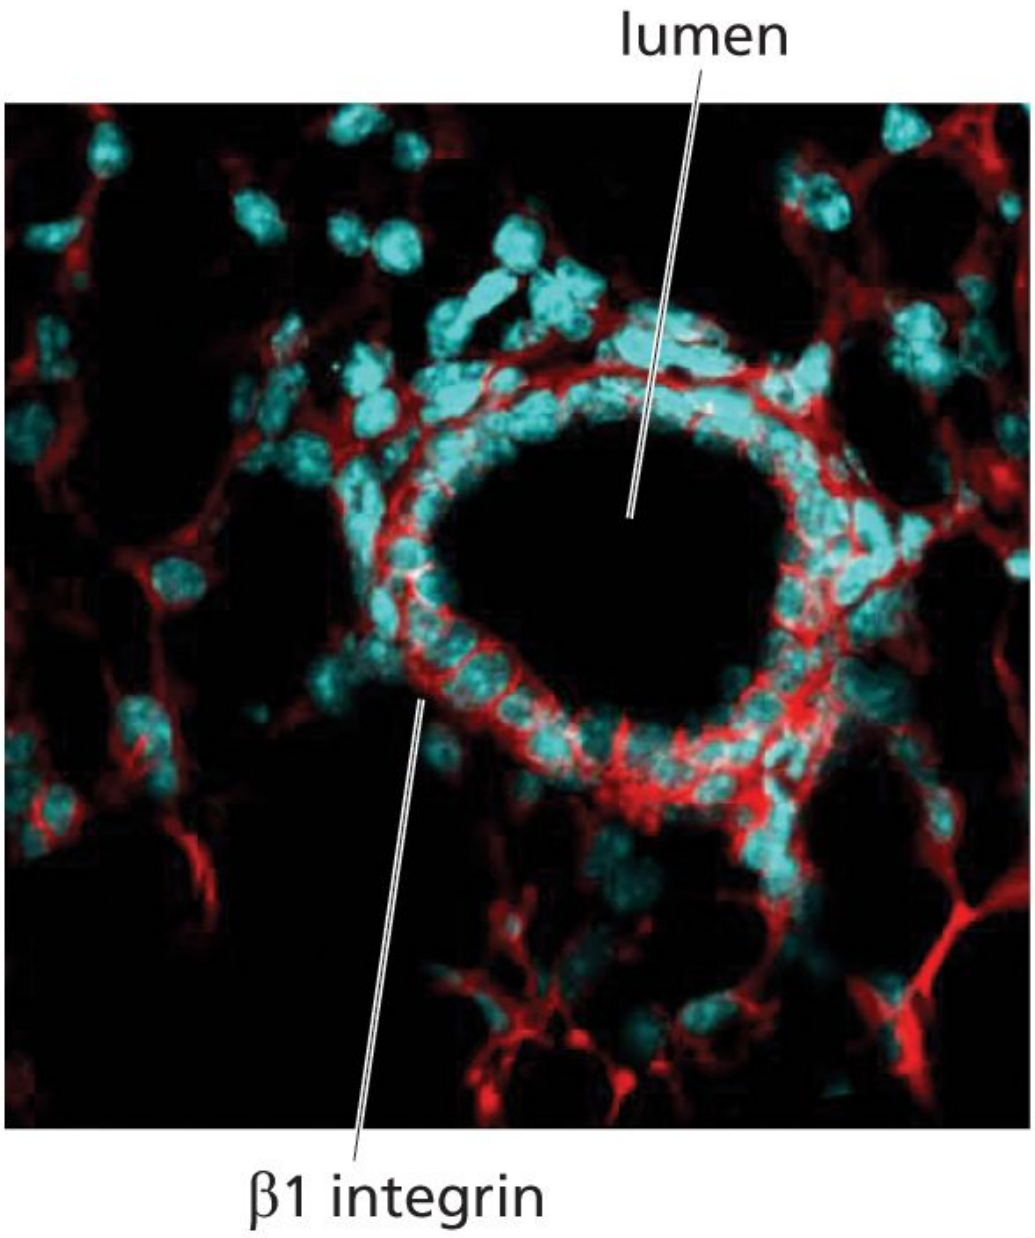
(C)

Figure 5.22 Integrin tethering to the ECM and cytoskeleton (A) This fluorescence micrograph illustrates the discrete elongated foci (*yellow/orange*) on the cell surface, termed focal adhesions, at which integrins tether cells to the extracellular matrix (ECM). Most of these foci seen here have been formed on the *ventral* sides of these cells, i.e., the undersides of these cells that are directly apposed to the ECM that is, in turn, adsorbed to the surface of the Petri dish. Formation of these focal adhesions also controls the organization of the actin fibers (*green*) forming the cytoskeleton inside the cell. (B) This schematic figure of the organization of integrins (*green, blue*) indicates their association with the ECM (*green fibers, above*) through their ectodomains and their association with the actin cytoskeleton (*pink chains*) through their cytoplasmic domains largely via the β subunit of each heterodimer. A series of intermediary proteins, such as actinin, vinculin, and talin, allows these linkages to be formed. (C) This transmission electron micrograph section, which is oriented in a plane perpendicular to the bottom surface of a Petri dish, reveals a single focal adhesion formed between the ventral surface of a chicken lens cell and the underlying solid substrate; in this case, ECM molecules adsorbed to the surface of the Petri dish are seen as a dark line (*arrows*). The electron-dense, cytoplasmic material (*white brackets*) that is immediately above the region of contact with the substrate

contains large numbers of integrin-associated proteins and actin fibers that in aggregate constitute this focal adhesion, which may be as much as several microns in width when viewed from this perspective. (The resolution of this image does not afford visualization of individual actin fibers or integrin molecules.) (A, courtesy of Keith Burridge. B, adapted from C. Miranti and J. Brugge, *Nat. Cell Biol.* 4:E83–E90, 2002. With permission from Nature. C, from O. Medalia and B. Geiger, *Curr. Opin. Cell Biol.* 22:659–668, 2010. With permission from Elsevier.)

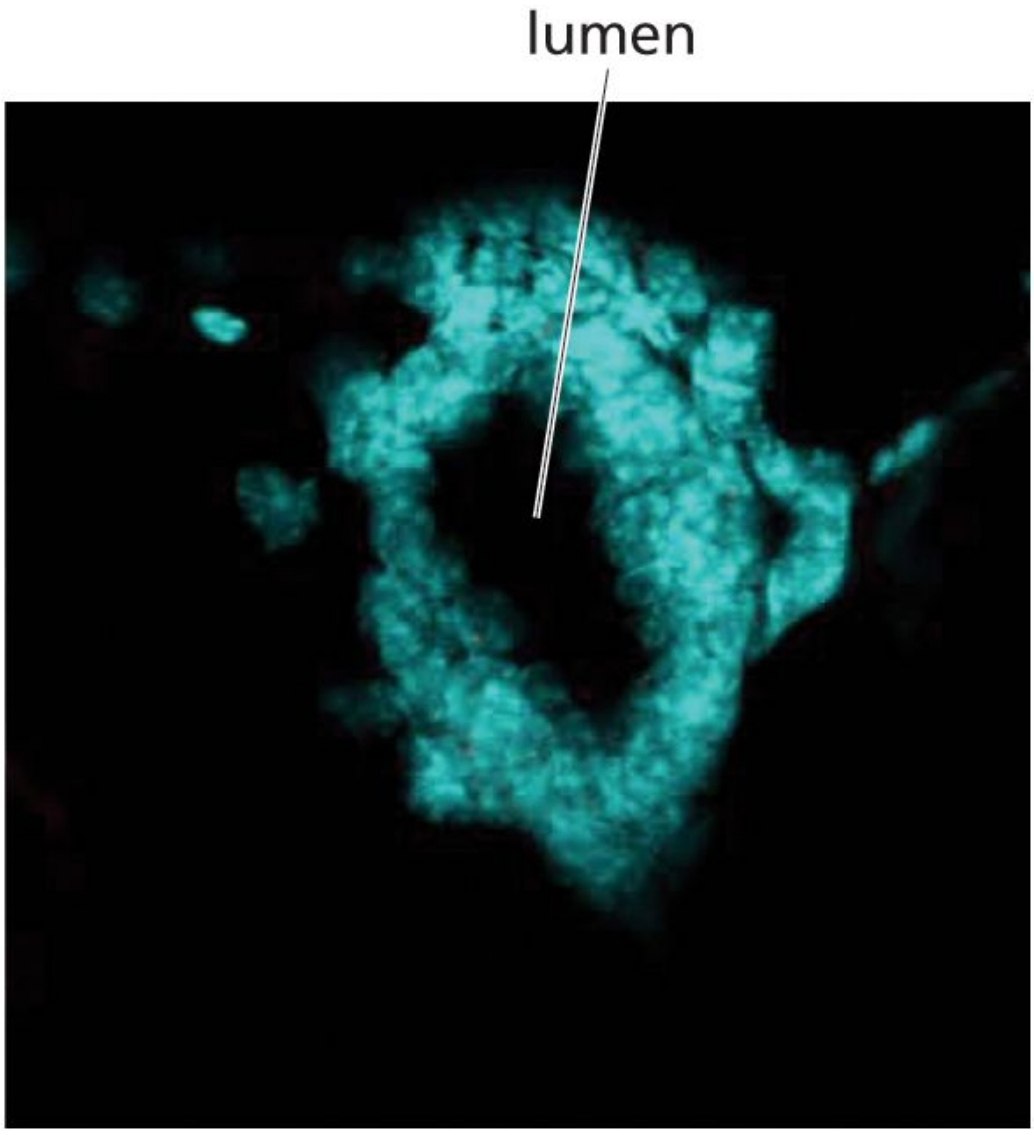
Sidebar 5.7 Some integrins are essential for tumorigenesis

The ability to selectively inactivate ("knock out") genes within targeted tissues has made it possible to evaluate the contributions of various signaling proteins to tumorigenesis (to be described in Sidebar 7.5). For example, inactivation of the gene encoding the β1 integrin in the mouse germ line leads to the absence of this integrin in all cells of the embryo and to embryonic lethality; however, introduction of a modified gene into the mouse germ line makes it possible to inactivate this gene in a targeted fashion in one or another specific organ or tissue. In the experiment shown in **Figure 5.23**, both copies of the β1 integrin allele have been selectively deleted from the genomes of epithelial cells of the mouse mammary gland, leaving the gene unperturbed in all other tissues. Such inactivation of both copies of the β1 integrin gene has minimal effects on the normal development of the mammary gland.



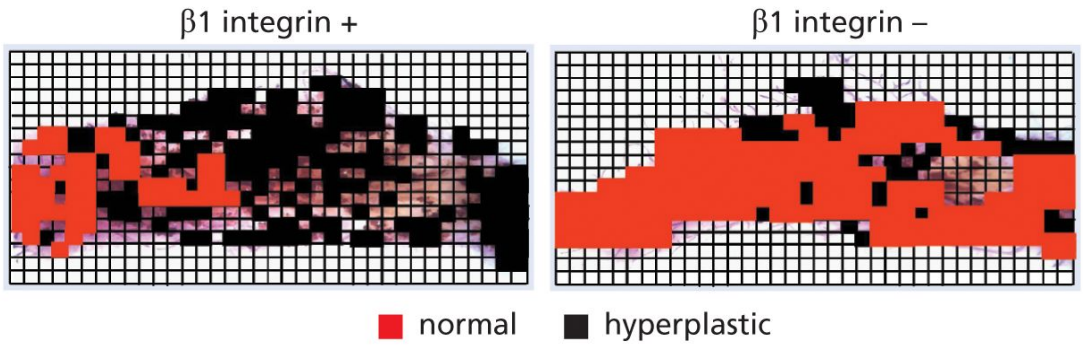
An image of a normal mouse mammary duct, with stained cells surrounding a dark lumen. Most of the cells are blue, but many are red, indicating the presence of beta 1 integrin.

(A)



An image of a mouse mammary duct where beta 1 integrin is missing, with stained cells surrounding a dark lumen. All the cells are blue.

(B)



Two images of a mouse mammary gland with a superimposed grid. The one on the left is of a gland in which beta 1 integrin is present. Some of the grid squares are coded red, denoting normal tissue, but many are coded black, denoting premalignant hyperplastic nodules. The image on the right is of a gland in which beta 1 integrin is absent. This image contains far more normal tissue and only a few hyperplastic nodules.

(C)

Figure 5.23 β1 integrin and mammary tumorigenesis The selective inactivation of the gene encoding β1 integrin in the mouse mammary gland allows a test of its importance in tumorigenesis. (A) The immunostaining of β1 integrin (*red*) on the surface of the epithelial cells forming a normal mouse mammary duct (*blue*), seen here in cross section. (B) In the absence of β1 integrin, ductal morphogenesis still proceeds normally. Moreover, the overall development of the mammary gland is normal (*not shown*). (C) Premalignant hyperplastic nodules in a transgenic mouse prone to mammary tumorigenesis (because of the selective expression of an oncogene in the mammary gland) have been scored visually by microscopic examination of whole mammary glands (*left*); the nodules are present in abundance and, wherever they have been detected, are represented by *black squares*, in contrast to areas in which only normal epithelium is observed in these glands (*red squares*). However, in mammary glands of transgenic mice in which β1 integrin is absent (because its encoding gene has been inactivated), the transgenic oncogene fails to induce the formation of large numbers of premalignant nodules (*right*). (From D.E. White et al., *Cancer Cell* 6:159–170, 2004. With permission from Elsevier.)

In these mice, a second germ-line alteration involved the insertion of the middle T oncogene of polyomavirus that had been placed under the control of a promoter that allows this transgene to be expressed only in the mice’s breast tissue. In mice with an intact β1 integrin gene, this oncogenic transgene generally triggers the formation of premalignant hyperplastic nodules that progress into aggressive mammary carcinomas.

However, when β1 integrin is absent from these oncogene-expressing mammary epithelial cells (because of selective gene inactivation), the number of normally observed hyperplastic nodules is reduced by more than 75% and the β1 integrin–negative cells in these nodules are fully unable to develop further to form mammary carcinomas (see Figure 5.23C). Detailed analyses indicate that this loss of β1 integrin expression permits the oncogene-expressing mammary epithelial cells to survive but precludes their active proliferation and thus their ability to spawn mammary carcinomas.

Integrins are most unusual in one other respect. Normally we think of receptors as passing information from outside the cell into the cytoplasm. Integrins surely do this. But in addition, it is clear that signals originating in the cytoplasm are used to control the binding affinities of integrins for their ECM ligands. Such "inside-out" signaling enables cells to modulate their associations with various types of ECM or with various points of contact with an ECM, breaking existing contacts and forging new ones in their place. Rapid modulation of extracellular contacts enables cells to free themselves from one microenvironment within a tissue and move into another, and to invade through a sheet of ECM *in vitro*. Cultured fibroblasts lacking focal adhesion kinase (FAK), one of the signaling molecules that associate with the cytoplasmic domains of integrins, are unable to remodel their focal contacts and lack motility, indicating that the signals transduced throughout the cytoplasm by FAK are important for reconfiguring the cytoskeleton—the structure that enables cells to change shape and to move. Later, in Chapter 14, we will see how cell motility is critical to the ability of cancer cells to invade and metastasize.

These various descriptions of tyrosine kinase receptors and integrins reveal that mammalian cells use specialized cell surface receptors to sense two very distinct classes of extracellular proteins. Some receptors, such as the EGF, PDGF, and Frizzled receptors, sense soluble (or solubilized) growth factors, while others, notably the integrins, sense attachment to the essentially insoluble scaffolding of the ECM. (Sometimes two types of receptors, such as integrins and RTKs, associate laterally with one another and regulate each other's signaling. As we learn more about these cell surface proteins, we increasingly realize the importance of these lateral interactions; see **Supplementary Sidebar 5.9**.) Together, these various receptors enable a normal cell to determine whether two preconditions have been satisfied before this cell undertakes growth and division: the cell must sense the presence of adequate levels of mitogenic and trophic growth factors in its surroundings and the existence of adequate anchoring to specific components of the ECM.

Both of these requirements for cell proliferation are known to be abrogated if a cell carries an activated *ras* oncogene. Thus, *ras*-transformed cells can grow in the presence of relatively low concentrations of serum and therefore serum-associated

mitogenic growth factors; in addition, many types of *ras*-transformed cells can proliferate in an anchorage-independent fashion. These behaviors suggest that, in some way, a Ras oncoprotein is able to mimic and thereby supplant the signals normally introduced into the cell by ligand-activated growth factor receptors and by integrins that have engaged ECM components. An understanding of the biochemical basis of these various signals demands some insight into the structure and function of the normal and oncogenic Ras proteins. So, we will move back in history to the early 1980s to see how the puzzle of Ras function was solved.

OceanofPDF.com

Glossary

apoptosis
: Complex program of cellular self-destruction, triggered by a variety of stimuli and involving the activation of caspase enzymes, which drive rapid fragmentation of diverse cellular structures and elimination of all breakdown products of a cell and phagocytosis of resulting cell fragments by neighboring cells or macrophages. *See also* **ferroptosis**, **necroptosis**, **pyroptosis**.

anoikis
: Form of apoptosis that is triggered by the failure of a cell to establish anchorage to a solid substrate, such as the extracellular matrix, or by loss of such anchorage.

integrin
: A heterodimeric cell surface receptor that binds components of the extracellular matrix and transmits information about this binding to the cell interior; the cytoplasmic domain of an integrin may also be coupled with components of the cytoskeleton, thereby linking the extracellular matrix to the cytoskeleton.

transgene
: (1) A cloned gene that has been inserted experimentally into the germ line of an animal, often that of a laboratory mouse. (2) Less commonly, any experimentally altered gene in the germ line.

trophic
: Aiding in or supporting cell growth, proliferation, or survival.

discoldin domain receptor
: A cell surface tyrosine kinase receptor that recognizes and binds extracellular collagen as its activating cognate ligand.

5.10 The Ras protein, an apparent component of the downstream signaling cascade, functions as a G-protein

The discoveries that two oncogenes—*erbB* and *sis*—encode components of the mitogenic growth factor signaling machinery (Sections 5.4 and 5.5) sparked an intensive effort to relate other known oncoproteins, notably the Ras oncoprotein, to this signaling machinery. The *ras* oncogene clearly triggered many of the same changes in cells that were seen when cells were transformed by either *src*, *erbB*, or *sis*. Was there some type of signaling cascade—a molecular bucket brigade—operating in the cell, in which protein A transferred a signal to protein B, which in turn signaled protein C? And if such a cascade did exist, could the Ras oncoprotein be found somewhere downstream of *erbB* and *sis*? Did the signals emitted by these various proteins all converge on some common target at the bottom of this hypothesized signaling cascade?

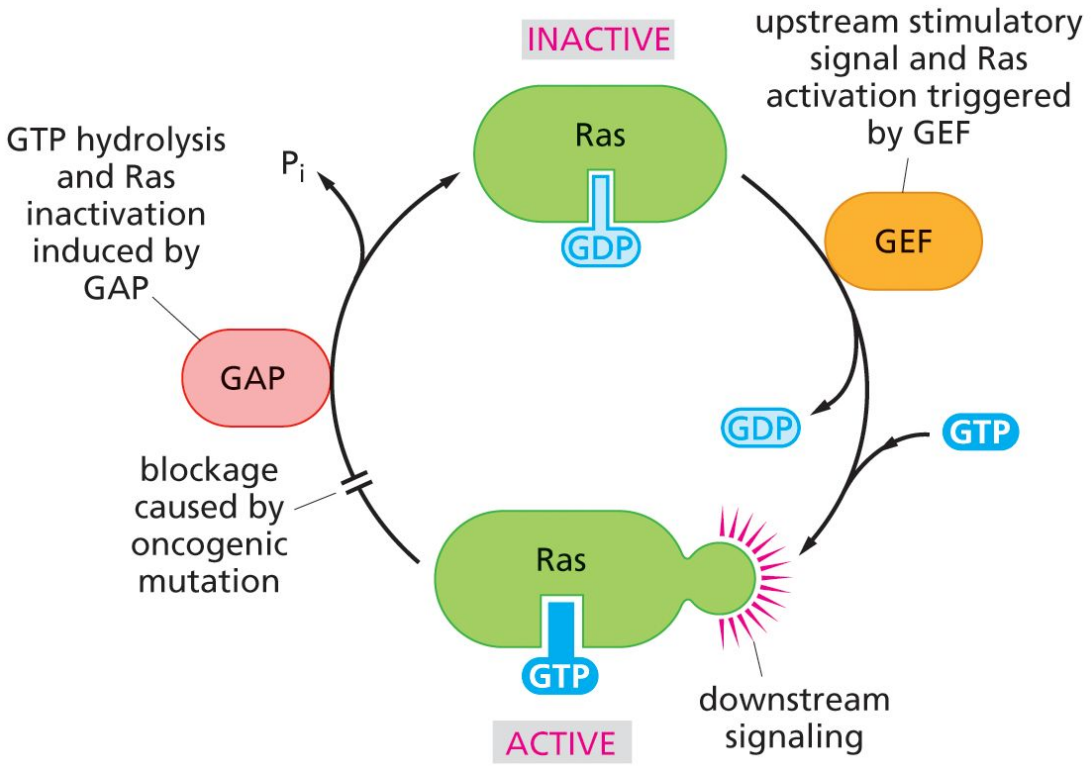
At the biochemical level, it was clear that growth factor ligands activated tyrosine kinase receptors, and that these receptors responded by activating their cytoplasmic tyrosine kinase domains. But which proteins were affected thereafter by the resulting receptor phosphorylation events? And how did this phosphorylation lead further to a mitogenic response by the cell—its entrance into a phase of active growth and division? In the early 1980s, progress on these key issues ground to a halt because biochemical experiments offered no obvious way to move beyond the tyrosine kinase receptors to the hypothesized downstream signaling cascades.

All the while, substantial progress was being made in understanding the biochemistry of the Ras protein. In fact, the three distinct *ras* genes in mammalian cells encode four distinct Ras proteins (since K-*ras* specifies a second protein via alternative splicing of a pre-mRNA). Because all four Ras proteins have almost identical structures and function similarly, we refer to them simply as “Ras” in the discussions that follow even though subtle differences in their functions have emerged in recent years. At their C-termini, they all carry covalently attached lipid tails, composed of farnesyl, palmitoyl, or geranylgeranyl groups (or combinations of several of these groups). These lipid moieties enable the Ras proteins, all of about 21 kD mass, to become anchored to cytoplasmic membranes, largely to the cytoplasmic face of the plasma membrane. There are, however, clear indications that isoforms of Ras are also tethered

to the membranes of the endoplasmic reticulum and the Golgi apparatus, where they may also emit signals.

Like the heterotrimeric G-proteins (Section 5.7), Ras was found to bind and hydrolyze (that is, cleave) guanosine nucleotides. This activity as a GTPase indicated a mode of action quite different from that of the Src and erbB tyrosine kinases, yet intriguingly, all three oncoproteins had very similar effects on cell behavior.

In further analogy to the G-proteins, Ras was found (1) to bind a GDP molecule when in its inactive state; (2) to jettison its bound GDP after receiving some stimulatory signal from upstream in a signaling cascade; (3) to acquire a GTP molecule in place of the recently evicted GDP; (4) to shift into an activated, signal-emitting configuration while binding this GTP; and (5) to cleave this GTP after a short period, using its own intrinsic GTPase function to do so, thereby placing itself, once again, in its non-signal-emitting configuration (**Figure 5.24**). In effect, the Ras molecule seemed to behave like a light switch that automatically turns itself off after a certain predetermined time.



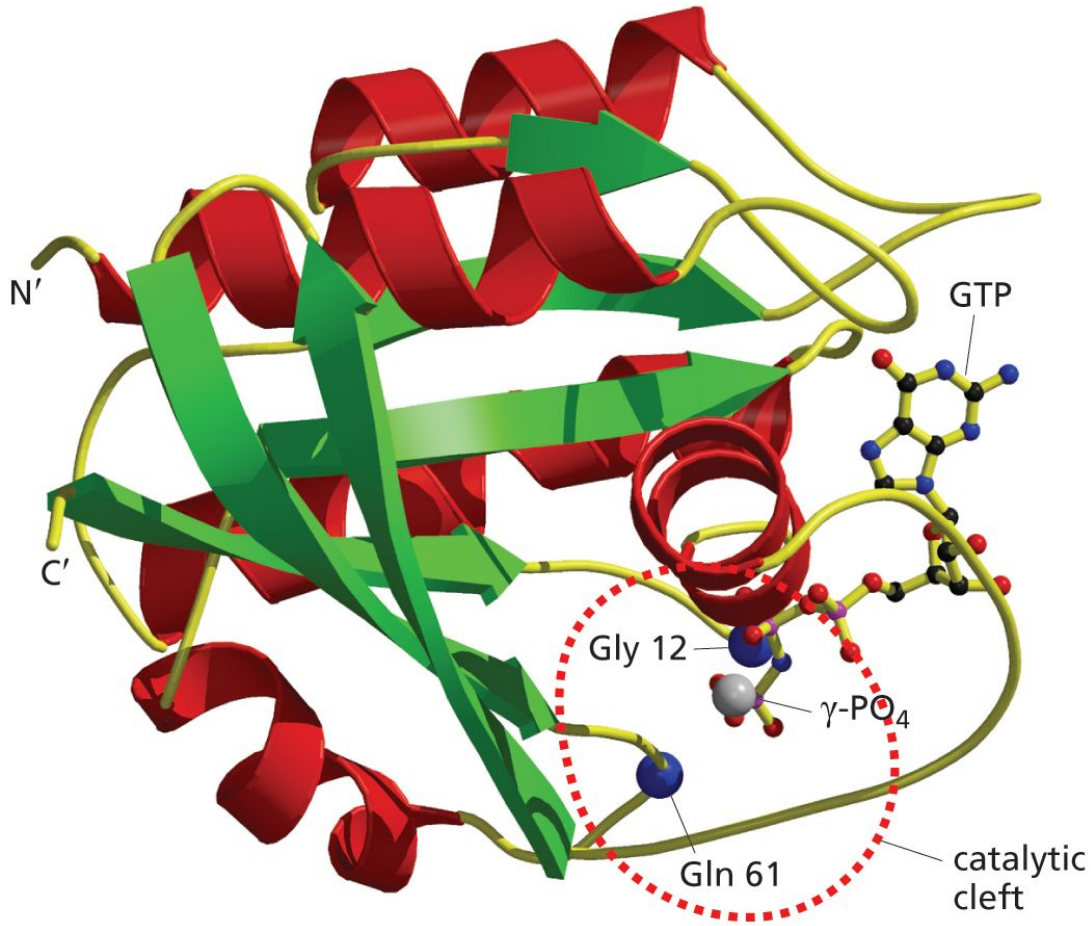
The R a s signaling cycle. A green R a s protein binding to a G D P is in an inactive state. An upstream stimulatory signal arrives in the form of an orange G E F. This triggers the release of the G D P and its replacement by a G T P. The R a s protein thereby transitions to an active, signaling state. When a pink G A P induces G T P hydrolysis, a P sub i is released and R a s returns to hits inactive, G D P

bound state. However, the deactivating action of G A P can be blocked by an oncogenic mutation.

Figure 5.24 The Ras signaling cycle Detailed study of the biochemistry of Ras proteins revealed that they, like the heterotrimeric G-proteins (see Figure 5.19A), operate as binary switches, binding GDP in their inactive state (*top*) and GTP in their active, signal-emitting state (*bottom*). Thus, an inactive, GDP-binding Ras protein is stimulated by a GEF (guanine nucleotide exchange factor, *orange*) to release its GDP and acquire a GTP in its stead, placing Ras in its active, signaling configuration. This period of signaling is soon halted by the actions of a GTPase activity intrinsic to Ras, which hydrolyzes GTP to GDP. This GTPase activity is strongly stimulated by GAPs (GTPase-activating proteins, *light red*) that Ras might encounter while in its activated state. Amino acid substitutions caused by oncogenic point mutations (see Figures 4.5 and 4.6) block this cycle by preventing the stimulatory GAPs from interacting with Ras, effectively inactivating the intrinsic GTPase activity of Ras; this traps Ras in its activated, signal-emitting state.

In more detail, the hypothesized chain of events went like this. Mitogenic signals, perhaps transduced in some way by tyrosine kinase receptors, activated a guanine nucleotide exchange factor (GEF) for Ras. This GEF induced an inactive Ras protein to shed its GDP and bind GTP instead. The resulting activated Ras would emit signals to a (still-unknown) downstream target or group of targets. This period of signaling would be terminated, sooner or later, when Ras decided to hydrolyze its bound GTP. By doing so, Ras would force itself to revert to its nonsignaling state. As was learned later, a group of other proteins known as GAPs (GTPase-activating proteins) could actively intervene and encourage Ras to undertake this hydrolysis (see Sidebar 5.8). Implied in this model (see Figure 5.24) is the notion that Ras acts as a signal-transducing protein, in that it receives signals from upstream in a signaling cascade and subsequently passes these signals on to a downstream target, doing so for a circumscribed period of time.

A striking discovery was made in the course of detailed biochemical analysis of a Ras oncoprotein made by a point-mutated *ras* oncogene, specifically, the Ras oncoprotein encoded by Harvey sarcoma virus. Like the normal Ras protein, the Ras oncoprotein could bind GTP. However, the oncoprotein was found to have lost virtually all GTPase activity (**Figure 5.25A**). In such condition, it could be pushed into its active, signal-emitting configuration (Figure 5.25B) by some upstream stimulatory signal and guanine nucleotide exchange factors (GEFs). But once in this activated state, the Ras oncoprotein was unable to turn itself off! The negative-feedback loop that is so essential to the operations of the normal Ras protein had been sabotaged by this point mutation and resulting amino acid substitution.



A ribbon diagram with five red coils and six directional arrows. A G T P molecule is attached on the right side. A space identified as the catalytic cleft is surrounded by a G l n 61, a G l y 12, and a gamma P O 4.

Figure 5.25 The structure of the Ras protein and its response to GTP binding
(A) This ribbon diagram of the structure of a Ras protein, as determined by X-ray crystallography, depicts the polypeptide backbone of Ras and its α-helical (*red*) and β-pleated sheet (*green*) domains. GTP is indicated as a stick figure, and two of the amino acid residues often found altered in the Ras oncoproteins present in human tumors —glycine 12 and glutamine 61—are shown as *dark blue balls*. Their close association with the γ-phosphate of GTP (*gray ball*) helps to explain why substitutions of these residues reduce or eliminate the Ras protein's GTPase activity, which normally converts GTP into GDP by removing the γ-phosphate. The catalytic cleft of the GTPase is outlined (*red dotted oval*). This provides an explanation of why the codons specifying these particular residues are commonly mutated in human tumor cell genomes; conversely, amino acid substitutions striking elsewhere in the Ras protein may compromise its intrinsic signal-emitting

functions and therefore are unlikely to potentiate Ras function. (B) The replacement of GDP by GTP, which results in the activation of Ras signaling, also causes a shift in two regions of the Ras protein (depicted here from a slightly different perspective as in panel A). Both Switch I (*magenta*) and Switch II (*aquamarine*) regions undergo the GDP-to-GTP conformational shift (as indicated by the positions labeled GDP and GTP). The conformational shift for a domain of Switch I induced by GTP binding is also indicated by the *magenta arrows*. These shifts allow the Ras protein to interact physically with its downstream effectors (see Figures 6.9, 6.10, and 6.15). The guanine nucleotide is indicated by a stick figure. (A and B, courtesy of I.R. Vetter and A. Wittinghofer.)

This provided a clear explanation of how Ras can operate as an oncoprotein: rather than sending out short, carefully rationed pulses of growth-stimulating signals (the behavior of a normal RAS protein), the oncoprotein emits signals for a long, possibly indefinite period of time, thereby flooding the cell with these signals. Subsequent analysis of Ras protein biochemistry has revealed additional levels of control that may go awry in cancer cells (**Sidebar 5.8**).

Sidebar 5.8 GTPase-activating proteins and cancer

When purified Ras proteins are examined in isolation, they show a very low level of GTPase activity. However, within living cells, it is clear that the GTP-bound form of Ras can interact with a second class of proteins termed GAPs (GTPase-activating proteins). This interaction increases the intrinsic GTPase activity of the Ras protein by as much as 100,000-fold and thus results in the rapid conversion of active, GTP-bound Ras into its inactive, GDP-bound form. (The Ras-GAP protein, one of two well-studied GAPs that act on Ras, has been found to insert an oligopeptide loop termed an “arginine finger” into the GTPase catalytic cleft of Ras; the tip of this finger then actively participates in the catalysis that converts GTP to GDP. Interestingly, Ras-GAP has almost no effect in stimulating the GTPase activity of mutant Ras oncoproteins, helping to explain the high proportion of GTP-loaded Ras in mutant cells.)

The lifetime of the activated, GTP-bound form of normal Ras may therefore be governed by the time required for its chance encounter with a GAP molecule. Since the GAPs themselves may be under the control of yet other signals, this means that the GTPase activity of the Ras proteins is modulated indirectly by yet other signaling pathways. Moreover, as described later (Section 7.10), the loss from a cell of the other well-studied Ras-GAP, termed NF1, leaves the GTPase activity of Ras at an abnormally low level in this cell, resulting in the accumulation of GTP-loaded Ras, the hyperactivity of Ras signaling, and ultimately the formation of neuroectodermal tumors.

These findings provided a solution to a puzzle created by the sequencing of the mutant *ras* oncogenes present in many human tumors. As we learned (see Section 4.3), invariably the point mutations creating these oncoproteins were missense mutations (which caused an amino acid substitution) rather than nonsense mutations (which caused premature termination of the growing polypeptide chain). Invariably these mutations struck either the 12th, 13th, or 61st codon of the reading frame of the *ras* genes (with the great majority altering codon 12; see Figure 4.6).

We might imagine that these particular nucleotides represent sites in the genomic DNA that are particularly susceptible to attack and alteration by mutagenic carcinogens. However, detailed study of the structure of the Ras proteins, as generated by X-ray crystallography, has led to a far more compelling model. Examination of the 12th, 13th, and 61st amino acid residues of these proteins reveals that these residues are located around the cavity in the Ras protein where the GTPase catalytic activity operates (Figure 5.25B). Consequently, almost all substitutions of these three amino acids, such as the glycine-to-valine substitution that we encountered earlier, compromise GTPase function. [To be more precise, they compromise the ability of GTPase-activating proteins (GAPs; see Figure 5.24) to trigger hydrolysis of the GTP bound by Ras.]

Knowing this, we can immediately understand why point mutations affecting only a limited number of amino acid residues are found in the *ras* oncogenes carried by human tumor cell genomes. Large-scale alterations of the *ras* proto-oncogenes, such as deletions, are clearly not productive for cancer, since they would result in the elimination of Ras protein function rather than an enhancement of it. Similarly, the vast majority of point mutations striking *ras* proto-oncogenes will yield mutant Ras proteins that have lost rather than gained the ability to emit growth-stimulatory signals. Only when the signal-emitting powers of Ras are left intact and its GTPase negative-feedback mechanism is inactivated selectively (by amino acid substitutions at one of these three amino acid residue sites in the protein) does the Ras protein gain *increased* power to drive cell proliferation and transform the cell.

This explains why only those rare cells that happen to have acquired mutations affecting one of the three amino acid residues of Ras (residues 12, 13, or, rarely, 61; see Figure 4.6) gain proliferative advantage over their wild-type counterparts and thereby stand the chance of becoming the ancestors of the cells in a tumor mass. Stated differently, even though point mutations affecting all the amino acid residues of a Ras protein are likely to occur with comparable frequencies, only those few conferring substantial proliferative advantage will actually be found in tumor cells. Other cells that happen to acquire point mutations affecting other residues in the Ras protein will retain a normal phenotype or may even lose proliferative ability.

OceanofPDF.com

Glossary

guanine nucleotide exchange factor
: Protein that interacts with a G-protein, inducing the latter to release whatever guanine nucleotide it is binding, thereby creating space for another to be bound. Since GTP is present in the cytosol in great molar excess over GDP, this induced change usually results in the replacement of a GDP with a GTP and the associated functional activation of the G protein. *See also* **G-protein**, **GTPase-activating protein**.

missense mutation
: Point mutation causing an amino acid substitution. *See* **missense codon**.

nonsense mutation
: Mutation causing premature termination of a growing polypeptide chain. *See also* **nonsense codon**.

5.11 Synopsis and prospects

In the early 1980s, the discovery of oncogenes such as *erbB* and *sis* revealed the intimate connections between growth factor signaling and the mechanisms of cell transformation. More specifically, these connections suggested that cell transformation results from hyperactivation of the mitogenic signaling pathways. This notion galvanized researchers interested in the biochemical mechanisms of carcinogenesis. Many began to study the growth factor receptors and their biochemical mechanisms of action.

A major problem surrounding growth factor receptors was ignorance about their mechanism for transferring signals from outside a cell into its interior. A simple model was soon developed to explain how this occurs. The growth factor ligands of receptors bind to their ectodomains. By doing so, the ligands encourage receptor molecules to come together to form dimers. This dimerization of the ectodomains then encourages dimerization of the receptor's cytoplasmic domains as well. Somehow, this enables the cytoplasmic domains to emit signals.

This model sheds no light on how, at the biochemical level, receptors are able to emit signals. Here, research on the biochemistry of the Src protein proved to be telling. It was found to be a tyrosine kinase (TK), an enzyme that transfers phosphate groups to the side chains of tyrosine residues borne by various substrate proteins. Once the amino acid sequences of several growth factor receptors were analyzed, the cytoplasmic domains of these receptors were found to contain sequences encoding kinases that were structurally (and thus functionally) related to Src. This indicated that tyrosine kinase domains create the means by which growth factor receptors emit biochemical signals.

This information was then integrated into the receptor dimerization model: when growth factor receptors are induced by ligand binding to dimerize, the tyrosine kinase of each receptor monomer transphosphorylates the cytoplasmic domain of the other monomer. This yields receptor molecules with phosphorylated cytoplasmic tails that allow signaling to proceed. Much of the next chapter is focused on these downstream signaling mechanisms. An overview and preview of how one subfamily of RTKs operates is provided in **Supplementary Sidebar 5.10**. This image, which involves only this group of receptors (all related to the EGF-R), indicates the complexity of these signaling processes and, by implication, the challenges at present encountered by those who would like to portray these interactions with various types of mathematical models.

While highly instructive, the RTK dimerization model has proven to be simplistic: we now realize that in the absence of ligand, certain growth factor receptors are found in large clusters, that ligand binding exerts subtle effects on the stereochemistry of individual receptor molecules, and that the activation of many types of RTKs cannot be understood simply by ligand-driven dimerization.

Hyperactive signaling by these receptors is encountered in many types of human cancer cells. Often, the receptors are overexpressed, resulting in ligand-independent firing via molecular mechanisms that remain unclear. Even more potent ligand-independent firing is achieved by various types of structural alterations of receptors. Most of these occur as the consequences of somatic mutations. However, some mutant alleles of receptor genes have been found in the human gene pool, and inheritance of such alleles is associated with a variety of inborn cancer susceptibility syndromes. In the case of commonly occurring lung cancers, some commonly observed mutations affect the structure of the kinase domain of the EGF receptor and result in ligand-independent firing. Yet other mutations affect the internalization of the receptor, which usually operates following ligand binding; by compromising this negative-feedback mechanism, this second class of mutations results in the accumulation of inappropriately high concentrations of receptor at the cell surface. Both classes of change result in driving the proliferation of these cancer cells.

In our discussions of receptor tyrosine kinases (RTKs) we have focused exclusively on the signaling powers of their cytoplasmic domains, specifically the TK catalytic domains and the multiple tyrosine residues phosphorylated as substrates of these TKs. In doing so, we have overlooked important understudied functions of RTKs: after ligand binding, entire receptors or fragments thereof migrate to the nucleus, where they operate as components of multiprotein complexes involved in the regulation of transcription. As an example, the entire PDGF-Rβ protein is conveyed to the nucleus following binding of its PDGF-BB ligand, where it participates in chromatin remodeling. In another case, in response to ligand binding by HER4/ErbB4 (cousin of the EGF-R), the intracellular domain of this receptor associates with several other transcription-regulating proteins in neural precursor cells, after which the resulting complexes migrate to the nucleus, where they repress genes involved in the formation of glial cells. These cases represent only the tip of the iceberg, since multiple RTKs have been found to move, either entirely or as proteolytic fragments, to the nucleus, where they exert various functions regulating transcription.

Such RTKs represent only one of multiple ways by which cells sense their surroundings. The TGF-β receptors, for example, are superficially similar to the RTKs, in that they have a ligand-binding ectodomain and a signal-emitting kinase domain in their cytoplasmic portion. However, the kinases of the TGF-β receptors are serine/threonine kinases and, as we will learn later, signal through entirely different mechanisms.

A variety of other signal-transducing receptors have been uncovered, including those of the Notch, Patched–Smoothened, and Frizzled classes. These receptors use a diversity of signal-transducing mechanisms to release signals into the cytoplasm. As we will see throughout this book, aberrant signaling by these receptors plays a key role in the pathogenesis of many types of human cancers. Moreover, we will encounter yet another class of receptors in Chapter 9, where their role in programmed cell death—apoptosis—is described. Descriptions of these diverse cell surface receptors do not address yet another class of receptors that operate in the nucleus, bind hydrophobic ligands, and in response function as transcription factors. The nuclear receptors play prominent roles in a group of common human carcinomas—those arising in the breast, ovary, and prostate. In these tumors, the ligands are steroid hormones—estrogen, progesterone, and androgens—and the roles of their corresponding nuclear receptors in tumor growth have been described in tens of thousands of research reports. (To provide an indication of their importance, note that—as of 2021—55,000 studies of the estrogen receptor and 41,000 studies of the progesterone receptor had been published in research journals worldwide.)

Cells must also sense their contacts with the extracellular matrix (ECM)—the cage of secreted glycoproteins and proteoglycans that surrounds every cell in living solid tissues. One class of RTKs binds directly to collagens as their signal-activating ligands. But another class of receptors, the far more common integrins, play a more central and multifaceted role. Having bound components of the ECM, the heterodimeric integrin receptors transduce signals into cells that stimulate proliferation, suppress cells' apoptotic suicide program, and participate in various ways in cell motility. (Altogether, almost 15% of the human proteome of ~20,000 proteins has been predicted to involve cell surface proteins mediating various types of communication of cells with their extracellular environment.)

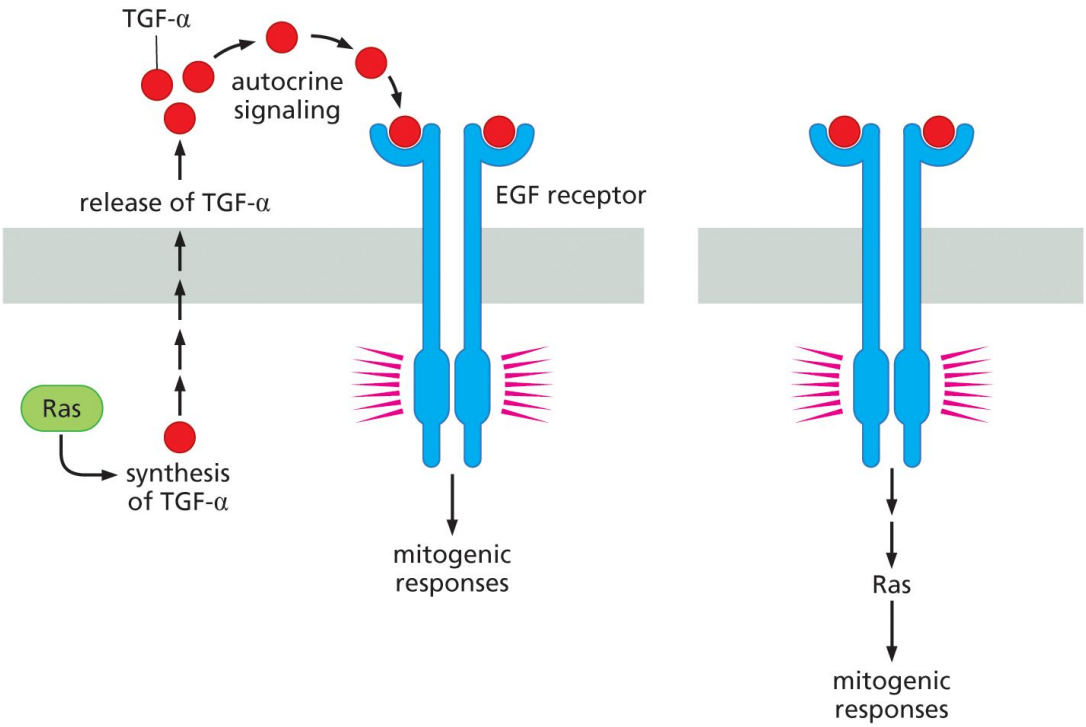
In recent years an entirely different channel of cell-to-cell communication has been proposed following the discovery of membranous vesicles—termed exosomes—that are released into the extracellular space by one cell, travel through the interstitial space between cells, and become fused with the plasma membranes of other cells that become the recipients of signals borne by these vesicles. The precise roles of these vesicles in the cell-to-cell signaling operating in normal and neoplastic tissues are still being uncovered.

A distinct line of research, pursued in parallel with the studies of RTKs, elucidated the biochemistry of the Ras protein, another key player in cancer pathogenesis. Ras operates like a binary switch, continually flipping between the active, signal-emitting state and the quiescent state. The mutant alleles found in cancer cells cause amino acid substitutions in the GTPase pockets of Ras proteins, thereby disabling the mechanism that these proteins normally use to shut themselves off. This traps the Ras proteins in

their active, signal-emitting configuration for extended periods of time, causing cells to be flooded with an unrelenting stream of mitogenic signals.

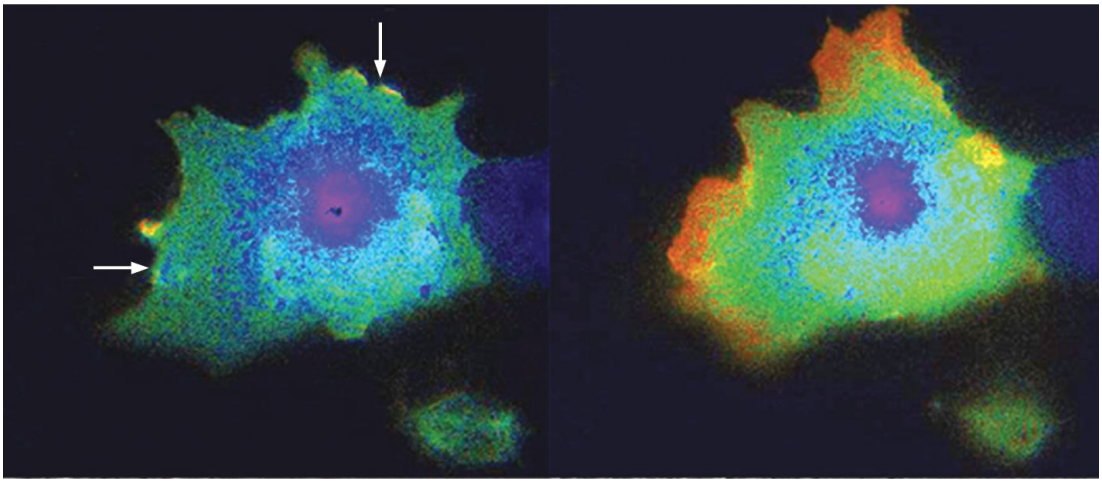
While these investigations revealed how isolated components of the cellular signaling machinery (for example, RTKs, Ras) function, they provided no insights into how these proteins communicate with one another. That is, the *organization* of the intracellular signaling circuitry remained a mystery. Cell physiology hinted strongly that ErbB (that is, the EGF-R) and other tyrosine kinase receptors operated in a common signaling pathway with the Ras oncoprotein. Src fit in somewhere as well. These various oncoproteins, while having diverse biochemical functions, were found to exert very similar effects on cells. They all caused the rounding up of cells in monolayer culture, the loss of contact inhibition, the acquisition of anchorage independence, and reduction of a cell's requirement for mitogenic growth factors in its culture medium. This commonality of function suggested participation in a common signaling cascade.

One possible connection between Ras and the tyrosine kinase receptors came from the discovery that an activated *ras* oncogene causes many types of cells to produce and release growth factors. Prominent among these was transforming growth factor-α (TGF-α), an EGF-like growth factor. Like EGF, TGF-α binds to and activates the EGF receptor. This suggested the following scenario. Once released by a *ras*-transformed cell, TGF-α might function in an autocrine manner (see Figure 5.8C) to activate EGF receptors displayed on the surface of that cell. This, in turn, would evoke a series of responses quite similar to those created by a mutant, constitutively activated EGF receptor. When viewed from this perspective, Ras appeared to operate *upstream* of a growth factor receptor rather than being an important component of the signaling cascade lying *downstream* of the receptor (**Figure 5.26A**).



Two diagrams, describing two different theories. According to the first, R a s stimulates synthesis of T G F alpha within the cell. The T G F alpha moves to the plasma membrane and then is released through it to the extracellular space. There, in an act of autocrine signaling, it binds to a T G F receptor in the same cell, whose cytoplasmic end begins signaling and promoting mitogenic responses. According to the second theory, the T G F alpha has another source, and R a s is part of the pathway by which the receptor's signaling promotes mitogenic responses.

(A)



Two color micrographs. The first shows a cell in blue and green with a purple nucleus. The second shows the same cell, but parts of the periphery are now red and orange.

(B)

Figure 5.26 Alternative mechanisms of transformation by Ras (A) One hypothetical depiction (*left*) of how Ras (*green*) normally operates to promote cell proliferation was inspired by the observation that *ras*-transformed cells release a number of growth factors into their surroundings, such as TGF-α (*red circles*). Once secreted, the growth factors might act in an autocrine fashion to activate a receptor, such as the EGF receptor shown here, thereby promoting cell proliferation. In this depiction, Ras operates "upstream" of the EGF receptor. An alternative scheme (*right*) placed Ras in the midst of a signaling cascade that operates "downstream" of such growth factor receptors. (B) Extensive evidence favoring the second scheme accumulated. This graphic example, produced years later, shows that 5 minutes after EGF is added to cells, previously inactive Ras protein (*blue shading*) becomes activated near the cell surface (*red–orange shading*). This response is so rapid that it indicates close biochemical communication between the EGF receptor and Ras. [Interestingly, this activation occurred only on the two sides of a cell (*white arrows*) that were not in direct contact with nearby cells.] (B, from N. Mochizuki et al., *Nature* 411:1065–1068, 2001. With permission from Nature.)

In the end, this autocrine scheme was able to explain only a small part of *ras* function, since *ras* was found to be able to transform cells that lacked receptors for the growth factors that it induced. In addition, ample biochemical evidence accumulated that ligand binding of growth factor receptors led rapidly to activation of Ras (Figure 5.26B). This left open only one alternative: direct intracellular signaling between ligand-activated growth factor receptors and Ras proteins. So the search was on to find the elusive biochemical links between tyrosine kinase receptors and the proteins like Ras that appeared to form components of the hypothesized downstream signaling cascade.

The use of biochemistry to discover the connections between RTKs and their downstream effectors had serious limitations. As this chapter has made clear, biochemistry provided researchers with powerful tools to elucidate the functioning of individual, isolated signaling proteins. However, it had limited utility in revealing how different proteins might talk to one another within a cell. If there really were linear signaling cascades of the form A → B → C, biochemistry might well reveal how A or C functioned in isolation (for example, as a kinase or GTPase) but would shed little light on the *organization* of the signaling pathway that lay between them.

Detailed biological characterization of human tumor cells overexpressing certain growth factor receptors also suggested another dimension of complexity. In the case of human breast cancers, overexpression of the HER2/Neu receptor (see Section 4.2) was found to be correlated with a bewildering array of phenotypes displayed by the associated cancer cells. Those breast cancer cells expressing elevated levels of this protein showed increased rates of DNA synthesis, better anchorage-independent growth, greater efficiency in forming tumors when implanted into host mice (that is, tumorigenicity), greater tendency to metastasize, and less dependence on estrogen for their growth. Hence, these receptor proteins were acting pleiotropically to confer a number of distinct changes on cancer cells. Such action seemed to be incompatible with a simple linear signaling cascade operating downstream of activated receptors. Instead, it appeared more likely that a number of distinct downstream signaling pathways were radiating out from these receptors, each involved in evoking a distinct cancer cell phenotype. But once again, there seemed to be little prospect of mapping these pathways and their signaling components.

This stalemate could be broken only by exploiting new types of experimental tools and a new way of thinking about the organization of complex signaling circuits. The science of genetics provided the new tool kit and mindset. However, genetics could be practiced with facility only on relatively simple experimental organisms, specifically, flies, worms, and yeast, for which powerful genetics techniques had been developed.

As it turned out, the elucidation of these signaling cascades also depended on one more factor. Much had already been learned from genetically dissecting the simpler metazoans and single-cell eukaryotes. Were lessons learned about their signaling systems transferable to the signaling cascades operating in mammalian cells? Here, fortune favored the cancer biologists. Because these intracellular signaling cascades were of very ancient lineage and had changed little over many hundreds of millions of years, discoveries about their organization and design in the worm, fly, and yeast proved to be directly applicable to mammalian cells. The consequence was the enrichment of cancer cell biology by research fields that had appeared, at least superficially, to be irrelevant to an understanding of human cancer. As was often the case in cancer research, the important advances came from unexpected quarters, from the laboratories of researchers who never thought of themselves as foot soldiers in the war against cancer.

More recent research on the biochemistry of receptor signaling continues to reveal new dimensions of complexity that impact the contributions that these proteins make to the development of human tumors. For example, RTKs often have extensive lateral interactions with other cell surface proteins, such as integrins; these side-by-side interactions influence the localization of the receptors and their access to different ligands (see **Supplementary Sidebar 5.9**). The control mechanisms that govern the concentrations of GFs in the extracellular space continue to be poorly understood;

included among these mechanisms are those that allow proteases to activate latent GF precursors or to liberate GFs from sequestration in the extracellular matrix.

Moreover, a variety of inhibitory proteins are released by cells that prevent GFs from binding to their cognate receptors, doing so by intercepting these ligands in the extracellular space; some of these interceptors may bind and sequester GFs in an inactive state, while others may function as “decoy receptors” that display the ligand-binding domains of bona fide receptors but are incapable of releasing downstream signals. Such inhibitory proteins seem to play especially important roles in regulating Wnt signaling.

Yet other negative-feedback controls operate to constrain receptor signaling, often confining it to brief periods of time. Many ligand-bound receptors are quickly internalized by the process of endocytosis as a means of curtailing their further signaling. In the case of RTKs, a variety of tyrosine phosphatases are often mobilized to quickly reverse the actions of the TK domains of these receptors, doing so by removing the phosphate groups from recently formed phosphotyrosine residues. This represents only one strategy to constrain signaling by RTKs. (In the next chapter, we will gain an appreciation of the fact that the release of stimulatory signals by various regulatory proteins must be counterbalanced by compensating negative-feedback controls in order to ensure proper regulation of the overall signal-processing circuitry operating within individual cells.)

We have mentioned, only in passing, members of another group of RTKs that actually constitute the largest subfamily—the Eph receptors and their ligands, termed ephrins. As is the case with Notch receptors and their cognate ligands, their signaling occurs between two cells that are in direct physical contact with one another. Thus, the ephrins are displayed as proteins tethered to the surface of the ligand-presenting cells; when an ephrin ligand binds and activates an Eph receptor displayed by an adjacent cell, signals are dispatched bidirectionally, that is, transduced into *both cells* that are engaged in these juxtacrine interactions. The roles of these ligand–receptor pairs in cancer pathogenesis are only beginning to emerge.

Yet other subtleties of receptor function remain underexplored. As one example, members of the family of 33 mammalian tetraspanins can be found embedded in various membranes throughout the cell. These abundantly expressed proteins are named after the four transmembrane domains carried by each of them. While not directly involved in transduction of ligand-triggered signal emission, they can move laterally in the plane of the plasma membrane and associate physically with other receptors, such as the RTKs and integrins, and influence signaling by the latter. We understand almost nothing about these membrane proteins and their contributions to the runaway signaling associated with the neoplastic cell state.

As we learn more about cell surface receptors, our current depictions of how they function will increasingly be seen as crude approximations of how they really operate within living tissues including tumors. Moreover, our focus on GFs and RTKs as the prime means of regulating communication between cells will be viewed as overly narrow. One hundred and three human phosphotyrosine phosphatases (PTPs), which reverse the actions of TKs, are likely to play key roles in regulating the levels of specific phosphotyrosines within cells, including those acquired by RTKs. Secreted proteases having narrow substrate specificities are also likely to sit astride numerous cell-to-cell signaling channels, controlling, for example, growth factor ligand availability as described above; at present we know virtually nothing about the 300 or so of these human enzymes and how they influence intercellular communication routes. Many of these normal signaling mechanisms are likely to be subverted by cancer cells. All of this suggests that we have explored only the most visible corners of the complex circuitry that drives neoplastic growth.

Implicit in this entire chapter is another idea that we only begin to confront in subsequent chapters: the fate of individual cells, including cancer cells, is heavily influenced by their surroundings. Hence, while we often focus on the intracellular signals governing the life of an individual cell, equally important determinants of a cell’s fate come from outside, from its immediate neighboring cells and from others far away in the body.

Glossary

exosomes
: Small (30- to 100-nm) membrane vesicles that are released by many cell types into the extracellular space, following which they may adsorb to and fuse with other cells, thereby conveying molecular cargo into the latter.

phosphatase
: An enzyme that removes phosphate groups from phosphorylated substrates, such as the phosphoamino acid residues in a protein or the phosphorylated inositol of a phospholipid.

tetraspanin
: A relatively small protein with four transmembrane domains that operates in various membranes to modulate signaling by a wide variety of other transmembrane proteins such as receptors.

Key concepts

- Because a multicellular organism can exist only if its individual cells work in a coordinated fashion, the problems of cell-to-cell communication were solved by the time the first metazoa arose. Deregulation of such cell signaling is central to the formation of cancer.
- Src provided the first insight into how oncoproteins function when it was found to operate as a protein kinase—an enzyme that transfers phosphates from ATP to other proteins in the cell. Since multiple distinct protein substrates could be phosphorylated and since each of these could affect its own set of downstream targets, this explained how Src could act pleiotropically to yield the numerous biological changes observed in RSV-transformed cells.
- Most protein kinases phosphorylate threonine or serine residues, but Src functions as a tyrosine kinase: it attaches phosphates to tyrosine residues of its protein substrate. Tyrosine phosphorylation is favored by mitogenic signaling pathways.
- Study of tyrosine kinase receptors (RTKs), such as the epidermal growth factor receptor (EGF-R), elucidated how they transduce signals from a cell's exterior into its cytoplasm. Binding of growth factor ligand to the N-terminal ectodomain of a cognate receptor induces dimerization of the receptor. This activates each monomer's kinase to phosphorylate its partner's tyrosines on the partner's C-terminal cytoplasmic domain. The resulting phosphotyrosines then enable emission of mitogenic signals to downstream target proteins within the cell.
- The dimerization model explains how overexpression of growth factor receptors favors cancer formation: when overexpressed, the high numbers of receptor molecules collide frequently as they move around the plane of the plasma membrane, resulting in dimerization, transphosphorylation, receptor activation, and emission of mitogenic signals.
- Mutations affecting any of the three RTK domains may create ligand-independent firing. An EGF-R with a truncated ectodomain cannot

recognize its ligand but nonetheless emits growth-stimulatory signals in a constitutive fashion. Gene fusion events may create receptors that signal unremittingly by virtue of their ectodomains becoming fused with proteins that are naturally prone to dimerize or oligomerize. Amino acid substitutions or deletions in the transmembrane and cytoplasmic domains of receptors are also found in some cancers.

- Another mechanism for cell transformation is exemplified by the Sis oncoprotein of simian sarcoma virus. The virus forces an infected cell to release copious amounts of a PDGF-like protein, which attaches to the PDGF receptors of the same cell. This creates an autocrine signaling loop in which a cell manufactures a mitogen to which it can also respond.
- Other classes of receptors besides RTKs are important in cancer:
    - Cytokine receptors lack tyrosine kinase domains and rely on noncovalently associated JAK tyrosine kinases for signaling instead of covalently associated TK domains.
    - Receptors for TGF-β have cytoplasmic kinase domains that phosphorylate serine and threonine rather than tyrosine residues.
    - Notch receptor forgoes activation by phosphorylation and instead relies on proteases to liberate a cytoplasmic domain fragment that migrates to the nucleus, where it regulates gene expression.
    - The Patched–Smoothened system relies on one transmembrane protein controlling another, which in turn controls a transcriptional regulator.
    - Binding of canonical Wnt factors to a Frizzled receptor triggers a cascade of steps that prevents a cytoplasmic kinase from tagging β-catenin for destruction.
    - G-protein–coupled receptors (GPCRs) induce heterotrimeric G-proteins to flip from an inactive GDP-bound state to a signaling GTP-bound state.
- Integrins constitute a large family of heterodimeric transmembrane cell surface receptors, almost all of which have ECM components as their ligands. Upon ligand binding, integrins form focal adhesions that link their cytoplasmic domains to the actin cytoskeleton. Integrins pass information both into and out of the cell.
- While Ras proteins seemed to be part of a signaling cascade lying downstream of RTKs, the biochemical mechanisms connecting them

were obscure, since the tyrosine kinase activity of RTKs had no apparent connection with the GTPase-bearing Ras protein.

- The difference between a normal Ras protein and its oncogenic counterpart is a missense mutation that alters a residue in the GTPase domain of Ras, preventing proper GTP hydrolysis; this in turn causes the mutant Ras protein to remain in its actively signaling state for extended periods of time rather than behaving like the normal protein and shutting itself off.

Thought questions

1. Why is autocrine signaling an intrinsically destabilizing force for a normal tissue?
2. The responsiveness of a cell to exposure to a growth factor is usually attenuated after a period of time (for example, half an hour), after which time it loses this responsiveness. Given what you have already learned about growth factor receptors, what mechanisms might be employed by a cell to reduce its responsiveness to a growth factor?
3. What lines of evidence can you cite to support the notion that growth factor receptor firing following ligand binding is often dependent on the dimerization of a receptor (rather than some other molecular change in the receptor)?
4. In what ways are the heterotrimeric G-proteins similar to the low–molecular-weight G-proteins (for example, Ras), and in what way do they differ fundamentally?
5. In what ways has the study of lower organisms, notably yeast, flies, and worms, proven to be highly revealing in characterizing the intracellular signaling cascades and the receptors operating at the cell surface?
6. Integrins exhibit a novel type of control, termed “inside-out signaling,” in which intracellular signals dictate the affinity of these receptors for their various extracellular ligands (that is, components of the extracellular matrix). Why is such signaling essential to the process of cell motility?

Supplementary Sidebars

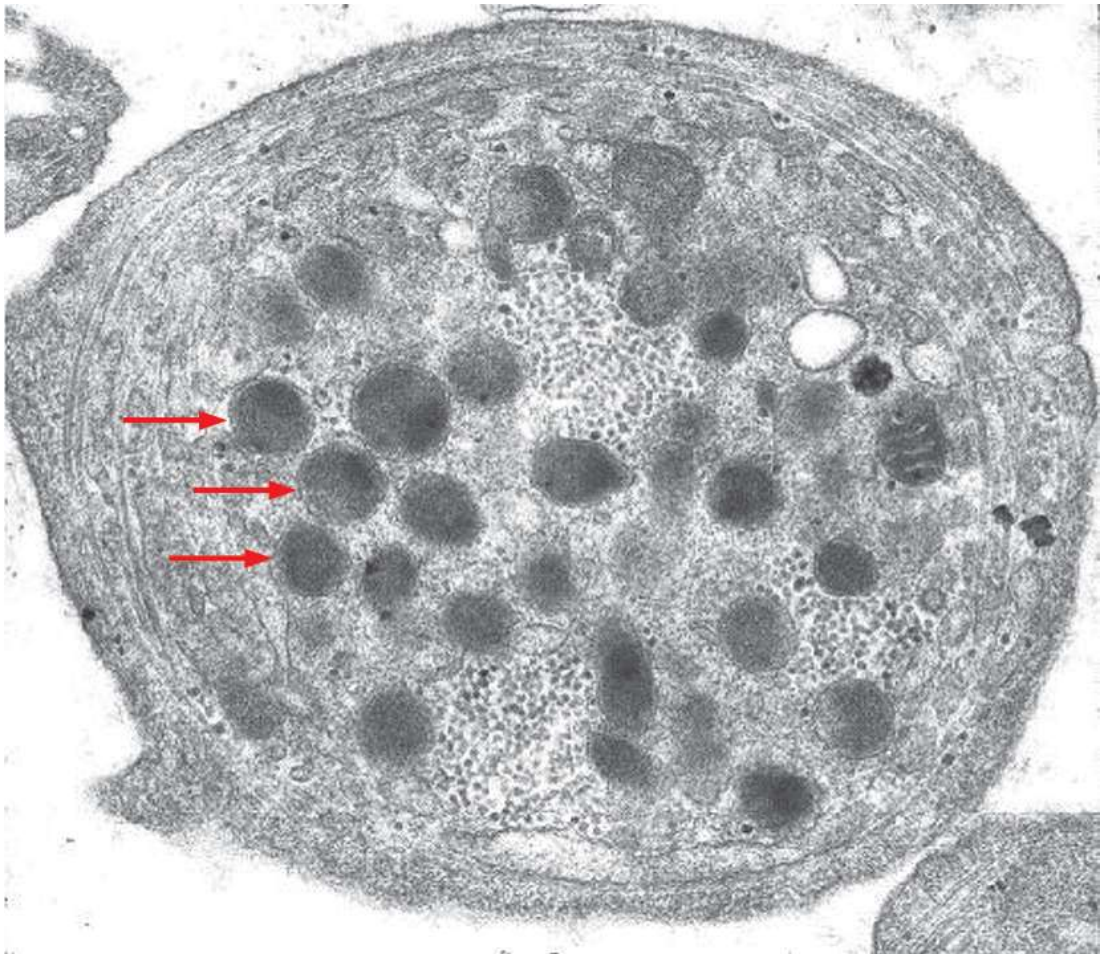

Figure S5.1 Storage of GFs by platelets Platelets carry numerous secretory (*exocytotic*) vesicles termed α-granules (*arrows*), which contain important signaling molecules, prominent among them being several types of platelet-derived growth factor (PDGF) and other GFs. When platelets become activated during clot formation, these vesicles fuse with the plasma membrane, releasing previously stored growth and survival factors into the extracellular space. (Courtesy of S. Israels.)

Supplementary Sidebar 5.1 Making anti-Src antibodies presented a major challenge

Thorough biochemical analyses of thousands of cellular proteins have depended upon the ability to detect and isolate a protein of interest (for example, Src) amid the complex soup of proteins present in cells. This detection frequently relies on the use of antibodies that specifically recognize and bind a protein such as Src while ignoring all other cellular proteins around it. The production of such antibodies involves the injection of an intact protein (for example, the entire Src protein) or a chemically synthesized oligopeptide (for example, a short protein whose amino acid sequence reflects the sequence of a small segment of the Src protein) into an animal, usually a mouse, rabbit, or goat. The hope is that the injected material will be immunogenic (will elicit an immune response) in the animal, causing it to form antibodies that will specifically bind and precipitate this protein from a cell lysate (a preparation of disrupted cells).

The immune system of a mammal often reacts vigorously to a foreign antigen, that is, a protein carrying peptide sequences that are unfamiliar, in that the immune system has not previously experienced or been exposed to that antigen. Conversely, the immune system often mounts no immune response at all (and thus fails to make antibody) against an injected protein that closely resembles one of the proteins normally present in the animal (and thus represents a protein that is familiar to the immune system). This lack of immunoreactivity against familiar proteins is termed immunological tolerance, a phenomenon that we will return to in Chapter 15.

Those researchers who first produced anti-Src antibodies used a strain of RSV that can infect and transform mammalian cells and can therefore induce tumors in mammals. They anticipated that the resulting tumors would express the chicken Src protein, and that dying tumor cells would expose this protein to the immune systems of the tumor-bearing mammalian hosts and thus provoke an immune response. In fact, the Src protein proved to be poorly immunogenic in most animals. The reason for this was discovered much later: the structure of the Src protein is highly conserved evolutionarily. Accordingly, the chicken Src protein is almost identical to the corresponding protein of most mammalian species and is therefore not readily recognized as a foreign protein by these species' immune systems. In the end, these investigators succeeded (for unknown reasons) in producing anti-Src antiserum only from rabbits bearing RSV-induced tumors. The factors that determine the immunogenicity of a protein such as Src in one or another species are complex and often obscure.

Once in hand, the anti-Src antiserum could be used to precipitate (that is, immunoprecipitate) Src protein from lysates of a wide variety of RSV-transformed cells and from normal, untransformed cells (**Figure S5.2**). As in many such analyses, these lysates were prepared from cells that had been incubated in the presence of radiolabeled amino acids, resulting in the incorporation of radiolabel in the cells' proteins. Following immunoprecipitation, the resulting proteins were resolved by gel

electrophoresis, and the presence of radiolabeled proteins was detected by autoradiography. In the present case, the long-sought Src protein was detected as a polypeptide migrating as a 60-kD protein.

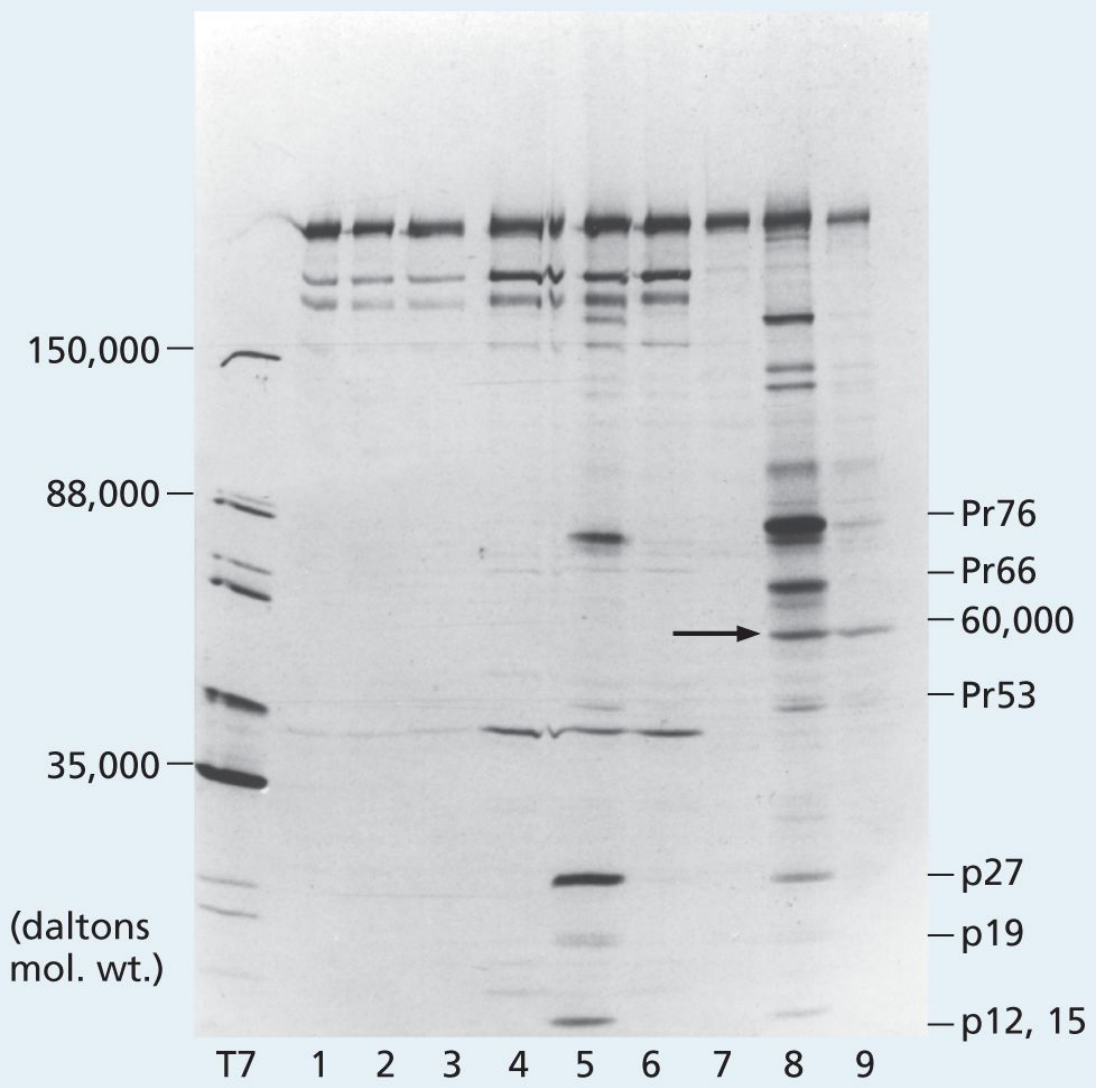

Figure S5.2 Immunoprecipitate of Src protein Initially, the only means of studying the Src protein depended on first *immunoprecipitating* it from the mixture of tens of thousands of other cellular proteins. Many attempts at making an anti-Src serum finally succeeded in isolating an antibody preparation that could be used to immunoprecipitate this protein from cells. Molecular weight markers are in the leftmost channel T7; channels 1–3, lysate of normal, uninfected cells; channels 4–6, lysate of cells infected with an RSV mutant with a deleted *src* gene; channels 7–9, lysate of cells infected with wild-type RSV. All lysates were immunoprecipitated with serum from tumor-bearing rabbits except channel 7 where normal serum was used. Channel 9 was first pre-incubated with lysate of

RSV particles. The band at 60 kD in channels 8 and 9 (*arrow*) represented the first detection of the RSV oncoprotein. (p12, p15, p19, p27, Pr53, Pr66, and Pr76 are RSV virion proteins.) (From A.F. Purchio et al., *Proc. Natl. Acad. Sci. USA* 75:1567–1571, 1978. With permission from the authors.)

Supplementary Sidebar 5.2 The discovery of phosphotyrosine phosphorylation by Src

The actions of Src to function as a protein kinase were likely due to its ability to attach phosphate groups to the amino acid side chains of protein substrates, specifically those side chains that carry hydroxyl moieties. This limited the likely substrate residues to serine, threonine, and tyrosine. Further analysis demonstrated that Src uses tyrosine as a substrate (**Figure S5.3**).

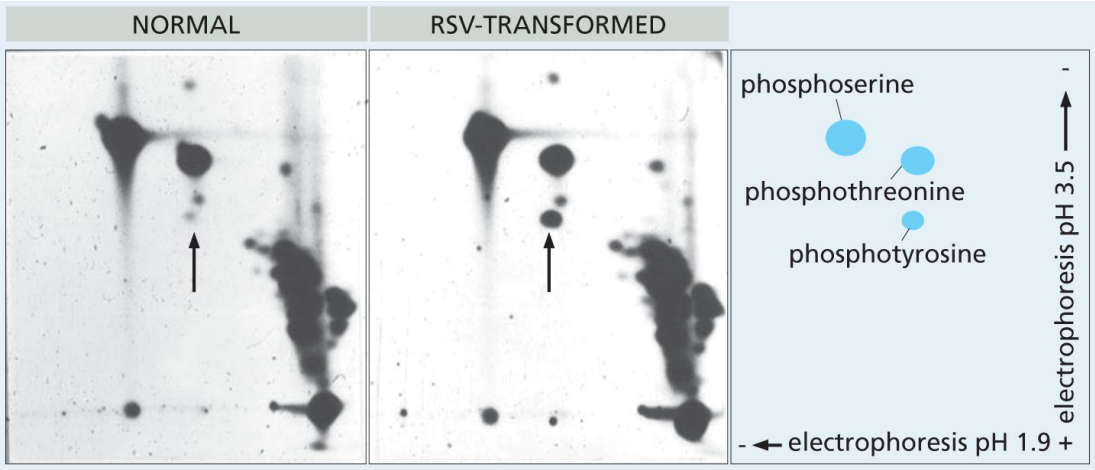

Figure S5.3 Substrate specificity of the Src kinase Electrophoresis can be used to resolve the three types of commonly encountered phosphoamino acids—phosphotyrosine, phosphothreonine, and phosphoserine. In the images shown, electrophoresis was performed toward the cathode at pH 1.9 (*right to left*) and pH 3.5 (*bottom to top*). The right panel shows the expected locations following electrophoresis of these three phosphoamino acids prepared by hydrolysis of proteins from cells previously exposed to $^{32}PO_4$ radioactive orthophosphate. In normal chicken embryo fibroblasts (CEFs; *left panel*), phosphoserine and phosphothreonine are present in abundance, while almost no phosphotyrosine is evident (*arrow*). However, in *src*-transformed CEFs (*center panel*), the level of phosphotyrosine (*arrow*) rises dramatically. Unrelated phosphorylated compounds and inorganic orthophosphate are seen at the lower right of each electrophoresis. (Courtesy of T. Hunter.)

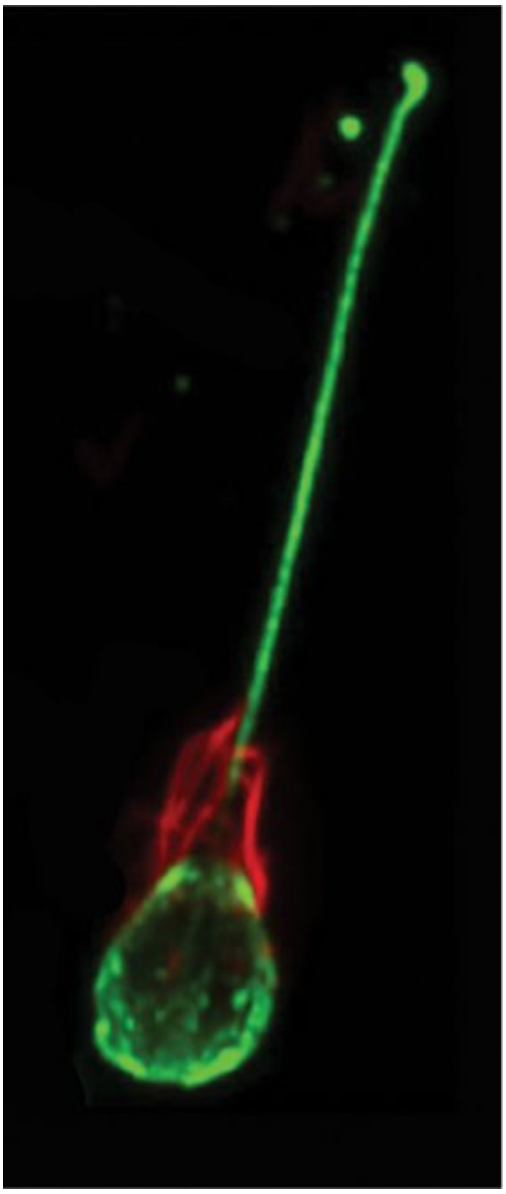
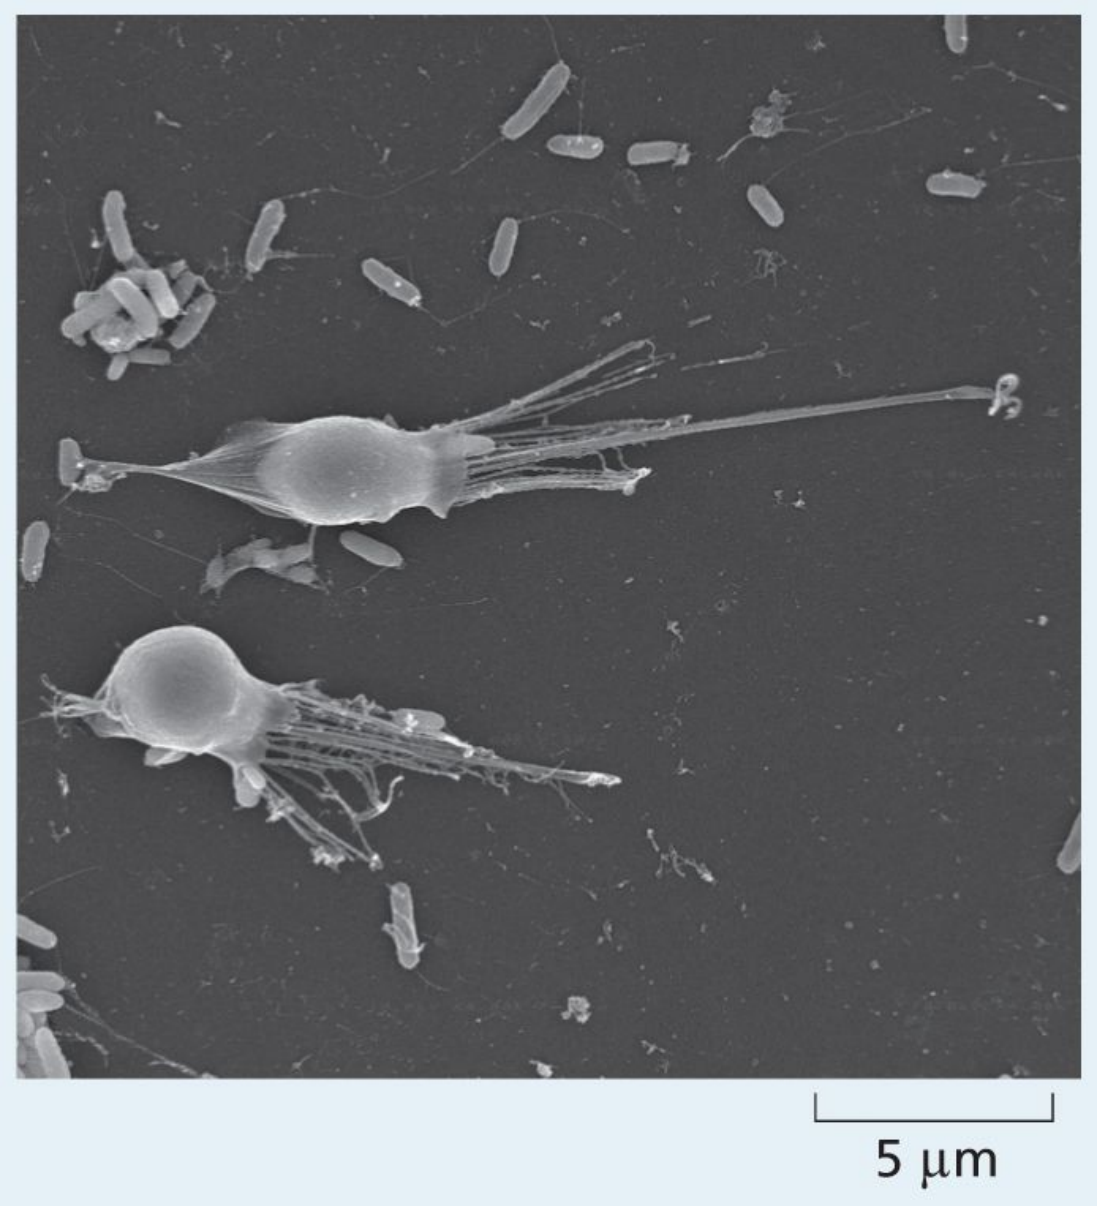
Supplementary Sidebar 5.3 The protozoan roots of metazoan signaling

In the Cambrian era, ∼540 million years ago, a diverse array of complex multicellular organisms appeared; many of these were the ancestors of contemporary metazoan phyla and already had recognizable features of modern organisms. Examination of contemporary animal phyla leads to a key insight into our origins: a metazoan organization plan was invented only once, and all modern metazoa descend from a common pre-metazoan ancestor that somehow solved the problem of cell–cell communication and the organization of complex tissues. This organization depended in significant part on the evolution of cell-to-cell signaling systems, including the growth factors, receptors, and cell–cell adhesion molecules that are found in all modern metazoa. The fossil record indicates that during the earlier Vendian/Ediacaran era, which spanned from 650 to 540 million years ago, a variety of soft-bodied metazoa were already present, pushing the evolutionary origins of metazoa back another ∼100 million years.

The nature of the common pre-metazoan ancestor has been obscure until recently. However, accumulating evidence now implicates choanoflagellates as being among the closest living relatives of the common ancestor of metazoans. (While closely related to the common ancestral species, these protozoans do not reveal the precise identity of this ancestral species.) Each single-cell form of a choanoflagellate has a single flagellum (which provides propulsion) that is surrounded by a large collar (assembled from 30–40 microvilli) that enables these protozoans to trap the bacteria that they consume for food (**Figure S5.4**). Large multicellular choanoflagellate colonies contain flagellated cells on the outside and possibly other flagellum-free cell types on the inside. The evolution of these multicellular colonies presumably depended on the development of cell–cell signaling and adhesion molecules that were subsequently adapted to enable metazoan tissues to form.



(A)



(B)

Figure S5.4 Origins of cell–cell communication The tyrosine kinase receptors, along with a series of other important signaling molecules, were clearly developed long before the Cambrian radiation generated the ancestors of the various modern metazoan phyla more than 550 million years ago. This raises the question of the most recent common ancestor of metazoa. Choanoflagellates are single-cell organisms that appear to be closely related to such an ancestor; their genomes encode many of the molecules that are critical to cell–cell signaling in contemporary metazoa. (A) The choanoflagellates received their name from the distinctive collar that surrounds their single and is composed of an array of actin-

rich microvilli (*red*). The single flagellum, like the microtubules of the cytoplasm, are revealed here by an anti-tubulin antibody (*green*), while the nuclei are stained *blue*. (B) This scanning electron micrograph reveals that each solitary cell extends a single long flagellum with a surrounding collar that, in this case, has been disrupted into its individual component microvilli. Bacteria, which are trapped by these microvilli and used as food by the choanoflagellates, are seen nearby. (A, Ryan Null. B, courtesy of M.J. Dayel, K. McDonald, and N. King.)

Importantly, sequencing of a choanoflagellate genome indicates that these protozoans make signaling proteins that are found in higher metazoa, including a receptor tyrosine kinase, EGF-like proteins, G-protein–coupled receptors, a TNF receptor-like molecule (Chapter 9), and SH2 groups (Chapter 6), as well as structural proteins such as cadherins (which bind metazoan epithelial cells together in two-dimensional sheets; see Chapter 6). Once evolved to enable the assembly of these primitive multicellular colonies, these proteins could then be adapted in various ways to permit the formation and explosive diversification of far more complex multicellular animals during the early Cambrian period. At the same time, the signaling systems that were assembled from these proteins laid the foundations for the disease that, half a billion years later, we call cancer.

Supplementary Sidebar 5.4 Demonstration of autocrine signaling by living cells

An important proof that autocrine signaling occurs in populations of cells comes from a demonstration that the same cells that release a ligand also display a receptor that can bind the ligand and release signals in response to such binding (**Figure S5.5**).

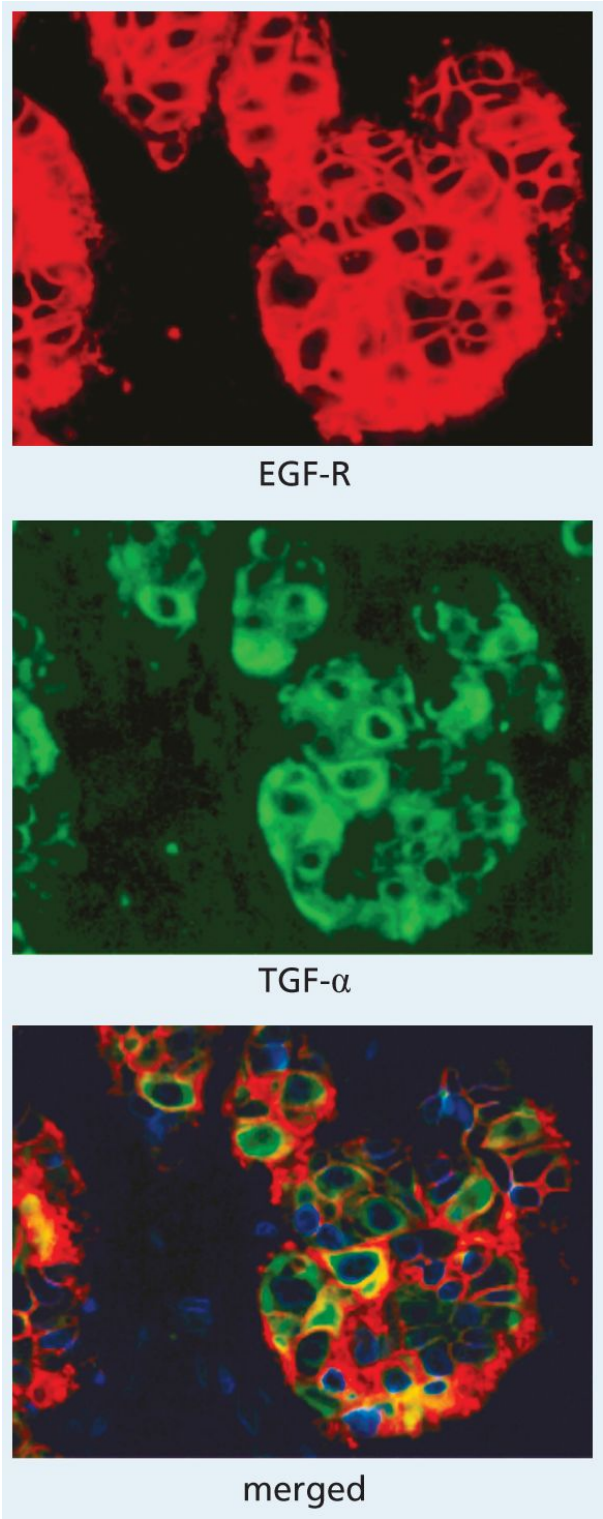


Figure S5.5 Autocrine signaling An example of autocrine signaling is seen in these successive sections of an invasive human breast carcinoma, in which islands of cancer cells are surrounded by nonstained stroma (*black*). The top section has been immunostained for expression of the EGF receptor (*red*), while the middle

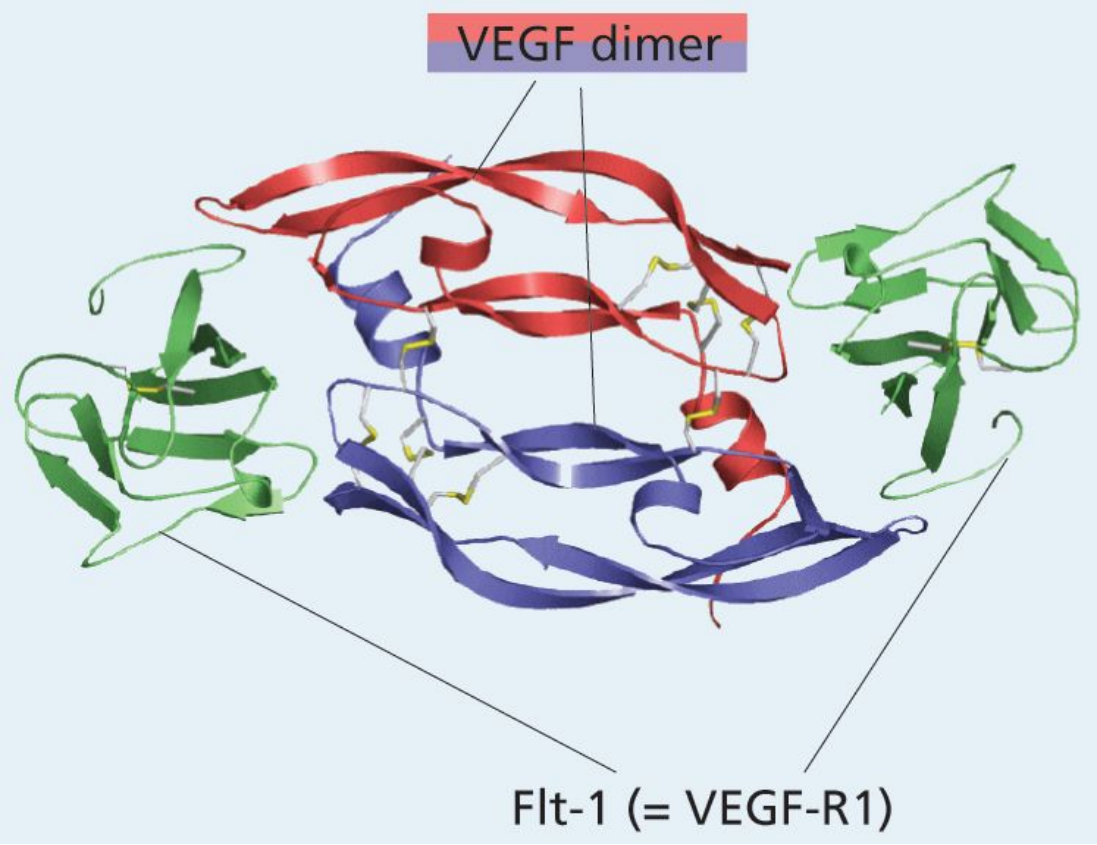
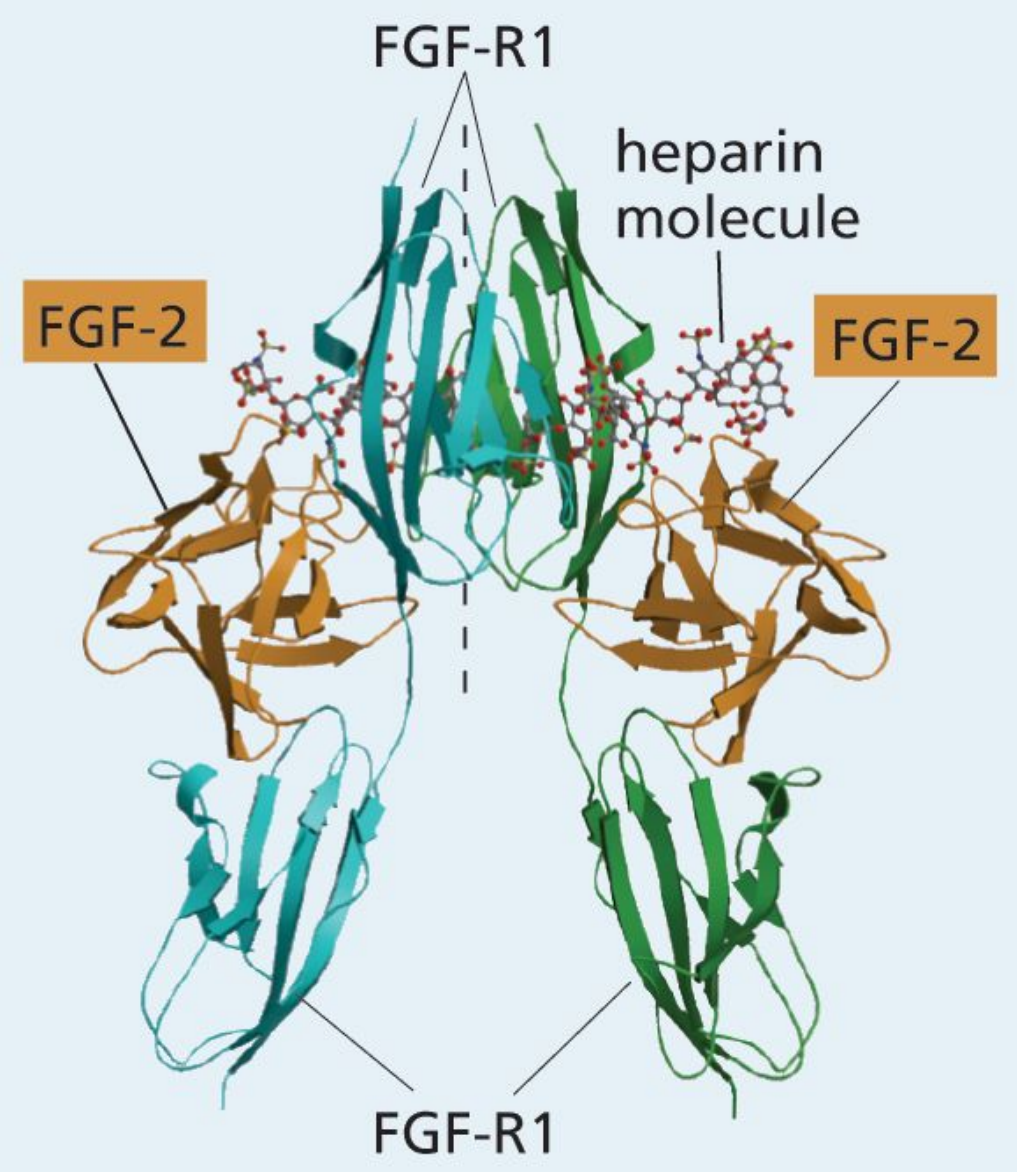
section has been stained for expression of TGF-α (*green*), an EGF-like ligand of the EGF receptor. When these two images are superimposed (*bottom panel*), cells that express both receptor and ligand are stained *yellow*. Nuclei are stained *blue*. (From J.S. de Jong et al., *J. Pathol.* 184:44–52, 1998. With permission from John Wiley and Sons.)

Supplementary Sidebar 5.5 Ligand-mediated dimerization of RTKs

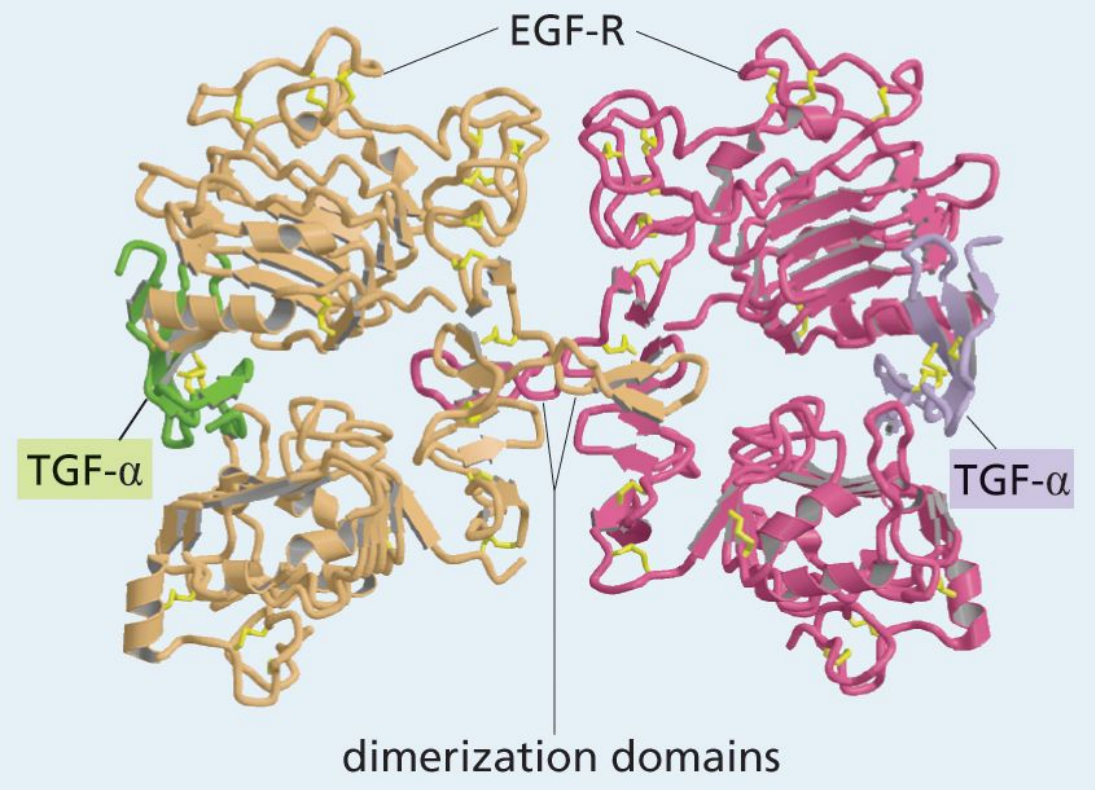
The ligands of RTKs come in various molecular configurations, allowing the ligands to trigger receptor dimerization through a diverse array of molecular mechanisms (**Figure S5.6**).



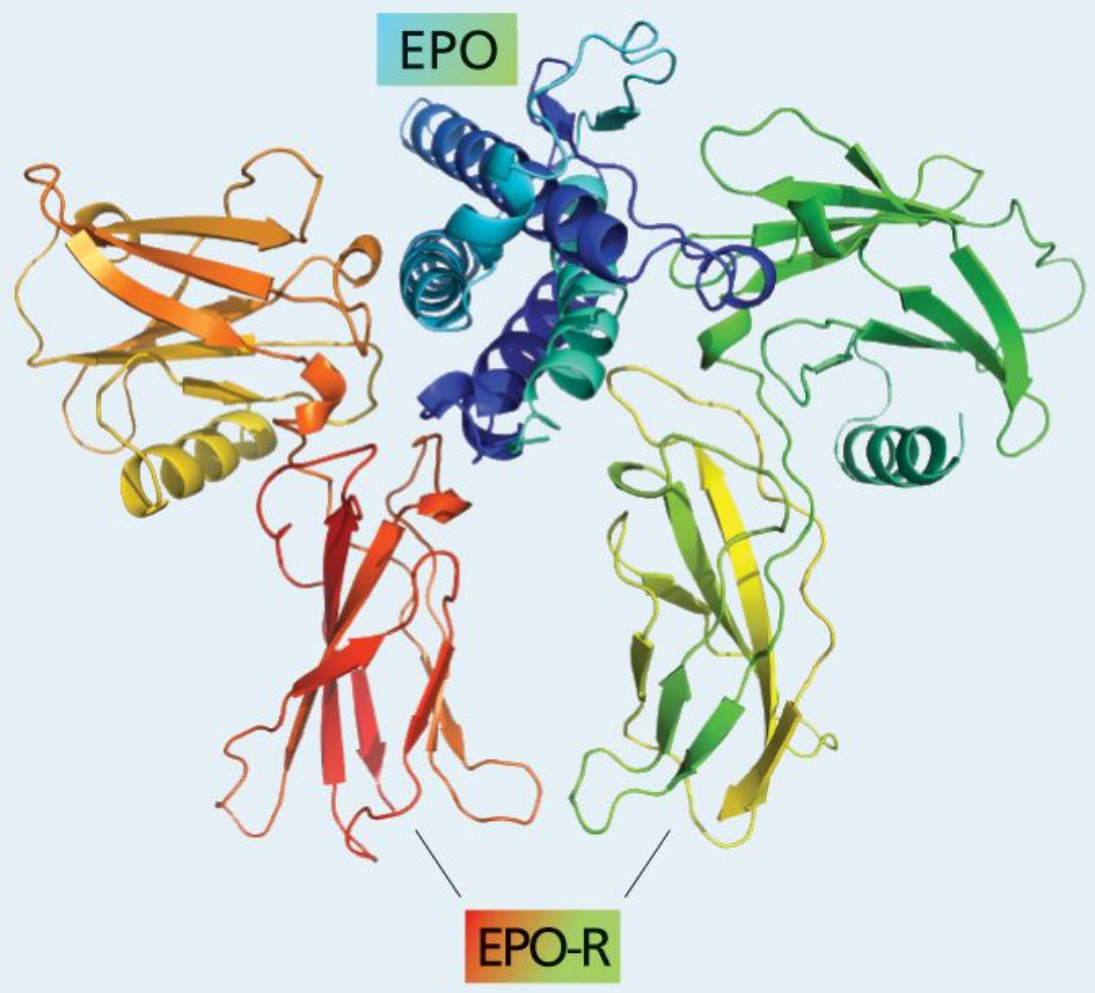
(A)



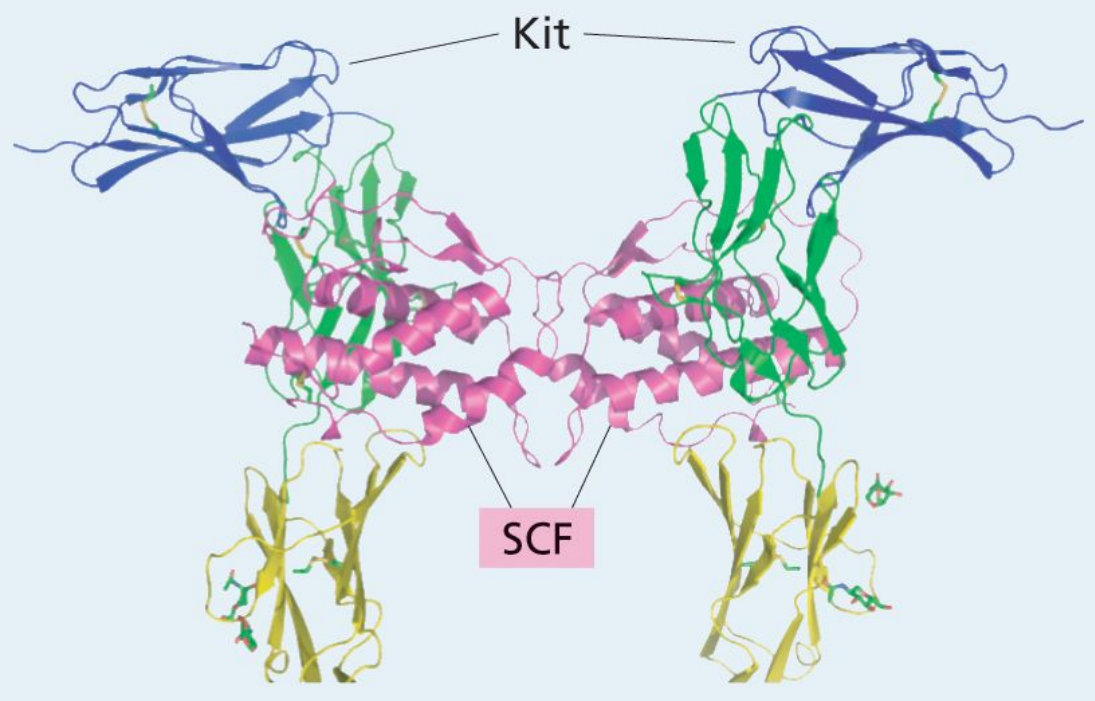
(B)



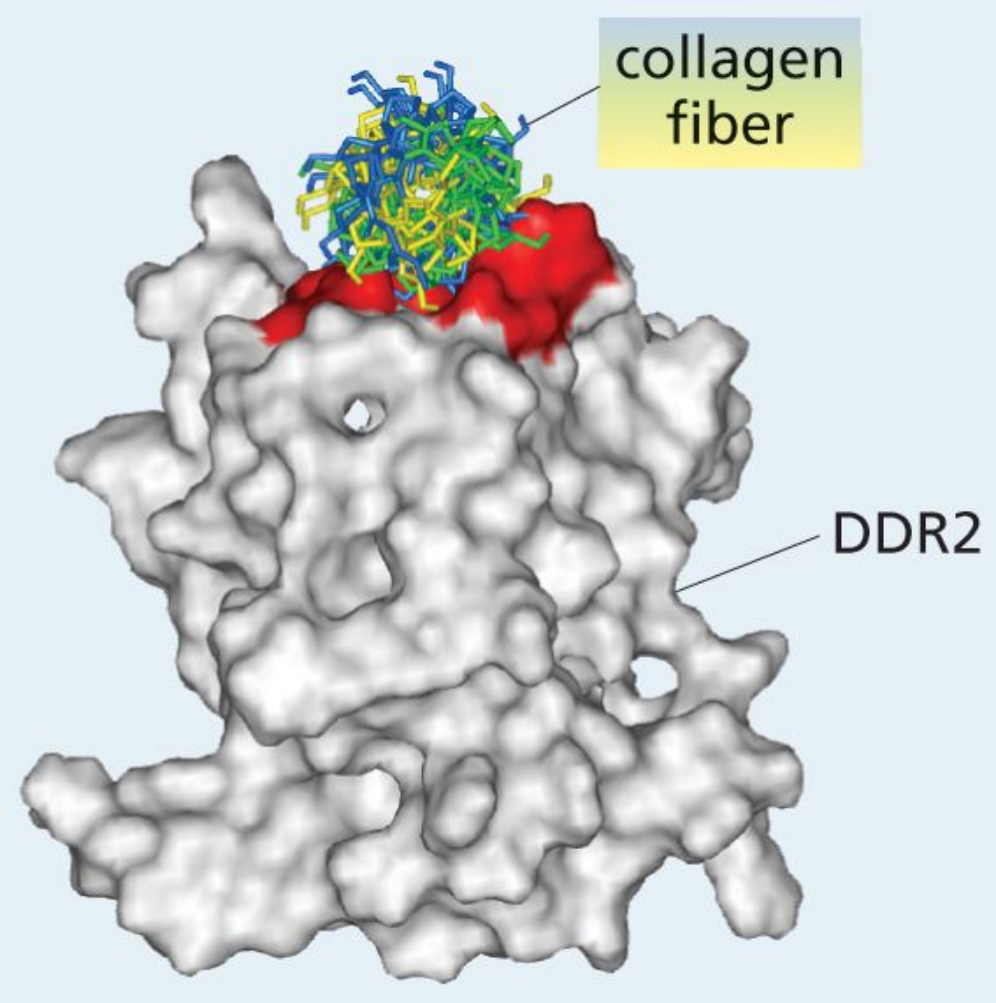
(C)



(D)



(E)



(F)

Figure S5.6 Alternative mechanisms of growth factor–induced receptor dimerization X-ray crystallography has revealed how a variety of growth factor ligands cause receptor dimerization. (A) Vascular endothelial growth factor (VEGF) binds as a homodimer (*red, blue*) to two monomers of its receptor, called Flt-1 (*green*), thereby bringing them together. This complex is seen as a bottom view, i.e., from the plasma membrane looking outward, and exemplifies the dimerization mechanism illustrated in Figure 5.11A. (B) In the case of the fibroblast growth factor receptor-1 (FGF-R1), the ligands are growth factor monomers (FGF-2) that do not contact each other directly but instead are linked by a heparin molecule to which both are bound (*stick figure*). (Heparin is a glycosaminoglycan component of the extracellular matrix.) Each FGF-2 monomer (*dark orange*) then attracts and binds the ligand-binding domain of a receptor monomer (*green, aquamarine*). Each ligand-binding domain of the receptor subunit, seen here in side view, is composed of two subdomains, one binding

above, the other below the FGF-2 ligand. The interface between the two dimerized receptor molecules is indicated by the dashed line. (C) In the case of the EGF-R, molecules of tumor growth factor-α (TGF-α), one of the alternative EGF-related ligands of this receptor, bind as individual monomers (*green, left; purple, right*) to the "front sides" of two receptor subunits (*dark yellow, dark pink*). As seen in a top view facing the plasma membrane, receptor monomers respond to ligand binding by exposing finger-like dimerization domains that mediate their "back-to-back" dimerization. Hence, there is no direct connection between the two ligand molecules, since each is actually far removed from the region of the receptor monomer that is directly involved in dimerization. (D) Some growth factors function as single polypeptide chains. Thus, a single molecule of erythropoietin (EPO; *blue/aquamarine*) is able to simultaneously contact two receptor molecules (EPO-R; *orange/red* and *green/yellow*), causing their dimerization. (E) Like VEGF, stem cell factor (SCF) is a homodimeric ligand that binds to two molecules of the Kit receptor; in the side view here, one molecule of SCF (*magenta*) binds in front of the left Kit molecule while the other passes behind the right Kit molecule. (F) Collagen, an extracellular matrix protein, is an unusual ligand for an RTK since it is not presented in a soluble form to its two cognate tyrosine kinase receptors, termed discoidin domain receptors (DDR1 and -2). Seen here is a space-filling representation of the collagen-binding domain (*red*) of DDR2, which is constitutively dimerized even in the absence of collagen ligand and active signaling. Binding of the triple-helix fibrillar collagen protein (in cross section, *blue*, *green*, *yellow stick figures*) causes activation of receptor signaling via a still-poorly understood mechanism. (A, from C. Wiesmann et al., *Cell* 91:695–704, 1997. B, from A. Plotnikov et al., *Cell* 98:641–650, 1999. C, from T.P.J. Garrett et al., *Cell* 110:763–773, 2002. All with permission from Elsevier. D, courtesy of J.S. Finer-Moore, from R.S. Syed et al., *Nature* 395:511–516, 1998. With permission from Nature. E, from S. Yuzawa et al., *Cell* 130:323–334, 2007. With permission from Elsevier. F, from O. Ichikawa et al., *EMBO J.* 26:4168–4176, 2007. With permission from John Wiley and Sons.)

Supplementary Sidebar 5.6 Mechanisms of activation of receptor signaling via transphosphorylation

The signaling output of an RTK derives from the phosphorylation of tyrosine residues in its C-terminal domain, as we will see in Chapter 6. However, even before this occurs through the actions of the kinase domain of the other RTK in the dimerized receptor, a series of phosphorylation events must happen in most RTKs that lead to the activation of the kinase domains of the two associated receptor molecules (**Figure S5.7**).

(C)

Figure S5.7 Mechanisms governing Kit receptor firing (A) As seen here, the Kit receptor may be found in a constitutively active, mutant form in a number of different types of human tumors (*red type*). Most of the alterations in the indicated exons involve missense point mutations in the reading frame of the Kit mRNA. GIST, gastrointestinal stromal tumor; AML, acute myelogenous leukemia. (B) The cytoplasmic domain of the Flt-3 receptor, which is very closely related to that of Kit, is shown here as a ribbon structure. Like almost all protein kinases, this one is composed of an N-terminal lobe (*red*) and a C-terminal lobe (*blue*), with a catalytic cleft in between. The catalytic cleft is normally obstructed by both an "activation loop" (*green*) and a juxtamembrane domain (*yellow*). In the activation loop, note the tyrosine residue, whose phosphorylation causes this loop to swing out of the way, allowing the catalytic cleft access to substrates. (C) The Kit receptor, which is found in mutant form in almost all gastrointestinal stromal tumors (GISTs), often carries alterations affecting the juxtamembrane (JM) domain, depicted here as a *yellow* cylinder that sits above the N-terminal lobe of the two-lobed Kit tyrosine kinase [*side view, plasma membrane* (*not shown*) *above*]. Ligand binding to the Kit receptor results initially in transphosphorylation of tyrosine residues in the JM domain, which causes it to dissociate from the side of the N-terminal lobe; the resulting phosphorylated structure (*yellow zigzag*) is depicted here as sitting above the kinase domain, out of the way. Subsequent transphosphorylation of the key tyrosine residue in the activation loops (*green*; see panel B), which normally obstruct the catalytic clefts, also contributes to activation of kinase function. Mutant Kit receptors with defective JM domains are therefore partially activated even in the absence of ligand binding. (A, courtesy of D. Emerson. B, from J. Griffith, *J. Mol. Cell* 13:169–178, 2004. With permission from Elsevier. C, from P.M. Chan et al., *Mol. Cell. Biol.* 23:3067–3078, 2003. With permission from the American Society for Microbiology.)

Supplementary Sidebar 5.7 Structural alterations of growth factor receptors leading to deregulated firing

A diverse array of structural alterations can also cause ligand-independent receptor dimerization, doing so in the absence of receptor overexpression. This lesson is driven home most dramatically by a mutant version of Neu, the rat ortholog of the human HER2/ErbB2 receptor. Exposure of pregnant rats to the mutagen ethylnitrosourea (ENU) results in the birth of pups that often succumb to neuroectodermal tumors 3 to 6 months later. The tumors almost invariably carry a point mutation in the sequence specifying the transmembrane domain of this receptor. The resulting substitution of a valine by a glutamic acid residue favors the constitutive dimerization of the receptors, even in the absence of ligand binding, thereby creating a potent oncoprotein.

Like HER2/ErbB2/Neu, the EGF and FGF (fibroblast growth factor) receptors may be affected by point mutations or small deletions that generate constitutively active receptors; the responsible somatic mutations alter the cytoplasmic domains of these receptors, perturbing the domains that regulate the receptor-associated tyrosine kinases. In a series of non-small-cell lung carcinomas, about 10% were found to have mutant EGF receptors, and these turned out to be particularly responsive to therapeutic drugs directed against the receptor molecule, as we will learn in Chapter 17. Structurally altered receptors have been found to be far more common in bladder carcinomas: at least 60% of these tumors have been found to harbor subtly altered versions of the FGF receptor-3. The precise mechanism by which truncated, mutant versions of the EGF receptor lacking ectodomains become constitutively activated (see Figures 5.9 and 5.8A) is less well understood. Similarly, the mechanisms by which relatively subtle structural alterations succeed in converting RTKs into the oncoproteins found in certain tumors (see Figure S5.7A) also lack clear explanation.

Quite different major structural alterations of RTKs can also generate oncoproteins. For example, Met, which functions as the receptor for hepatocyte growth factor (HGF), and TrkA, which serves as the receptor for nerve growth factor (NGF), have both been found to have become converted into oncoproteins in some tumors as a consequence of gene fusion events. In addition to truncated ectodomains, the consequences of gene fusions may be receptors whose other parts are fused to unrelated proteins that are normally prone on their own to dimerize or oligomerize (see Figure 5.12). This results in a constitutive, ligand-independent dimerization of these receptors, explaining the oncogenic powers of these fusion proteins. Yet other, subtle changes in receptor structure can also encourage ligand-independent firing in diverse cell types (see Sidebar 5.6).

Supplementary Sidebar 5.8 Mutant forms of a single tyrosine kinase receptor may play a causal role in very different types of cancer

The Kit protein was originally discovered as an oncoprotein encoded by a feline sarcoma retrovirus. The *kit* proto-oncogene encodes a tyrosine kinase receptor whose ligand is stem cell factor (SCF), a growth factor that is important in stimulating the formation of various types of blood cells (the process of hematopoiesis), as well as the development of a variety of nonhematopoietic cell types, including melanocytes and the cells mediating gut motility. Mutant forms of the Kit receptor, which fire constitutively in a ligand-independent fashion, are found in a diverse array of malignancies. In many leukemias of dogs, mutant Kit receptors carrying amino acid substitutions in the cytoplasmic juxtamembrane residues—those close to the transmembrane domain—are common.

The pacemaker cells of the intestine, which control the peristaltic contractions of the smooth muscles of this organ, also rely on the Kit receptor for their proper development, and indeed, these cells are absent if the *kit* gene is inactivated in the germ line (and thus in all cells) of a mouse. In human gastrointestinal stromal tumors (GISTs), which seem to arise from these same cells, juxtamembrane amino acid substitutions similar to those seen in dog leukemias are commonly observed. Analyses of the structure of the Kit receptor and related tyrosine kinase receptors indicate that the juxtamembrane domain plays an *inhibitory* role in regulating the receptor, and that its ability to suppress receptor firing is compromised by the amino acid substitutions and deletions in this domain that are commonly seen in GISTs (see Figure S5.7). In one group of GIST patients, those whose tumors carried subtle (missense) mutations affecting exon 11 of the *kit* gene were all alive four years after initial diagnosis and treatment, while only half of those whose GISTs carried deletions of this entire exon survived that long.

Supplementary Sidebar 5.9 Lateral interactions of cell surface receptors

While GF receptors, such as those responding to EGF or PDGF, as well as integrins have been presented here as independently acting signaling proteins, it is becoming increasingly apparent that these cell surface receptors often form lateral complexes with one another and regulate each other's signaling. In addition, integrin:RTK complexes are formed following association of certain integrins with components of the ECM (**Figure S5.8**). For example, after binding its extracellular matrix (ECM) ligands, the αvβ1 integrin can cause phosphorylation of the EGF receptor even in the absence of EGF or EGF-related ligands. This cross-phosphorylation appears to require physical association between the integrin and the EGF-R and depends, as well, on the complex of signaling molecules that the integrin attracts to its C-terminal tail in the cytoplasm. The Src tyrosine kinase, an important component of these integrin signaling complexes (see Figure 6.17), is activated following αvβ1 integrin binding to the ECM and is required for the phosphorylation of tyrosine residues in the C-terminal tail of the closely apposed EGF-R. This phosphorylation occurs independently of the EGF-R's binding any of its normal ligands and results in the formation of a spectrum of phosphotyrosines on the C-terminal tail of EGF-R that is different from the spectrum of phosphotyrosines seen after the EGF-R binds one of its ligands. In addition, the amount of EGF-R present on the cell surface increases after the αvβ1 integrin binds ECM ligands. Indeed, efficient EGF-R signaling may actually require integrin association and integrin-mediated signaling.

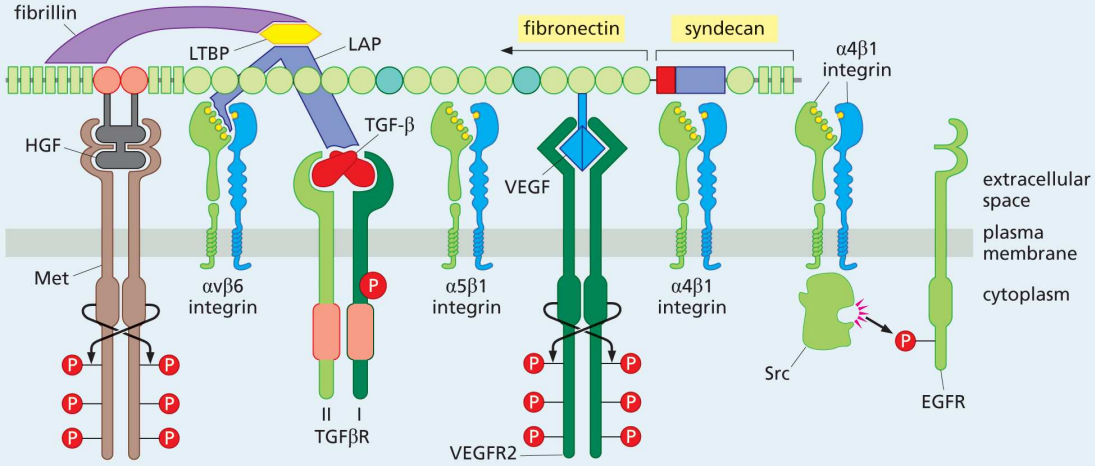

Figure S5.8 Association of integrins and growth factor receptors with extracellular matrix components and with one another Many growth factors do not function as diffusible signaling molecules. Instead, they are frequently attached to components of the extracellular matrix (ECM) following initial synthesis and secretion by a signal-emitting cell and later are either mobilized from the ECM and activated by proteases produced by a second, signal-receiving cell or, alternatively, presented as solid-phase ligands attached to the matrix. Fibronectin is a key component of the ECM (*green* and *pink circles*). The HGF, TGF-β, and VEGF growth factors are bound to the ECM and are apparently presented to their cognate receptors in the form of immobilized ligands. In addition, TGF-β is synthesized in an inactive form and is activated in association with LAP (*dark blue*), LTBP (*yellow*), and fibrillin (*purple*), and αvβ6 integrin. Moreover, integrins αvβ6, α5β1, and α4β1 provide physical anchorage to the ECM via their association with fibronectin and syndecan, a third ECM protein that binds, via a specialized domain (heparan sulfate, *purple*, *blue*), to fibronectin. These various associations with common ECM components serve also to nucleate multiprotein complexes containing integrins, RTKs, and other signaling molecules like Src. (Adapted from R.O. Hynes, *Science* 326:1216–1219, 2009. With permission from AAAS.)

This example is only one of many. Thus, integrin-mediated modulation of tyrosine kinase receptor (RTK) signaling has been described for the platelet-derived growth factor-β (PDGF-β) receptor; a vascular endothelial growth factor (VEGF) receptor; the hepatocyte growth factor (HGF) receptor (termed Met), and the Met-related Ron RTK, which binds the HGFL (HGF-like) ligand; the insulin receptor (IR); and the EGF-R–related ErbB2/HER2 receptor. And not unexpectedly, interactions between integrins and RTKs can be reciprocal: activation of RTKs by their respective ligands can stimulate signaling by the proteins associated with the C-terminal tails of integrins. Taken together, such reciprocal signaling indicates that RTKs emit signals in part by

activating integrin-associated signaling proteins, while integrins release signals in part by activating RTK-associated proteins.

Supplementary Sidebar 5.10 Cross-phosphorylation and the complexity of signaling processes

As receptor biochemistry is studied in increasing detail, it is also apparent that cross-phosphorylation between receptors occurs commonly and may represent a critical mechanism for controlling cell type–specific signaling. Within the EGF-R family of receptors, for example, HER2 can form heterodimeric complexes with HER3 and phosphorylate the C-terminal tail of the latter, thereby creating binding sites for SH2-containing proteins such as those discussed in Chapter 6; in fact, HER3 itself lacks a catalytically functional kinase (**Figure S5.9**). Perhaps more unexpected are the signals exchanged between unrelated receptors. Thus, the mutant truncated EGF-R present in glioblastomas (Section 5.4) can drive phosphorylation of the *activation loop* of the tyrosine kinase domain of Met (also discussed in Chapter 6); such phosphorylation causes the activation loop to swing out of the way of the catalytic cleft of this kinase, permitting access by the kinase to its substrates and thus its active signaling. In lung carcinomas that have become resistant to a low–molecular-weight inhibitor of the EGF-R tyrosine kinase, a new signaling channel is established in which the Met receptor can drive HER3 tyrosine phosphorylation—a biochemical function that is usually mediated by the HER2 receptor–associated kinase. The formation of physical complexes between these various cross-talking receptors has yet to be directly demonstrated.

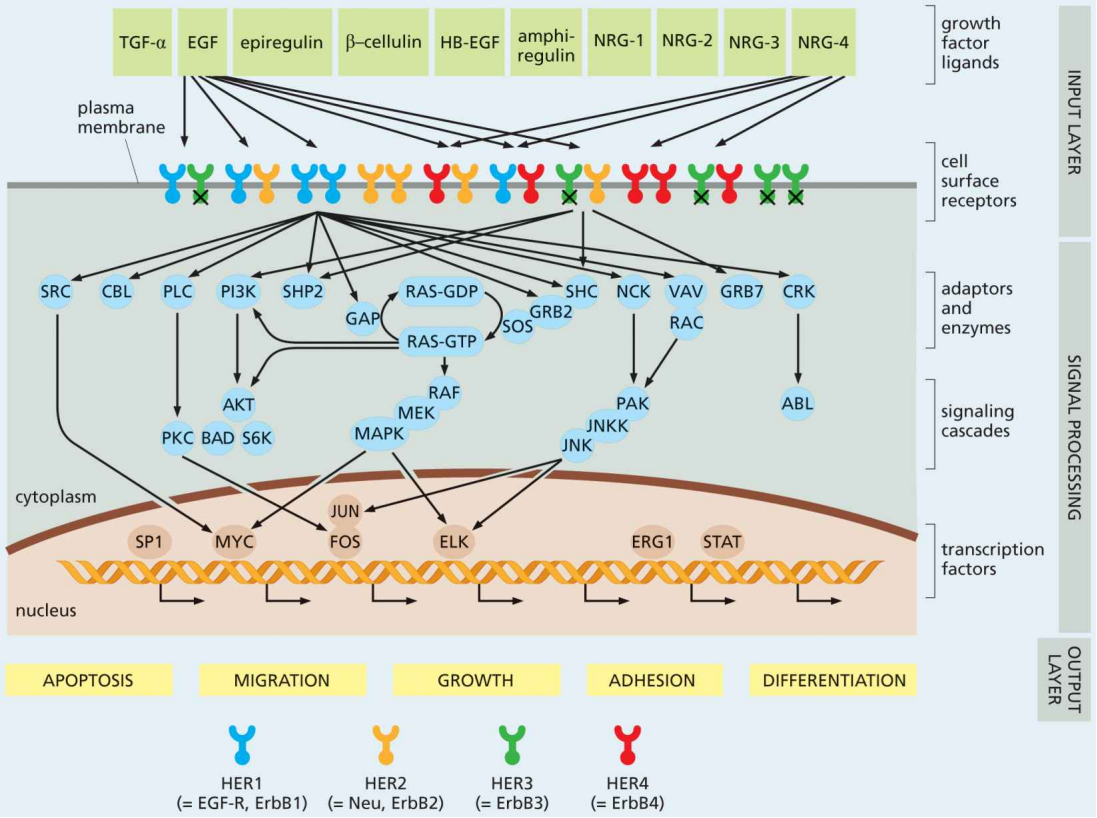

Figure S5.9 The human EGF receptor (HER) signaling network This diagram describes the outlines of the organization of the signaling network that is activated by members of the EGF-R family of receptors. The EGF-R itself is sometimes termed HER1 or ErbB1, while HER2 is often termed HER2/Neu. A variety of protein messengers (growth factor ligands, *light green rectangles*, *top*) interact with a complex array of cell surface receptors, which transduce signals across the plasma membrane (*gray*) into the cytoplasm. There, a complex network of signal-transducing proteins processes these signals, funnels signals into the nucleus (*bottom*), and ultimately evokes a variety of biological responses ("output layer," *yellow rectangles*, *bottom*). Many of the components of this circuitry, both at the cell surface and in the cell interior, are involved in cancer pathogenesis. This cartoon focuses on a small subset of the receptors—the EGF receptor and its cousins—that are displayed on the surfaces of mammalian cells. Note that heterodimeric complexes of certain receptors are indicated (e.g., HER1 + HER2) and that downstream signaling is indicated for only a subset of the receptors expressed at the cell surface. The X's associated with the cytoplasmic domain of HER3 indicate the absence of detectable tyrosine kinase activity in contrast to the readily detectable kinase activity of the other three members of this family of receptors. OceanofPDF.com

Glossary

oligopeptide
: A short protein chain consisting of a relatively small number of amino acids.

immunogen
: (adj., **-genic**) A chemical structure that is capable of provoking some type of immune response, e.g., an antigen that can provoke the synthesis of antibody molecules capable of recognizing and binding it.

lysate
: Product of experimentally dissolving the structure of a tissue or a population of cells, usually generated in order to liberate the internal contents of the tissue or cells.

antigen
: (adj., **-genic**) Molecule or portion of a molecule, often an oligopeptide, that can be specifically recognized and bound by an antibody or a T-cell receptor or that provokes the production of an antibody. *See also* **immunogenic**.

tolerance
: Physiological state that reflects the ability of the immune system to ignore or overlook the body's normal complement of antigens and the cells expressing such antigens.

immunoprecipitate
: Process of precipitating a molecule or molecular complex using an antibody that specifically recognizes and binds such a molecule or a component of such a molecular complex.

hematopoiesis
: (adj., **-poietic**) Process that results in the formation of all of the cells in the blood, including its red and white cells, the latter including various cells of the immune system.

juxtamembrane
: Located immediately adjacent to a membrane.

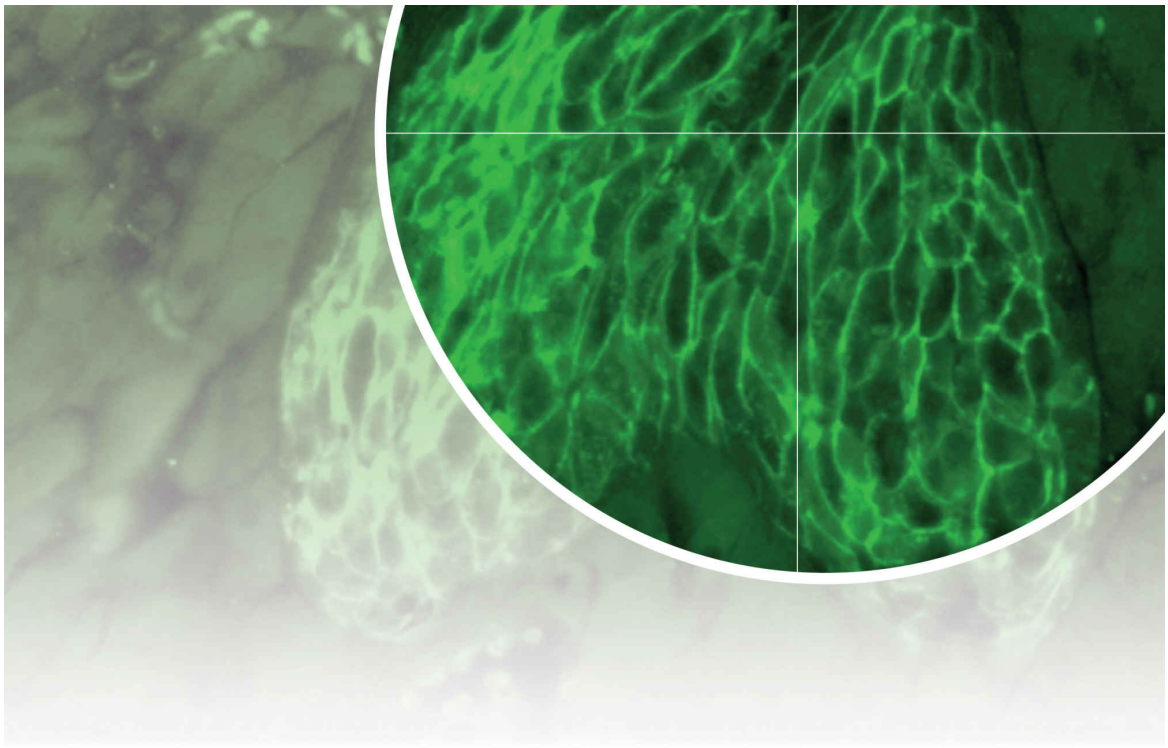
Chapter 6

Cytoplasmic Signaling Circuitry Programs Many of the Traits of Cancer



Enlarged cells from a mouse pancreas glow green due to fluorescent staining.

Considering the wonderful frame of the human body, this infinitely complicated engine, in which, to the due performance of the several functions and offices of life, so many strings and springs, so many receptacles and channels are necessary, and all to be in their right frame and order; and in which, besides the infinite, imperceptible and secret ways of mortality, there are so many sluices and flood-gates to let death in, and life out, it is next to a miracle we survived the day we were born.

James Puckle, inventor, 1711

Any living cell carries with it the experiences of a billion years of experimentation by its ancestors. You cannot expect to explain so wise an old bird in a few simple words.

Max Delbrück, geneticist, 1966

Cancer is a disease of uncontrolled cell proliferation. Because the proliferative behavior of cancer cells is so aberrant, we might imagine that cancer cells invent entirely new ways of programming their growth and division—that the control circuitry within cancer cells is organized quite differently from that of normal, healthy cells. Such thinking greatly exaggerates the actual differences between normal and neoplastic cells. In truth, the two types of cells utilize control circuitry that is almost identical. Cancer cells discover ways of making relatively minor modifications to the control machinery operating inside cells. They tweak existing controls rather than demolishing the entire machinery and assembling a new version from the remnants of the original.

The present chapter is about this control machinery—really about the signal-processing circuitry that operates within the cell cytoplasm and governs cell growth and proliferation. An electronic circuit board is assembled from complex arrays of hard-wired components that function as resistors, capacitors, diodes, and transistors. The cell also uses circuits assembled from arrays of intercommunicating components, but these are, almost without exception, proteins. While individual proteins and their functions are relatively simple, the operating systems that can be assembled from these components are often extraordinarily complex.

In Chapter 5, we read about the receptors displayed at the cell surface that gather a wide variety of signals and funnel them into the cytoplasm. Here, we study how these signals, largely those emitted by growth factor receptors, are processed and integrated in the cytoplasm. Many of the outputs of this signal-processing circuitry are then transmitted to the nucleus, where they provide critical inputs to the central machinery that governs cell proliferation. Our discussion of this nuclear governor—the *cell cycle clock*—will follow in Chapter 8.

A single cell may express 20,000 or more distinct proteins, many of which are actively involved in the cytoplasmic regulatory circuits that are described here. These regulatory proteins are found in various concentrations and in different locations throughout the cytoplasm; often intercommunicating proteins

congregate in specific organelles or focal areas within the cytoplasm. Moreover, rather than floating around in dilute concentrations in the intracellular water, they form a thick soup. Indeed, as much as 30% of the volume of a cell is taken up by proteins rather than aqueous solvent.

These proteins must be able to talk to one another and to do so with great specificity and precision. The problem of specificity is complicated by the fact that important components of the signaling circuitry, such as kinases, have many paralogs—proteins that share a common evolutionary origin and retain common structural features. For example, there are more than 400 similarly structured serine/threonine kinases in mammalian cells. In spite of this complexity, a signaling protein operating in a linear signaling cascade must recognize only those signals that come from its upstream partner protein(s) and pass them on to its intended downstream partner(s). In so doing, it will largely ignore the thousands of other proteins within the cell.

This means that each protein component of a signaling circuit must actually solve two problems. The first is one of specificity: how can it exchange signals only with the small subset of cellular proteins that are its intended signaling partners in the circuit? Second, how can this protein acquire rapid, almost instantaneous access to these signaling partners, doing so while operating in the viscous soup that is present in the cytoplasm and nucleus?

We study this circuitry because its design and operations provide key insights into how cancer cells arise. Thus, many of the oncoproteins described in previous chapters create cancer through their ability to generate signaling imbalances in this normally well regulated system. At one level, cancer is surely a disease of inappropriate cell proliferation, but as we bore deep into the cancer cell, we will come to understand cancer at a very different level: cancer is really a disease of aberrant signal processing.

The present chapter will perhaps be the most challenging of all chapters in this book. The difficulty comes from the sheer complexity of signal transduction biochemistry, a field that is afflicted with many facts and blessed with only a small number of unifying principles. So, absorb this material in pieces; the whole is far too much for one reading.

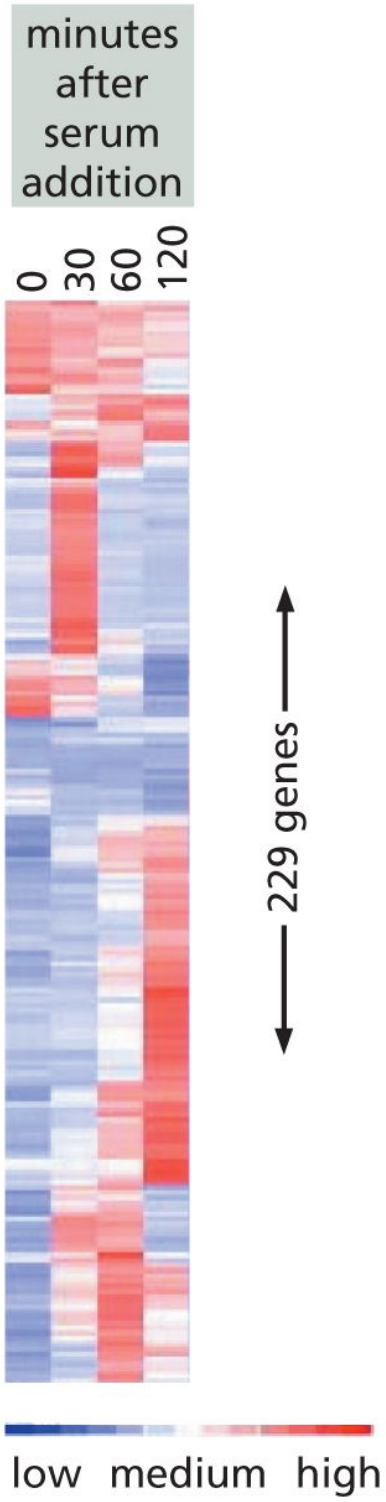
6.1 A signaling pathway reaches from the cell surface into the nucleus

The growth and division that cells undertake following exposure to mitogens clearly represent complex regulatory programs involving the coordinated actions of hundreds, even thousands of distinct cellular proteins. How can growth factors succeed in evoking all of these changes simply by binding and activating their receptors? And how can the deregulation of these proliferative programs lead to cell transformation? And where does Ras fit into this circuitry, if indeed it does?

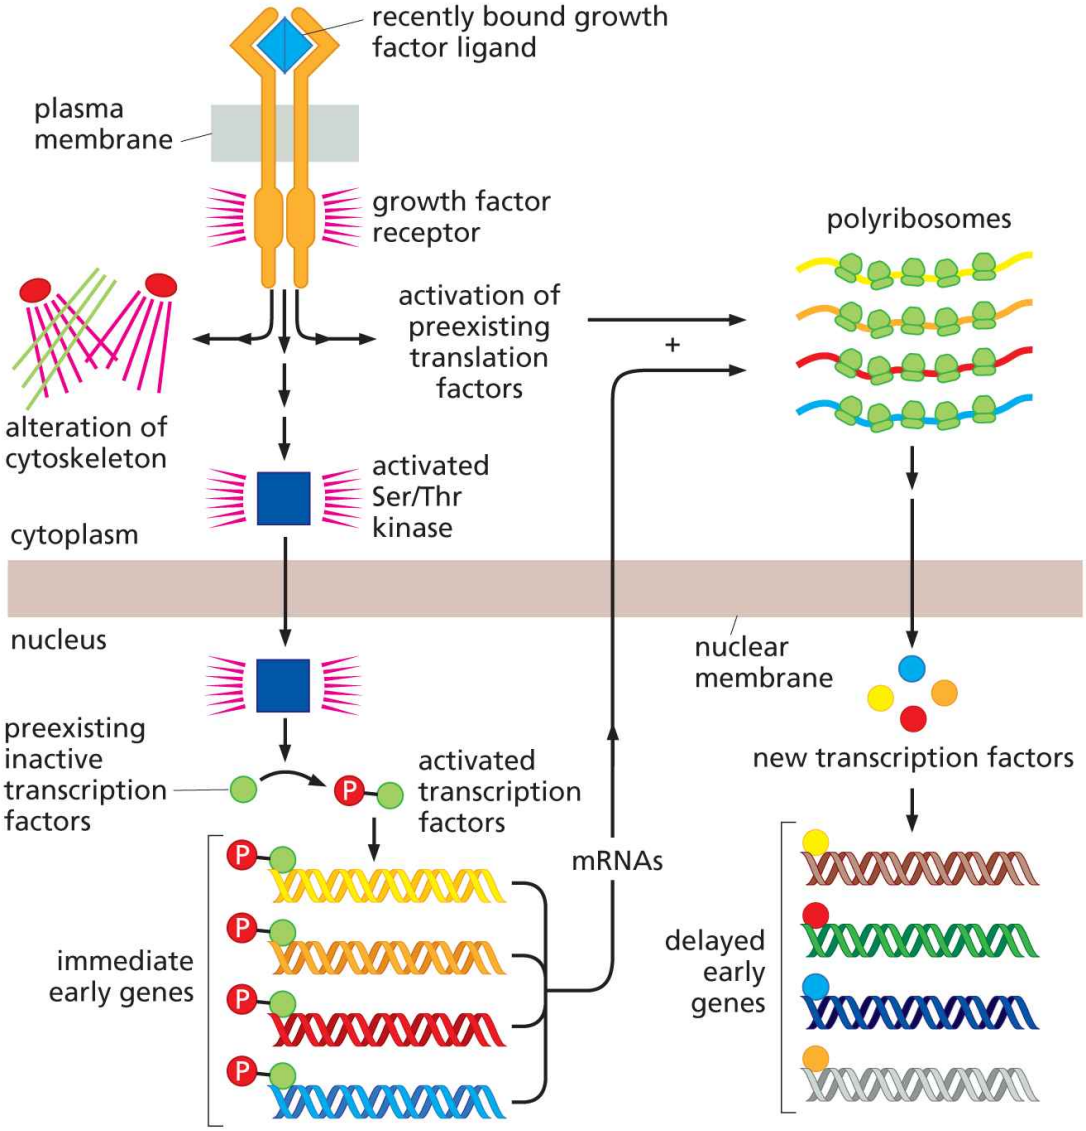
A major insight into these issues came in 1981 from examining the behavior of cultured normal cells, specifically, fibroblasts that had been deprived of serum-associated growth factors for several days. During this period of "serum starvation," the cells within a culture were known to enter reversibly into the nongrowing, quiescent state termed G_0 ("G zero"). After remaining in this G_0 state for several days, serum-starved cells were then exposed to fresh serum and thus to abundant amounts of mitogenic growth factors. The intent of this experiment was to induce all the cells in such cultures to enter into a state of active growth and division synchronously (coordinately). Indeed, within a period of 9 to 12 hours, the great majority of these previously quiescent cells would begin to replicate their DNA and initiate cell division a number of hours later.

These readily observed changes in cell behavior provided no hint of the large number of less obvious but nonetheless important molecular changes that occurred in these cells, often within minutes of exposure to fresh growth factors. For example, within less than an hour, transcription of an ensemble of more than 100 cellular genes was induced (**Figure 6.1**). Expression of these genes, which we now call immediate early genes (IEGs), increased rapidly in the half hour after growth factor stimulation. As is suggested by the contents of **Table 6.1**, the products of some of these genes help cells in various ways to emerge from the quiescent G_0 state into their active growth-and-division cycle. In fact, experiments involving several of these genes showed that blocking their expression prevents the emergence of cells from the G_0 state.



A tall image with four vertical lanes representing instants in time: 0, 30, 60, and 120 minutes after serum addition. Each lane contains 229 thin horizontal bands representing 229 genes. The bands are color-coded, from blue for low expression, through white for medium expression, up to red for high

expression. Some genes remain blue or white up to 60 minutes but then shift to red at 120 minutes. Other genes start out blue, then shift to red at 30 minutes, but then back down to white or even blue at 60 and 120 minutes. Stil other genes remain blue throughout.
(A)



A diagram of a sequence of events that begins with a growth factor receptor in a plasma membrane binding to a growth factor ligand and then signaling. The signaling causes alteration of the cytoskeleton. It also activates S e r slash T h r kinase, which moves through the nuclear membrane into the cell nucleus, where it causes activation through phosphorylation of preexisting inactive transcription factors. These attach to the immediate early genes and produce m R N Aze, which move outside the nucleus. There, they meet up with

preexisting translation factors that were also activated by the growth factor receptor, resulting in polyribosomes. These produce new transcription factors released back into the nucleus to attached delayed early genes.
(B)

Figure 6.1 Expression of immediate and delayed early genes (A) Expression of a large array of "immediate early genes" (IEGs) is induced within the first two hours after serum-starved cells are exposed to fresh serum. The expression of IEGs, by definition, occurs even when protein synthesis is blocked during this period, indicating that the transcription factors regulating expression of these genes are already present in the serum-starved cells. Analyses of the expression patterns of the 14,824 genes surveyed here at 30, 60, and 120 minutes following serum addition led to the identification of 229 genes (*unlabeled, arrayed top to bottom*) that behave like IEGs. Complex signaling cascades explain why some IEGs are only induced with some delay. *Red* indicates a high level of RNA expression, while *blue* indicates low expression. Note that some IEGs are expressed for only a brief period of time before being repressed even though the serum and associated mitogens continue to be present in the culture medium. (B) The profound changes in cell physiology following the application of serum-associated mitogenic growth factors to a cell indicate that growth factor receptors can release a diverse array of biochemical signals once they are activated by ligand binding. The transcription of some IEGs can already be observed within minutes of growth factor stimulation (*lower left*). These contrast with the expression of delayed early genes that requires the synthesis of new transcription factors (*lower right*). (A, from A. Selvaraj and R. Prywes, *BMC Mol. Biol*. 5:13, 2004. With permission from Springer.)

Table 6.1 A sampling of immediate early genes[a]

Name of gene or gene product	**Location of gene product**	**Function of gene product**
fos[b]	nucleus	component of AP-1 TF
junB	nucleus	component of AP-1 TF
egr-1	nucleus	zinc finger TF

Name of gene or gene product	Location of gene product	Function of gene product
nur77	nucleus	related to steroid receptors
Srf-1[c]	nucleus	TF
myc	nucleus	bHLH TF
β-actin	cytoplasm	cytoskeleton
γ-actin	cytoplasm	cytoskeleton
tropomyosin	cytoplasm	cytoskeleton
fibronectin	extracellular	extracellular matrix
glucose transporter	plasma membrane	glucose import
JE	extracellular	secreted cytokine
KC	extracellular	secreted cytokine

Adapted in part from H.R. Herschman, *Annu. Rev. Biochem*. 60:281–319, 1991; and from B.H. Cochran, in R. Grzanna and R. Brown (eds.), Activation of Immediate Early Genes by Drugs of Abuse. Rockville, MD: National Institutes of Health, 1993, pp. 3–24.

A variation of this 1981 experiment was undertaken in which fresh serum was added together with cycloheximide, a drug that shuts down all cellular protein synthesis. In spite of the inhibition of protein synthesis, induction of the immediate early genes

proceeded quite normally. This indicated that all of the proteins required to activate transcription of these genes were already in place at the moment when the serum was added to the cell. Stated differently, the induction of these genes did not require *de novo* (new) protein synthesis.

These results also demonstrated that, in addition to the growth factor receptors at the cell surface, an array of other proteins was present within the cell that could rapidly convey mitogenic signals from the receptors located at the cell surface to transcription factors (TFs) operating in the nucleus. Clearly, the functional activation of such cytoplasmic signal-transducing proteins did not depend upon increases in their concentration (since cycloheximide had no apparent effect on this signaling). Instead, changes in the proteins' structure, configuration, and intracellular localization appeared to play a dominant role in their functional activation soon after the stimulation of tyrosine kinase receptors by their growth factor ligands.

The immediate early genes encode a number of interesting proteins (Table 6.1). Some of them specify transcription factors that, once synthesized, help to induce a second wave of gene expression. Included here are the *myc*, *fos*, and *jun* genes, which were originally identified through their incorporation as oncogenes into the genomes of transforming retroviruses (see Table 3.3). Yet other immediate early genes encode proteins that are secreted growth factors (cytokines) or help to organize the cellular cytoskeleton.

The levels of *myc* mRNA were found to rise steeply following mitogen addition and to collapse quickly following mitogen removal. Moreover, the Myc protein itself turns over rapidly, having a half-life ($T_{1/2}$) of only 25 minutes. Such observations indicated that the levels of the Myc protein serve as a sensitive and responsive intracellular indicator of the amount of mitogens present in the nearby extracellular space.

As an aside, we might note that the activity of Myc operating as a signaling protein derives in large part from major changes in its *concentration* within the cell nucleus. This contrasts starkly with the behavior of cytoplasmic signal-transducing proteins such as Ras and Src. These and many other cytoplasmic signaling proteins respond to mitogenic signals by undergoing *relocalization* within the cell as well as alterations in their *structure* rather than exhibiting significant increases in concentration. This difference is mirrored by the changes occurring when the normal *myc*, *ras*, and *src* genes are converted into oncogenes: the *levels* of Myc protein become deregulated (being expressed constitutively rather than being modulated in response to physiologic signals), whereas the *structures* of the Ras and Src proteins undergo alteration but the amounts of these proteins do not necessarily increase.

Within an hour after the immediate early mRNAs appear, a second wave of gene induction was found to occur. Significantly, the induction of these delayed early genes

was largely blocked by the presence of cycloheximide, indicating that their expression did indeed depend on *de novo* protein synthesis (see Figure 6.1B). (In fact, expression of these delayed early genes seems to depend on transcription factors cited above that are synthesized in the initial wave of immediate early gene expression.)

Addition of growth factors to quiescent cells was found to provoke yet other changes in cell physiology besides the rapid induction of nuclear genes. Following exposure of cells to serum, their rate of protein synthesis increases significantly, this being achieved through functional activation of the proteins that enable ribosomes to initiate translation of mRNAs. Some growth factors were discovered to induce motility in cells, as indicated by the movement across the bottom surfaces of Petri dishes. Yet others can provoke a reorganization of actin fibers that help to construct the cell's cytoskeleton—the intracellular scaffolding that defines cell shape (**Supplementary Sidebar 6.1**). Subsequently, many growth factors were discovered to provide survival signals to cells, thereby protecting them from inadvertent activation of the cell suicide program known as apoptosis, which is described later in Chapter 9.

These diverse responses indicated that a variety of distinct biochemical signals radiate from ligand-activated growth factor receptors, and that these signals impinge on a diverse array of cellular targets. Some of these signals seemed to be channeled directly into the nucleus, where they altered gene expression programs, while others were clearly directed toward cytoplasmic targets, including the protein-synthesizing machinery and the proteins that organize the structure of the cytoskeleton.

Clearly, an understanding of how these signaling cascades operate was very relevant to the cancer problem: if it were true that some oncoproteins flood cells with a continuous stream of mitogenic signals (see Chapter 5), then the transformed state of cancer cells might well represent an exaggerated version of the responses that normal cells exhibit following exposure to growth factors. In fact, many of the traits of cancer cells can indeed be traced to responses evoked by growth factors, while others cannot be predicted by the initial responses of cells to these factors (**Sidebar 6.1**).

Sidebar 6.1 Short-term transcriptional responses to mitogens provide no indication of the gene expression in continuously growing cells

Simple logic would dictate that the transcriptional responses observed shortly after growth factor stimulation of a serum-starved cell ought to predict the transcriptional state of cells in which mitogenic signaling occurs continuously, whether in response to ongoing exposure to growth factors or the activity of certain oncoproteins. Accordingly, the spectrum of immediate and delayed early genes induced within the first hour of growth factor stimulation should also be expressed continuously and at a high rate in transformed cells.

In fact, some genes that are members of the immediate and delayed early gene expression groups are found to be expressed at high levels in cancer cells, while others are not. This discordance derives from negative-feedback controls that force the shutdown of certain genes shortly after they have been expressed. For example, expression of the *fos* gene, itself a proto-oncogene, increases rapidly in response to serum stimulation, peaks, and then declines dramatically, all within an hour or so (see, for example, Figure 6.1A). This shutdown is due to the ability of the Fos protein, once synthesized, to act as a transcriptional repressor of the synthesis of more *fos* mRNA. Numerous other negative-feedback mechanisms operate in cells to ensure that many of the initial biochemical responses evoked by growth factors function only transiently. More generally, negative-feedback loops are installed in virtually all signaling pathways to ensure that the flow of signals through these pathways is tightly controlled in both intensity and duration (see Section 6.14).

Glossary

immediate early genes
: Referring to the group of genes whose expression is induced within half an hour of growth factor stimulation of previously factor-deprived cells, occurring even when protein synthesis is inhibited. *See also* **delayed early**.

cycloheximide
: Drug that prevents the forward movement of ribosomes down mRNA templates, thereby blocking protein synthesis.

cytokine
: (1) Secreted protein that operates like growth factors to stimulate or inhibit various cell types, notably those constituting various branches of the hematopoietic and immune systems. (2) Less commonly, secreted proteins that convey signals between cells, including mitogenic growth factors.

half-life
: (1) Time during which half of a population of metabolically unstable molecules decays or is eliminated or the time required for half of a physiological signal to decrease. (2) Time in which 50% of the atoms of a quantity of a radioactive isotope decay. (3) Time during which half of the entities forming a large population disappear or are removed.

apoptosis
: Complex program of cellular self-destruction, triggered by a variety of stimuli and involving the activation of caspase enzymes, which drive rapid fragmentation of diverse cellular structures and elimination of all breakdown products of a cell and phagocytosis of resulting cell fragments by neighboring cells or macrophages. *See also* **ferroptosis**, **necroptosis**, **pyroptosis**.

de novo
: (1) Arising or formed anew. (2) Occurring for the first time.

synchronous
: (1) Occurring at the same time; i.e., in a temporally coordinated fashion. (2) Referring to a population of cells that enter a specific phase of the cell cycle at the same time. *See also* **asynchronous**.

delayed early

Referring to genes whose expression depends on prior *de novo* protein synthesis and is induced with some delay following growth factor stimulation of a factor-starved cell. *See also* **immediate early**.

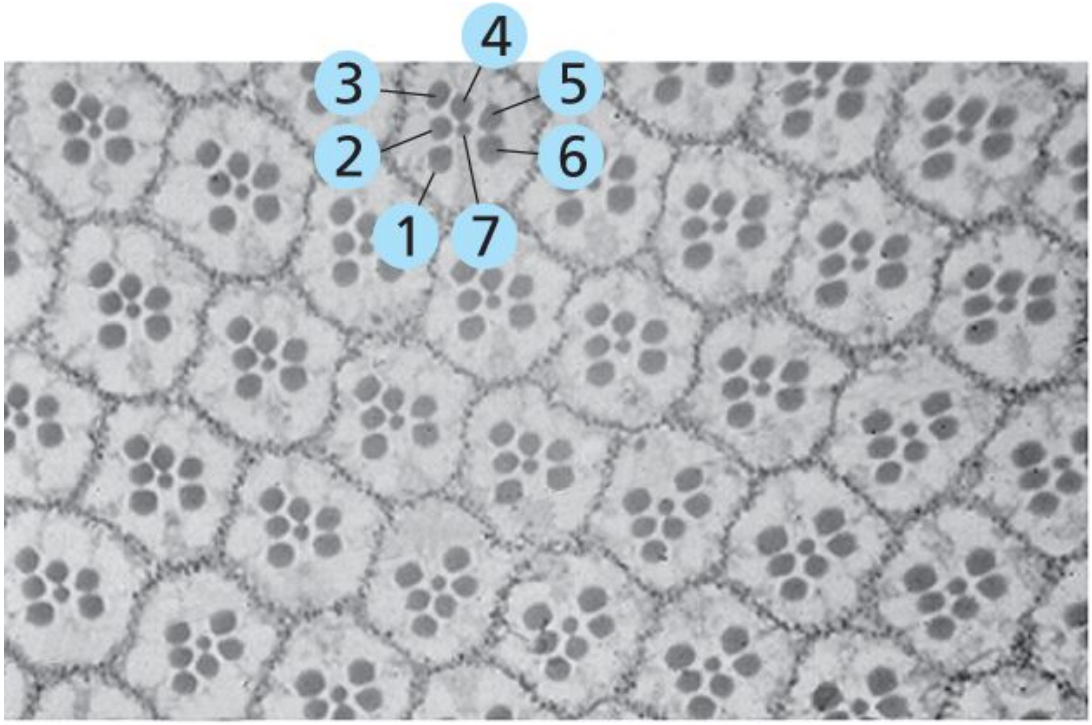
6.2 The Ras protein stands in the middle of a complex signaling cascade

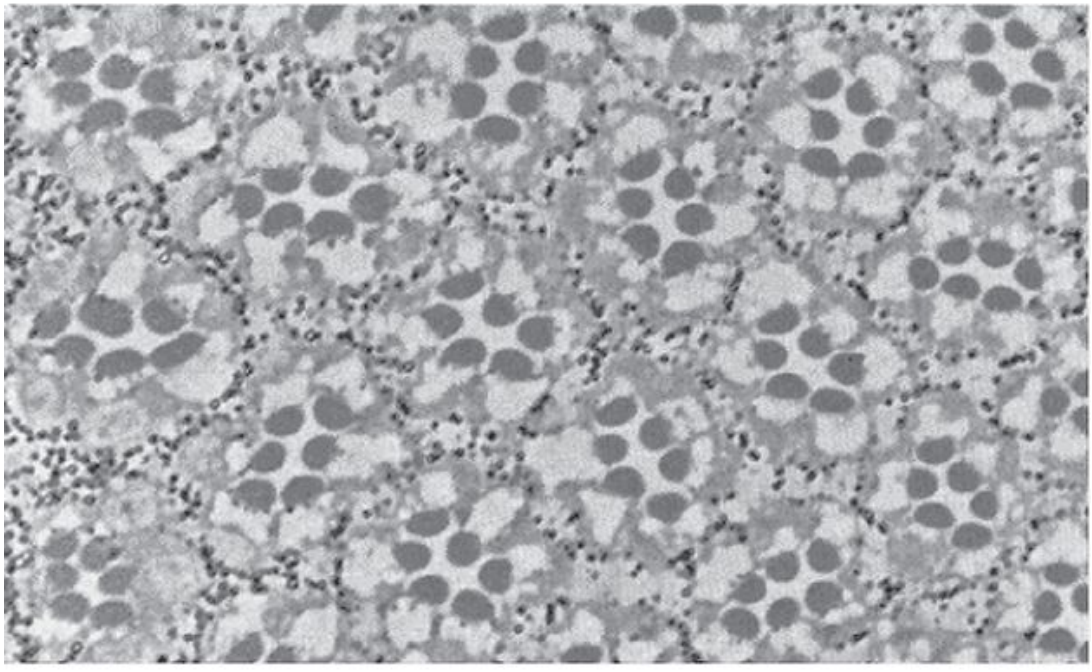
The disparate responses of cells to growth factors represented a challenge to those interested in intracellular signal transduction, since almost nothing was known about the organization and function of the communication channels operating within the cell. Over a period of a decade (the 1980s), these circuits were slowly pieced together, much like a jigsaw puzzle. The clues came from many sources. The story started with Ras and then moved up and down the signaling cascades until the links in the signaling chains were finally connected.

The advances in Ras biochemistry that we discussed in the last chapter (Section 5.10) seemed to explain much about how it operates as a binary switch, but provided no insight into its context—how this protein is connected with the overall signaling circuitry in which it is embedded. Indeed, it remained possible that the Ras protein functioned in a signaling pathway that was independent of the one controlled by growth factors and their receptors.

In the end, the solution to the Ras problem came from a totally unexpected quarter. The genetics of eye development in the fruit fly *Drosophila melanogaster* revealed a series of genes whose products were essential for the normal development of the ommatidia, the light-sensing units forming the compound eye. One important gene here came to be called *Sevenless*; in its absence, the seventh cell in each ommatidium failed to form (**Figure 6.2A**). Provocatively, after cloning and sequencing, the *Sevenless* gene was found to encode a protein with the general structural features of a tyrosine kinase receptor, specifically a mammalian FGF receptor.



wild type



sevenless mutant

A micrograph of wild-type receptors, in which six large cells surround a smaller seventh one, compared with a micrograph of so-called sevenless receptors in which the seventh cell is missing. This causes a more disorganized appearance of the cells.

?
Son of
sevenless
(Sos)
GDP
GTP
Ras

A receptor in sevenless, the homolog of an F G F receptor, is bound by a growth factor ligand and is signaling. An unknown cascade, denoted by question marks, leads to a protein named Son of Sevenless, or S o s, that can activate an R a s protein by replacing G D P with G T P.

(B)

Figure 6.2 Son of Sevenless and Ras (A) Study of the light-sensing units in *the Drosophila melanogaster* eye—the ommatidia—revealed that each ommatidium is normally formed from a series of seven cells, with six outer ones surrounding a seventh in the center, as seen in this electron micrograph section (*upper panel*). A fly carrying the mutation in the gene that came to be called *sevenless* produced ommatidia lacking the seventh, central cell (*lower panel*). Later, *sevenless* was found to encode a homolog of the mammalian fibroblast growth factor (FGF) receptor. (B) Genetic studies of *Drosophila* eye development revealed another gene whose product appeared to lie downstream of *Sevenless* in a signaling cascade and specified a guanine nucleotide exchange factor (GEF; *orange*), capable of activating the Ras protein. This gene was named *Son of sevenless* or simply *Sos*. (A, courtesy of E. Hafen.)

Yet other mutations mimicked the effects of *Sevenless* mutation. Genetic complementation tests revealed that these mutations affected genes whose products operate downstream of *Sevenless*, ostensibly in a linear signal transduction cascade. One of these downstream proteins was encoded by a gene that was named *Son of sevenless* or simply *Sos*. Close examination of the Sos amino acid sequence showed it to be related to proteins known from yeast biochemistry to be involved in provoking nucleotide exchange by G (guanine nucleotide–binding) proteins such as Ras. The yeast proteins, often called guanine nucleotide exchange factors (GEFs), were known to induce G proteins to release their bound GDPs, thereby making room for GTPs to jump aboard (see Figure 5.24). The consequence was an activation of these G proteins from their inactive to their active, signal-emitting configuration. This was precisely the effect that Sos exerted on Ras proteins (Figure 6.2B). Therefore, Sos appeared to be the long-sought upstream stimulator that kicked Ras into its active configuration.

Soon other intermediates in the signaling cascade were uncovered. Two of these, Shc (pronounced “shick”) and Grb2 (pronounced “grab two”), were discovered through genetic and biochemical screens for proteins that interacted with phosphorylated receptors or derived peptides. It became apparent that these two

proteins function as adaptors, forming physical bridges between growth factor receptors and Sos; such bridging proteins will be discussed in greater detail later. A third such adaptor protein, called Crk (pronounced “crack”), was identified as the oncoprotein encoded by the CT10 avian sarcoma virus (see Table 3.3).

These discoveries demonstrated the very ancient origins of this signaling pathway, which was already well developed more than 600 million years ago in the common ancestor of all contemporary metazoan phyla. Once in place, the essential components of this cascade remained relatively unchanged in the cells of descendant organisms. Indeed, the individual protein components of these cascades have been so conserved that in many cases the protein components prepared from the cells of members of one phylum (for example, chordates) can be exchanged with those of another (for example, arthropods) to reconstitute a functional signaling pathway.

Together, the genetic and biochemical data from these distantly related animal phyla could be combined in a scheme that suggested a linear signaling cascade organized like this: tyrosine kinase receptor → Shc → Grb → Sos → Ras. While this cascade provided the outline of a signaling channel, it gave little insight into the biochemical interactions that enabled these various proteins to exchange signals with one another.

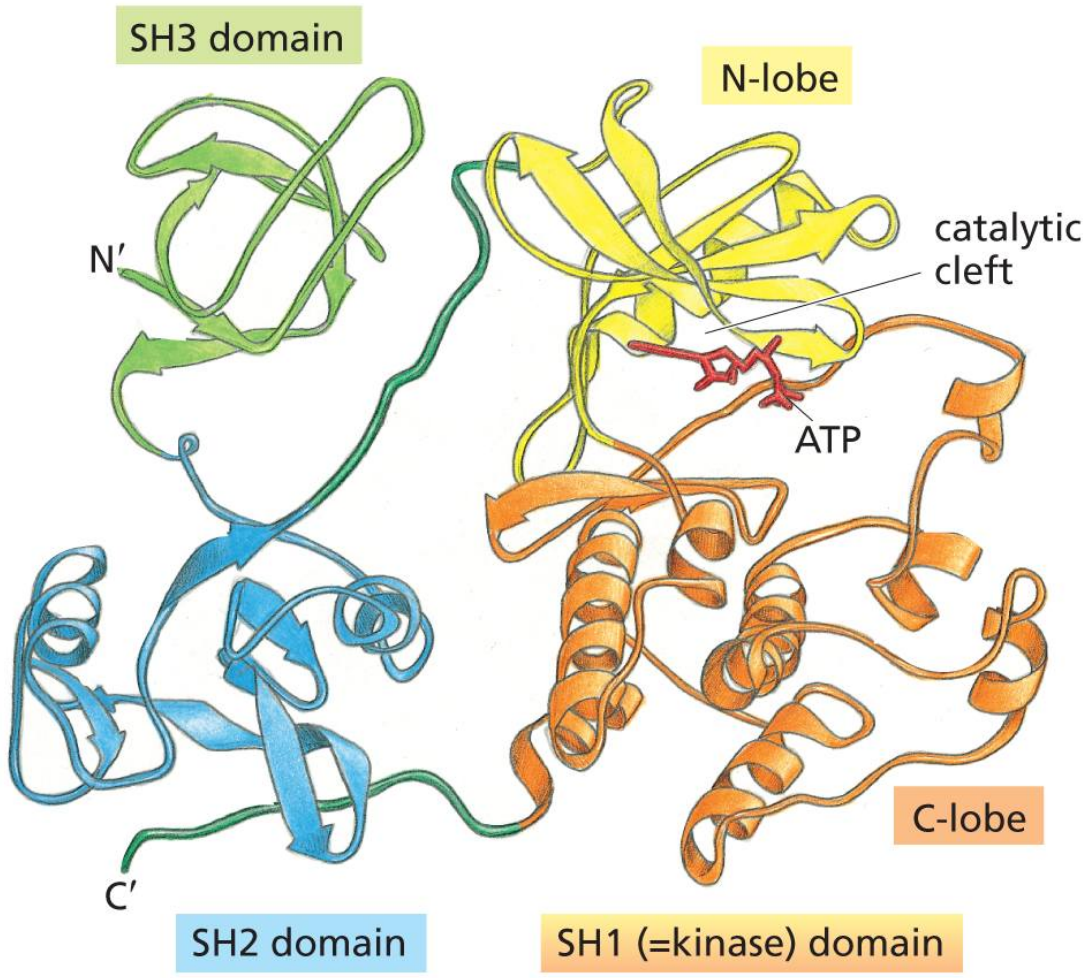
6.3 Tyrosine phosphorylation controls the location and thereby the actions of many cytoplasmic signaling proteins

Among the major biochemical issues left unanswered, perhaps the most critical were the still-mysterious actions of the kinases carried by many growth factor receptors. Was the phosphorylation of these receptors on tyrosine residues crucial to their ability to signal, or was it a distraction? And if this phosphorylation was important, how could it activate the complex signaling circuitry that lay downstream?

Two alternative mechanisms seemed plausible. The first predicted that a receptor-associated tyrosine kinase would phosphorylate a series of target proteins in the cytoplasm. Such covalent modification would alter the three-dimensional *conformation* of the proteins and associated changes in biochemical function (that is, their stereochemistry), thereby placing each of them in an actively signaling state that allowed them to transfer signals to partners one step further down in a signaling cascade. This model implied, among other things, that the phosphorylation of the receptor molecule itself was of secondary importance to signaling.

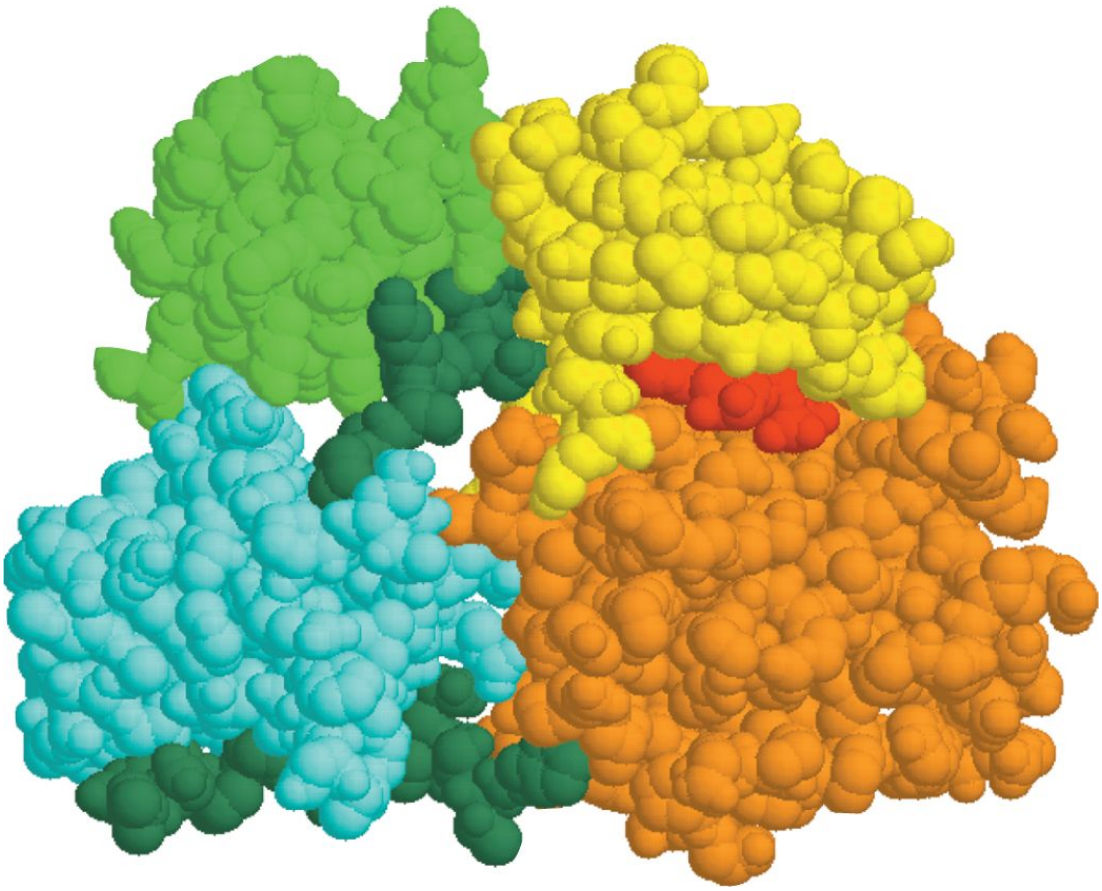
According to the alternative model, the phosphorylation of the cytoplasmic tail of a receptor following growth factor binding (see Figure 5.11A) affected the *physical location* of its downstream signaling partners without necessarily changing their intrinsic activity. Once relocalized to new sites within the cytoplasm, these downstream partners could then proceed with their task of emitting signals to yet other targets in the cell.

As it turned out, the second model, involving protein relocalization, proved to be more important. The salient insights came from analyzing the detailed structure of the Src protein. Researchers noted three distinct amino acid sequence domains, each of which appeared both in Src and in a number of other, otherwise unrelated proteins. These sequences, called Src homology domains 1, 2, and 3 (SH1, SH2, and SH3), provided the key to the puzzle of receptor signaling (**Figure 6.3**).



A ribbon diagram with four domains. The upper left S H 3 domain appears in green; it consists of a few flattened ribbons. The lower left S H 2 domain appears in blue; it consists of a few flattened ribbons. The right side is the S H 1 domain or kinase domain. Its upper half is the N lobe, which appears in yellow; it consists of flattened ribbons. The lower half is the C lobe, which appears in orange; it consists of coils. A red A T P molecule is shown in the catalytic cleft between the N and C lobes.

(A)



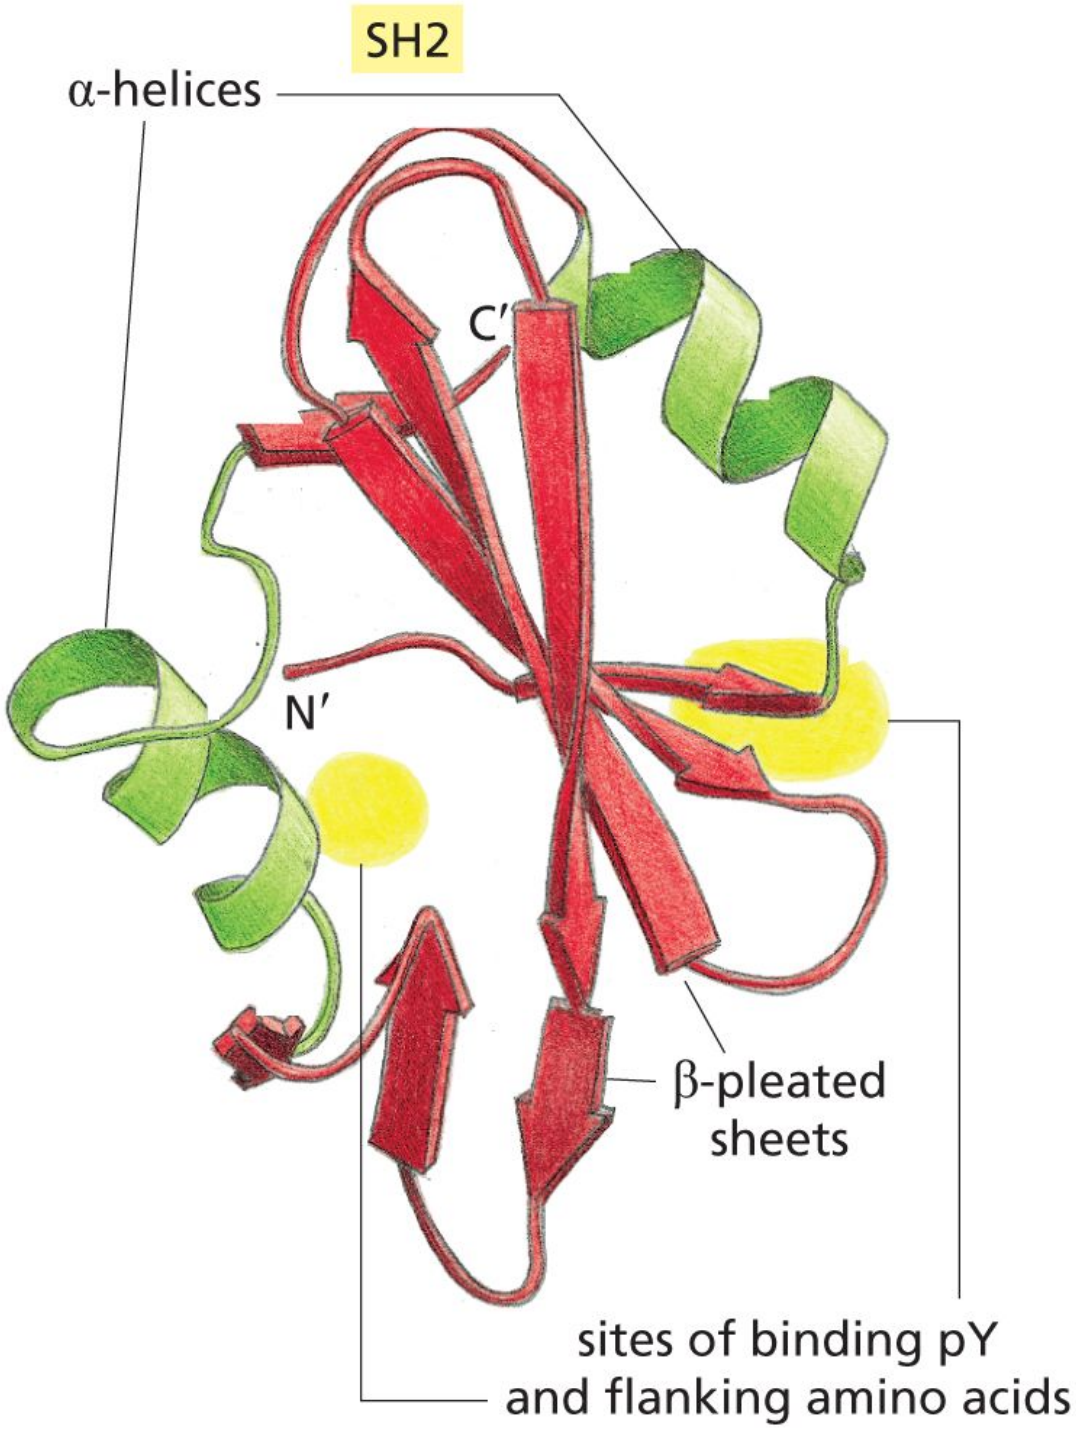
A space filling model of the Sarc protein, with green, blue, yellow and orange components as in Part A.

(B)

Figure 6.3 Domain structure of the Src protein Sequence analyses of the Src protein revealed three distinct structural domains that are also found in a number of otherwise-unrelated proteins. (A) In this ribbon diagram of Src—the product of X-ray crystallography—coils indicate α-helices, while flattened ribbons indicate β-pleated sheets. Like the great majority of other subsequently analyzed protein kinases, the catalytic SH1 (Src homology) domain is seen to be composed of two subdomains (*right*), termed the N- and C-lobes of the kinase (*yellow, orange*; *right*). Between these lobes is the ATP-binding site (ATP—*red stick figure*) where catalysis takes place. The SH2 and SH3 domains (*blue, light green*; *left*) are involved in substrate recognition and regulation of catalytic activity. (B) A space-filling model of Src is presented in the same color scheme. Connecting segments are shown in *dark green*. (From B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton & Company, 2015.)

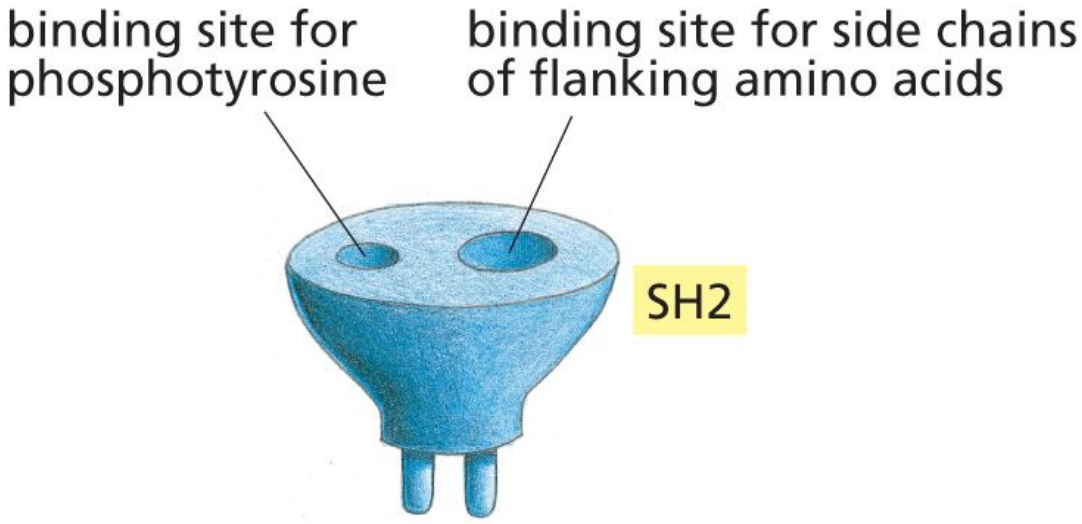
The SH1 domain of Src represents its catalytic domain, and indeed similar sequence domains are present in all receptor tyrosine kinases, as well as in the other, nonreceptor tyrosine kinases that are configured like Src. This shared sequence relatedness testifies to the common evolutionary origin of all these kinases.

Clever biochemical sleuthing conducted in the late 1980s uncovered the role of the SH2 domain present in Src and other signaling proteins. This relatively small structural domain of about 100 amino acid residues (**Figure 6.4A and B**) acts as an intracellular "receptor." The "ligand" for this SH2 receptor is a short oligopeptide sequence that contains both a phosphorylated tyrosine and a specific oligopeptide sequence 3 to 6 residues long that flanks the phosphotyrosine on its C-terminal side.



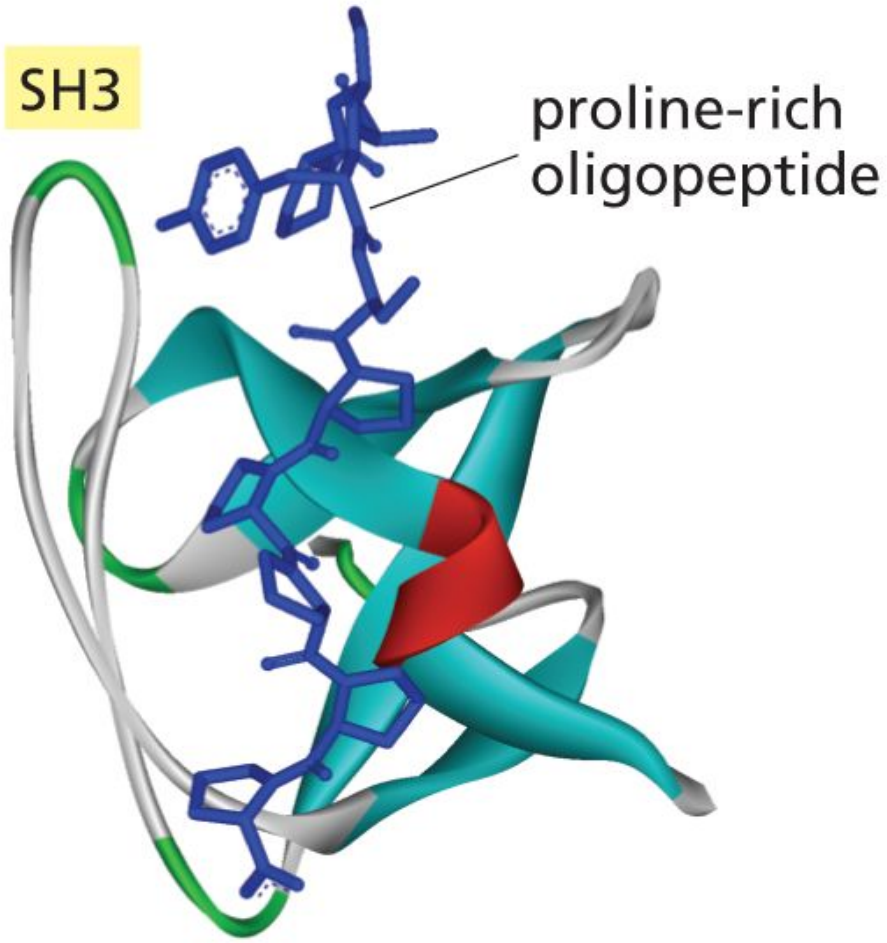
The S H 2 domain is shown to consist of beta-pleated sheets in red, which include the N prime and C prime ends, flanked by alpha-helices in green. Two sites of binding p Y and flanking amino acids are indicated.

(A)



The S H 2 domain is shown very schematically as a plug with two prongs at the bottom pointing down and two different-size sockets on top. The smaller one is the binding site for phosphotyrosine; the larger one is the binding site for side chains of flanking amino acids.

(B)



A ribbon diagram of S H 3 in aqua, red and white, with a long proline-rich oligopeptide attached in dark blue.

(C)

Figure 6.4 Structure and function of SH2 and SH3 domains (A) This SH2 domain is seen in a different orientation from that in Figure 6.3. As revealed by X-ray crystallography, a typical SH2 domain is composed of about 100 amino acid residues and is assembled from a pair of anti-parallel β-pleated sheets (*red*) surrounded by a pair of α-helices (*green*). (The N′- to C′-terminal orientation is indicated by the arrowheads.) The sites of interaction by the SH2 domain with its "ligand"—a phosphotyrosine (pY)-containing peptide (composed of a pY and flanking amino acids)—are indicated by the *yellow* spots. (B) As indicated, the SH2 domain can be thought to function like a modular plug: it recognizes both a phosphotyrosine and the amino acids that flank this phosphotyrosine on its C-terminal side. These flanking amino acid residues determine the specificity of binding, i.e., the identities of the particular phosphotyrosine-containing

oligopeptides that are recognized and bound by a particular SH2 domain. (C) The SH3 domain (*ribbon diagram*), shown in a different orientation from that of Figure 6.3, recognizes as its ligands proline-rich oligopeptide (*blue stick figure*) sequences in partner proteins. (A, from G. Waksman et al., *Cell* 72:779–790, 1993. With permission from Elsevier. B, from B. Alberts et al., Molecular Biology of the *Cell*, 6th ed. New York: W.W. Norton & Company, 2015. C, adapted from S. Casares et al., *Protein* 67:531–547, 2007.)

Soon, it became apparent that there are dozens of distinct SH2 domains, each carried by a different protein and each having an affinity for a specific phosphotyrosine-containing oligopeptide sequence that functions as its ligand. By now, the sequence specificities of a substantial number of SH2 groups have been cataloged. The human genome is estimated to encode at least 120 distinct SH2 groups, each constituting a domain of a larger protein and each apparently having an affinity for binding a particular phosphotyrosine together with a flanking oligopeptide sequence. (Ten proteins carry two SH2 domains, yielding a total census of 110 distinct SH2-containing proteins in our cells.)

Most commonly, an SH2 domain enables the protein carrying it to associate with a partner protein that is displaying a specific phosphotyrosine plus flanking amino acid sequence, thereby forming a physical complex between these two proteins. Some SH2-bearing proteins carry no enzymatic activity at all. Other such proteins, in addition to their SH2 domains, carry catalytic sites that are quite different from the tyrosine kinase (TK) activity present in Src itself. For example, one form of phospholipase C carries an SH2 domain, as does the p85 subunit of the enzyme phosphatidylinositol 3-kinase (PI3K). The SHP-1 protein, discussed in **Sidebar 6.2**, carries two SH2 domains linked to a protein tyrosine phosphatase (PTP) catalytic domain, that is, a domain with an enzymatic activity that removes phosphate groups from tyrosine residues, thereby reversing the actions of tyrosine kinases.

Sidebar 6.2 A negative-feedback control mechanism leads to an SH2-containing molecule that can determine outcomes of Olympic competitions

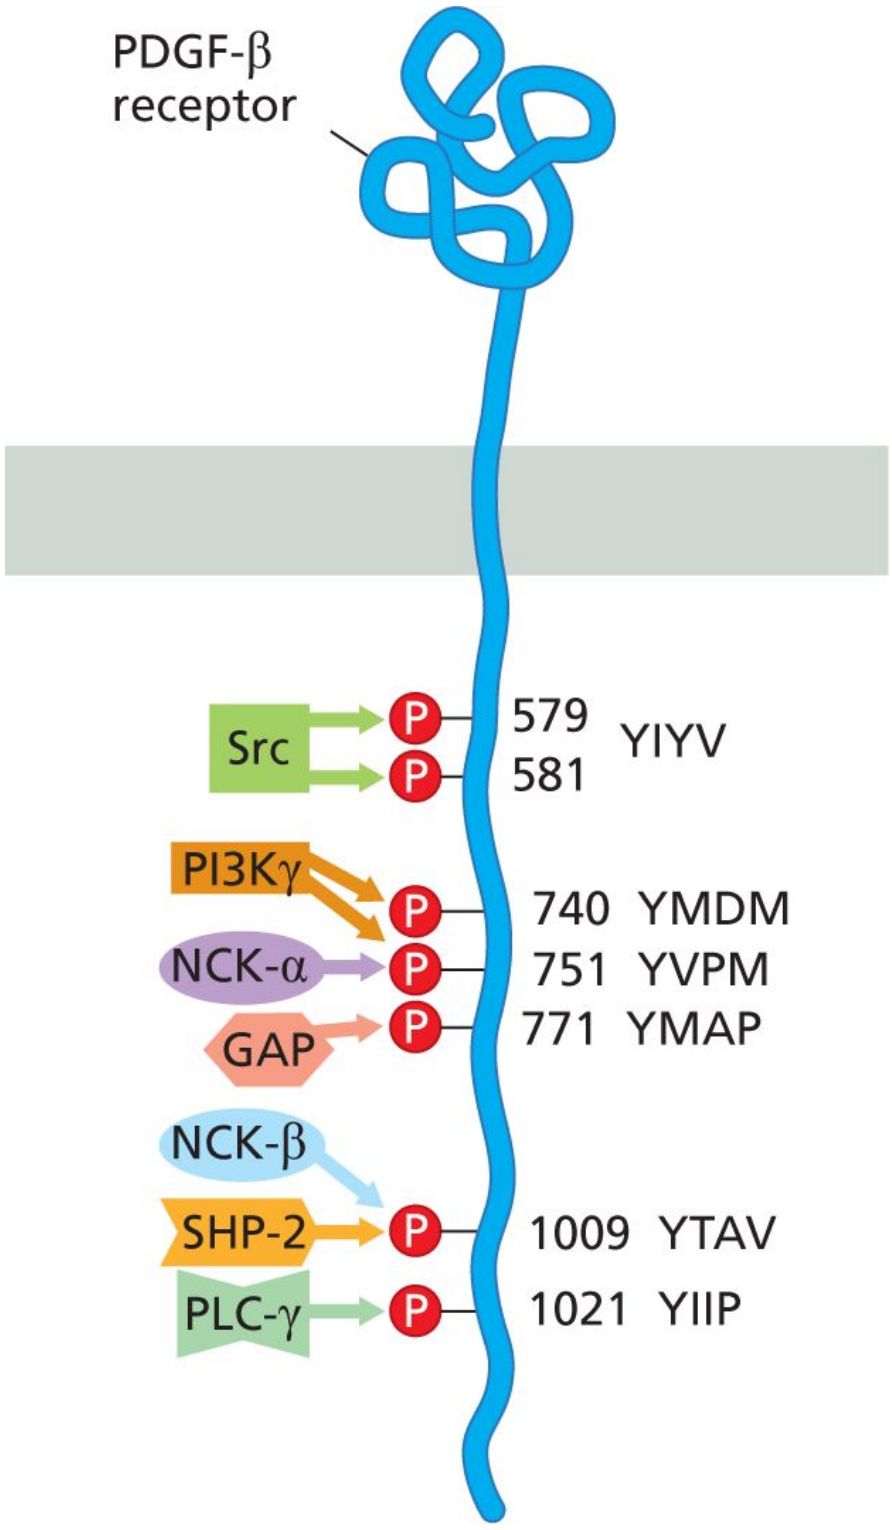
One of the SH2-containing partners of tyrosine kinase receptors is a phosphotyrosine phosphatase (PTP), an enzyme that removes the phosphate group from phosphotyrosine. Once tethered via its SH2 group to a ligand-activated, tyrosine-phosphorylated receptor, this particular phosphatase, termed SHP-1, begins to chew away the phosphate groups on tyrosine residues that have enabled the receptor to attract other downstream signaling partners. In this fashion, an enzyme such as SHP-1 creates a negative-feedback loop to shut down further receptor firing. In fact, the SHP-1 phosphatase is responsible for shutting down signaling by a variety of receptors,

among them the receptor for the erythropoietin (EPO) growth factor, which normally responds to EPO by triggering erythropoiesis—red blood cell formation (see Section 6.8 and Figure 6.16). (The catalytic activity of the phosphatase domain of the related SHP-2 protein is increased by >100-fold following binding of its two SH2 groups to phosphotyrosines.)

Some individuals inherit a mutant gene encoding an EPO receptor that lacks the usual docking site for the SHP-1 phosphatase. In individuals whose cells express this mutant receptor, the resulting defective negative-feedback control leads to a hyperactive EPO receptor, and, in turn, to higher-than-normal levels of red cells and thus oxygen-carrying capacity in their blood. In the case of several members of a Finnish family with this inherited genetic defect, this condition seems to have played a key role in their winning Olympic medals in cross-country skiing! Provocatively, expression of SHP-1 is shut down in many leukemias and non-Hodgkin's lymphomas; this permits multiple mitogen receptor molecules to fire excessively in the tumor cells.

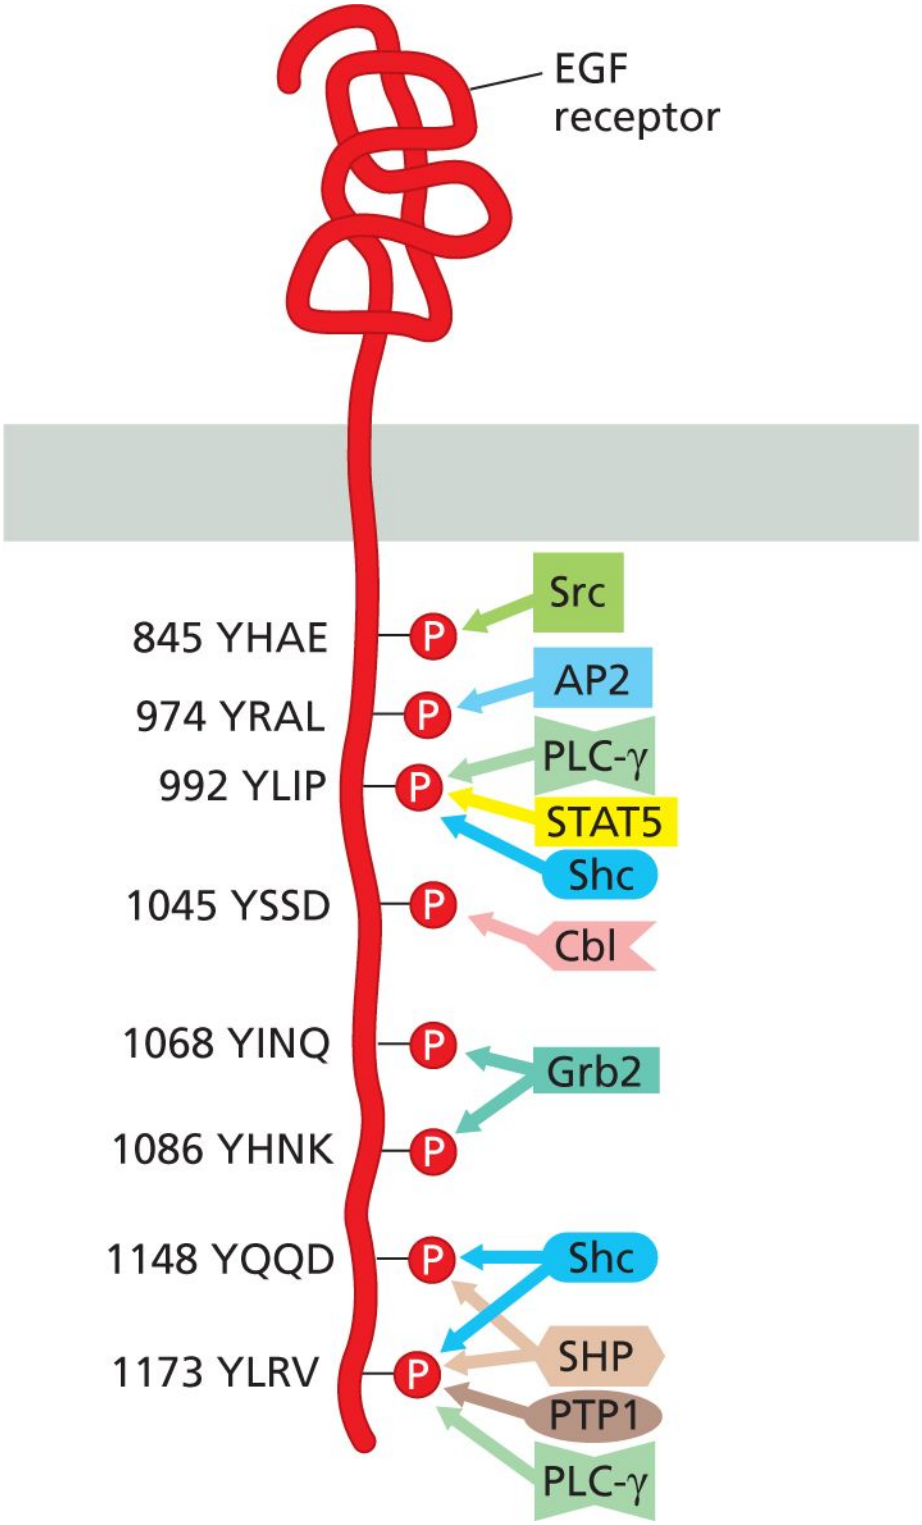
These findings indicated that the catalytic domains of the various proteins and their SH2 groups function as independent structural modules that have been pasted together in various combinations by evolution. The SH2 group(s) borne by each of these proteins allows them to become localized to certain sites within a cell, specifically to those sites that contain particular phosphotyrosine-bearing proteins to which the SH2-containing protein can become tethered.

The discoveries about SH2 groups finally solved the puzzle of how tyrosine kinase receptors are able to emit signals. The story is illustrated schematically in **Figure 6.5A and B**. As a consequence of ligand-induced transphosphorylation, a receptor molecule, such as the PDGF-β receptor, will acquire and display a characteristic array of phosphotyrosine residues on its cytoplasmic tail; likewise, the EGF receptor will display its own spectrum of phosphotyrosines on its cytoplasmic tail. The unique identity of each of the phosphotyrosine residues borne by these tails is dictated by the sequence of amino acid residues flanking the phosphotyrosine on its C-terminal side. These phosphotyrosines become attractive homing sites for various SH2-containing cytoplasmic proteins, specifically, proteins that normally reside in the soluble portion of the cytoplasm (the cytosol) and are therefore free to move from one location to another in the cytoplasm. Consequently, shortly after becoming activated by ligand binding, a growth factor receptor becomes decorated with a specific set of these SH2-containing partner proteins that are attracted to its various phosphotyrosines.



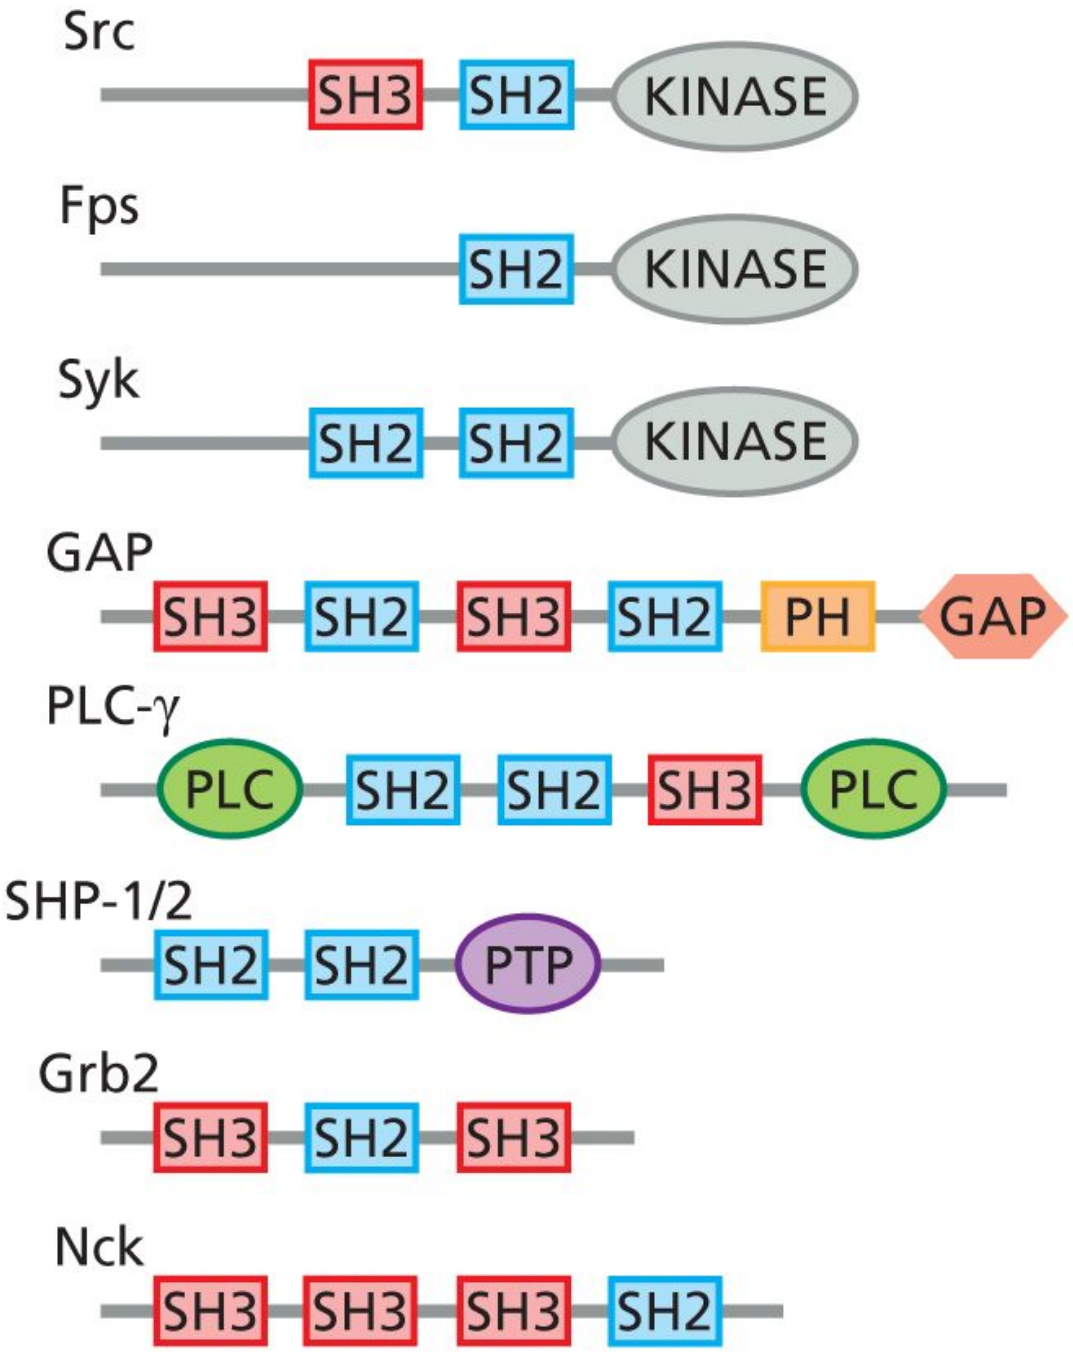
A schematic of the P D G F-beta receptor. The C-terminal domain has seven phosphorylated tyrosine residues attached, at positions 579, 581, 740, 751, 771, 1009 and 1021. In rough correspondence, seven cytoplasmic proteins are shown down the left: Sarc, P I 3 K gamma, N C K alpha, G A P, N C K beta, S

H P 2 and P L C gamma. On the right is a list of six codes: Y I Y V, Y M D M, Y V P M, Y M A P, Y T A V and Y I I P.
(A)



Aschematic of the E G F receptor. The C-terminal domain has eight phosphorylated tyrosine residues attached, at positions 845, 974, 992, 1045, 1068, 1086, 1148 and 1173. In very rough correspondence, eleven cytoplasmic proteins are shown down the right: Sarc, A P 2, P L C gamma, STAT 5, S h c, C b l, G r b 2, S h c again, S H P, P T P 1 and P L C gamma again. On the right is a list of eight codes, one for each position: Y H A E, Y R A L, Y L I P, Y S S D, Y I N Q, Y H N K, Y Q Q D, Y L R V.

(B)



A list of eight proteins showing a sequence of domains for each. For Sarc the sequence is S H 3, S H 2, KINASE. For F p s, the sequence is S H 2, KINASE. For S y k, the sequence is S H 2, S H 2, KINASE. For G A P, the sequences is S H 3, S H 2, S H 3, S H 2, P H, and G A P. For P L C gamma, the sequence is P L C, S H 2, S H 2, S H 3, P L C. For S H P one half, the sequence is S H 2, S H 2, P T P. For G r b 2, the sequence is S H 3, S H 2, S H 3. Finally, for N c k, the sequence is S H 3, S H 3, S H 3, S H 2.

(C)

Figure 6.5 Attraction of signal-transducing proteins by phosphorylated receptors (A) This schematic diagram of a molecule of the platelet-derived growth factor-β (PDGF-β) receptor, which omits its tyrosine kinase domain, reveals a large number of tyrosine residues in its C-terminal domain that undergo phosphorylation following ligand binding and receptor activation. (The positions of these tyrosine residues in the receptor polypeptide chain are indicated by the numbers.) Listed to the left are seven distinct cytoplasmic proteins, each of which can bind via its SH2 domain(s) to one or more of the phosphotyrosines of the PDGF-β receptor. The three amino acid residues (denoted by the single-letter code) that flank each tyrosine (Y) residue on its C-terminal side define the unique binding site recognized by the various SH2 domains of these seven associated proteins. (The "kinase insert region" and associated phosphotyrosine in the middle of the PDGF-β receptor tyrosine kinase domain is not shown.) (B) Similarly, a constellation of phosphotyrosines can be formed after the EGF receptor binds its ligand, often forming heterodimers with the HER2 receptor protein. However, the spectrum of SH2-containing proteins that associates with the EGF-R is quite different, allowing this receptor to activate a set of downstream signaling pathways that are different from those associated with the PDGF-β receptor. Not shown here is the binding of Grb2 to Y1045, Y1101, Y1148, and Y1173, as well as the binding of Shc to Y1045, Y1068, Y1086, and Y1101. (C) Specific multiprotein complexes are formed using domains such as the SH2, SH3, and PH domains, which bind phosphotyrosines, proline-rich sequences, and PIP3, respectively (discussed in Section 6.6). As is indicated here, evolution has shuffled these domains in a modular fashion, attaching them to tyrosine kinase catalytic domains in the case of the first three tyrosine kinases (Src, Fps, and Syk), to a GAP (Ras GTPase-activating protein) domain, to a PLC (phospholipase C) domain, or to a protein tyrosine phosphatase domain (SHP-1, SHP-2). At the bottom are shown two adaptor or "bridging" proteins that contain only SH2 and SH3 domains and lack catalytic domains; each of these adaptors serves as a linker between pairs of other proteins, one of which carries a certain phosphotyrosine (to which an SH2 domain can bind) and the other of which carries a proline-rich domain (to which an SH3 domain can bind; see Figure 6.7). (A and C, adapted from T. Pawson, *Adv. Cancer Res*. 64:87–110, 1994. B, adapted from R. Sordella et al., *Science* 305:1163–1167, 2004.)

For example, one ligand-activated form of the PDGF receptor attracts Src, PI3K, Ras-GAP (which stimulates Ras GTPase activity; refer to Sidebar 5.8), SHP-2 (SH2-containing tyrosine phosphatase 2), and PLC-γ (phospholipase C-γ). Each of these recruited proteins carries at least one SH2 domain (Figure 6.5C), and all of them flock to the PDGF-R after its cytoplasmic tail and a short segment in the middle of its kinase

domain (called a “kinase insert region”) become tyrosine-phosphorylated. Once tethered to the PDGF-R, some of these SH2-containing proteins may then become substrates for tyrosine phosphorylation by the PDGF-R kinase. Yet other proteins serve as bridges by attracting additional proteins to these multiprotein complexes (see Figure 6.7 in the next section). (It remains unclear whether all of these SH2-containing proteins can bind simultaneously to a single ligand-activated PDGF receptor molecule.)

The biochemical diversity of these associated proteins provides us with at least one solution to the question of how a growth factor receptor is able to elicit a diversity of biochemical and biological responses from a cell: each of these associated proteins controls its own downstream signaling cascade, and each of these cascades, in turn, influences a different aspect of cellular behavior. By becoming tethered to a receptor molecule, these SH2-containing proteins are poised to activate their respective cascades. Some of these SH2-bearing proteins function to activate negative-feedback loops that ultimately shut down receptor signaling, as discussed in Sidebar 6.2 and again later in this chapter.

Because the cytoplasmic domains of tyrosine kinase receptors are found near the inner surface of the plasma membrane, the SH2-containing partner proteins attracted to the receptor are brought into close proximity to the plasma membrane and thus close to other molecules that are, for their own reasons, already tethered to this membrane. This close juxtaposition enables various SH2-containing proteins to interact directly with the membrane-associated proteins and phospholipids, thereby generating a variety of biochemical signals that can thereafter be transmitted to various downstream signal-transducing cascades.

For example, the Ras GTPase-activating protein (Ras-GAP), having become attached to a phosphorylated receptor, is tethered in close proximity to Ras proteins, many of which are permanently anchored to the plasma membrane via their C-terminal lipid tails. This allows Ras-GAP to interact with nearby Ras molecules, stimulating them to hydrolyze their bound GTPs and thereby convert from an active to an inactive signaling state (see Figure 5.24).

Similarly, when phosphatidylinositol 3-kinase (PI3K) becomes tethered via its SH2 group near the plasma membrane, it is able to reach over and phosphorylate inositol lipids embedded in the membrane; we return to this enzyme and its mechanism of action in Section 6.6. Yet another example is provided by phospholipase C-γ (PLC-γ), which, when juxtaposed to the plasma membrane via receptor tethering, is able to cleave a membrane-associated phospholipid [phosphatidylinositol (4,5)-diphosphate, or PIP2] into two products (IP3 and DAG; see Figure 6.11), each of which, on its own, has potent signaling powers. The point here is that many reactions become possible (or

can proceed at much higher rates) when enzymes and their substrates are brought into close proximity through tethering of these enzymes to phosphorylated receptors.

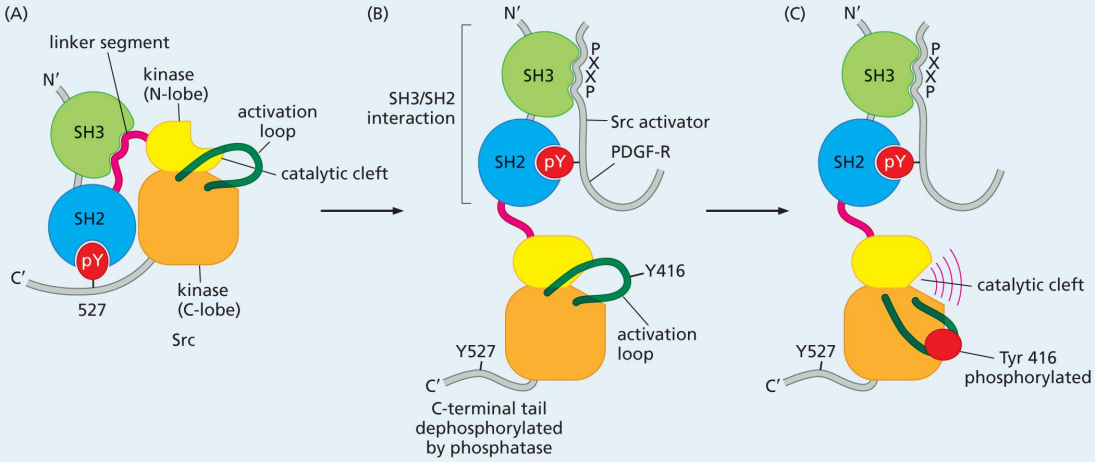
The discovery of SH2 domains and their presence in a diverse array of signaling proteins solved a long-standing paradox. The dozens of distinct RTKs expressed by human cells were known to carry essentially identical tyrosine kinase signal-emitting domains, yet these receptors, when activated by ligand binding, clearly induced very different cellular responses. This puzzle was resolved when it was realized that, following ligand binding, each RTK acquires its own particular array of phosphotyrosine-containing peptides (see Figure 6.5A and B), enabling it to attract its own combination of downstream signaling partners. In recent years, systematic surveys have been undertaken to reveal the full range of interactions between RTKs, such as the EGF receptor, and the various SH2 domain–containing proteins in the cytoplasm (**Supplementary Sidebar 6.2**). In the longer term, such surveys will provide the databases that will make it possible to construct mechanistic models that help to predict how individual receptors, once activated by their ligands, operate to change the biochemistry and physiology of a cell. Nonetheless, even with this information in hand, a significant number of other variables complicate attempts to understand precisely how individual ligand-activated RTKs function (**Supplementary Sidebar 6.2**).

The last of the sequence motifs present in Src (see Figure 6.3)—SH3 domains—were initially found to bind specifically to certain proline-rich sequence domains in partner proteins; these proline-rich sequences thus serve as the ligands of the SH3 domains (see Figure 6.4C). (A rapidly growing minority of SH3 groups has been found to recognize ligands of a quite different structure.) These SH3 domains are a relatively ancient invention (apparently originating in an array of protozoa more than one billion years ago), since there are at least 28 of them in various proteins of the yeast *S. cerevisiae*. The SH2 domain, in contrast, seems to be of more recent vintage, having been invented and subsequently diversified possibly at the same time as tyrosine phosphorylation came into widespread use—perhaps 900 million years ago when the first metazoa arose.

In the specific case of the SH3 domain of Src, there is evidence that this domain is used to recognize and bind certain proline-rich substrates, which can then be phosphorylated by Src's kinase activity. Yet other evidence points to a proline-rich linker domain within Src itself, to which Src's SH3 domain associates, creating intramolecular binding (**Sidebar 6.3**). Through analyses of the human genome sequence, almost 300 distinct human SH3 domains have been documented, each part of a larger protein.

Sidebar 6.3 The SH2 and SH3 domains of Src both have alternative functions

We have portrayed SH2 as a protein domain that enables its carrier to recognize and bind to other phosphotyrosine-containing partner proteins, thereby forming bimolecular complexes. In tyrosine kinases such as Src, however, the SH2 group can also play a quite different role. Like most signaling molecules, the Src kinase is usually held in a functionally silent configuration. It is kept in this inactive state by a negative regulatory domain of Src—a stretch of polypeptide that lies draped across the catalytic site of Src and blocks access to the substrates of this kinase. This obstructing domain (sometimes called an "activation loop" (*dark green*); see **Supplementary Sidebar 5.6**) is held in place, in part, through the actions of the Src SH2 group, which recognizes and binds a phosphotyrosine in position 527 of Src itself. Hence, this SH2 group is forming an *intra*molecular rather than an *inter*molecular bridge (**Figure 6.6A**).



A three-part figure describing the Structure and function of Sarc. Following the N terminal, Sarc contains a green S H 3 domain, a complex consisting of a blue S H 2 domain and a red p Y, a red linker segment, a yellow kinase N lobe, an orange kinase C lobe with an attached activation loop, and finally the C terminal. In Part A, the p Y is attached to position 527 on the C terminal and the S H 3 is attached to the linker segment. The catalytic cleft between the two kinase lobes is closed by the positioning of the activation loop. In Part B, the p Y is no longer attached to the C terminal, and the S H 3 is no longer attached to the linker segment. Instead, both are attached to a Sarc activator in the form of a P D G F R. A position on the activation loop is marked as Y416. The C-terminal tail is dephosphorylated by phosphatase and position 527 is marked as Y527. In Part C, position 416 is marked as Tyr 416 phosphorylated, and the activation looped has moved downward to open up the catalytic cleft.

Figure 6.6 Structure and function of Src (A) The SH2 group of Src (*blue*) normally binds in an intramolecular fashion to a phosphotyrosine residue (pY; *red*) at position 527 near the C-terminus of Src. This binding causes the catalytic cleft

of Src, which is located between the N-lobe and the C-lobe of the kinase domain (*yellow, light orange*), to be obstructed. At the same time, the SH3 (*light green*) domain binds a proline-rich portion in the linker segment (*dark red*) between the N-lobe of the kinase domain and the SH2 domain. (B) However, when a domain of the PDGF receptor (indicated here as a "Src activator") becomes phosphorylated, one of its phosphotyrosines (*red*) serves as a ligand for this SH2 group of Src, causing the SH2 to switch from intramolecular binding to intermolecular binding. Concomitantly, the SH3 group of Src detaches from its intramolecular binding to bind a proline-rich domain (PXXP) on the receptor. These changes open up the catalytic cleft of Src, placing it in a configuration that poises it to fire. (C) The full tyrosine kinase activity of Src only occurs following a final phosphorylation of tyrosine 416, which moves an obstructing oligopeptide activation loop (*dark green*) out of the way of the catalytic cleft; the formation of Y416 may occur in dimerized Src molecules that transphosphorylate one another. (Adapted from W. Xu et al., *Mol. Cell* 3:629–638, 1999. With permission from Elsevier.)

Some receptors, such as the PDGF receptor, may become activated by ligand binding and display phosphotyrosines in their cytoplasmic domains that are also attractive binding sites for the SH2 group of Src. As a consequence, the fickle Src SH2 group breaks its intramolecular bond and forms an intermolecular bond with the PDGF receptor instead; this results in the tethering of Src to the PDGF receptor (Figure 6.6B). Concomitantly, the SH3 group of Src breaks its intramolecular association with the linker segment of Src and binds to an oligopeptide in the PDGF receptor. Now Src's catalytic cleft shifts into an active configuration and, following phosphorylation of its activation loop (*red*), begins to phosphorylate its clientele of substrates, thereby amplifying the signal broadcast by the PDGF receptor (Figure 6.6C).

The Src oncoprotein specified by Rous sarcoma virus is a mutant form of the normal c-Src protein, in which the C-terminal oligopeptide domain containing the tyrosine 527 residue has been replaced by another, unrelated amino acid sequence. As a consequence, a phosphotyrosine can never be formed at this site and the intramolecular inhibitory loop cannot form and, in turn, obstruct the Src catalytic site. The viral oncoprotein (v-Src) is therefore given a free hand to fire constitutively. A similar mutant Src, in which the six C-terminal amino acids are deleted (including tyrosine 527), has been reported in liver metastases of human colon carcinomas. While the Src kinase is hyperactive in many colon carcinomas, this is one of the very rare examples of a mutant, structurally altered Src in human cancers.

The SH2 and SH3 domains were the first of a series of specialized protein domains to be recognized and cataloged (see **Supplementary Sidebar 6.3**). Each of these

specialized domains is able to recognize and bind a specific sequence or structure present in a partner molecule. Some of these specialized domains recognize and bind phosphoserine or phosphothreonine on partner proteins, while others bind to phosphorylated forms of certain membrane lipids (**Table 6.2**). These partner-binding domains are critical to ensure the specific, focused intercommunication between appropriate pairs of signaling molecules operating throughout the intracellular signaling circuitry.

Table 6.2 Binding domains that are carried by various proteins[a]

Name of domain	**Ligand**	**Examples of proteins carrying this domain**
SH2	phosphotyrosine	Src (tyrosine kinase), Grb2 (adaptor protein), Shc (scaffolding protein), SHP-2 (phosphatase), Cbl (ubiquitylation)
PTB	phosphotyrosine	Shc (adaptor protein), IRS-1 (adaptor for insulin RTK signaling), X11 (neuronal protein)
SH3	proline-rich	Src (tyrosine kinase), Crk (adaptor protein), Grb2 (adaptor protein)
14-3-3	phosphoserine	Cdc25 (CDK phosphatase), Bad (apoptosis regulator), Raf (Ser/Thr kinase), PKC (protein kinase C Ser/Thr kinase)
Bromo	acetylated lysine	P/CAF (transcription co-factor), chromatin proteins
PH[b]	phosphorylated inositides	PLC-δ (phospholipase C-δ), Akt/PKB (Ser/Thr kinase), BTK

Taken together, these various domains illustrate how the lines of communication within a cell are restricted, since the ability of signaling molecules to physically associate in highly specific ways with target molecules ensures that signals are passed only to these intended targets and not to other proteins within the cell. In addition, examination of an array of signaling proteins has revealed that these various domains have been used as modules, being assembled in different combinations through evolution to ensure the specificity of a variety of intermolecular interactions (see Figure 6.5C).

The discovery of SH2 groups also explained how Src, the original oncoprotein, operates within the normal cell, and how Rous sarcoma virus has reconfigured the structure of Src, making it into an oncoprotein (see Sidebar 6.3).

OceanofPDF.com

Glossary

stereochemistry
: Description of the three-dimensional structure of a molecule (such as a protein or drug) and the influence that this structure exerts on the chemical behavior or biochemical function of the molecule.

phosphatase
: An enzyme that removes phosphate groups from phosphorylated substrates, such as the phosphoamino acid residues in a protein or the phosphorylated inositol of a phospholipid.

erythropoiesis
: Process by which red blood cells are formed.

cytosol
: Portion of the cytoplasm that contains soluble material untethered to either cytoskeleton or membranes including those associated with organelles.

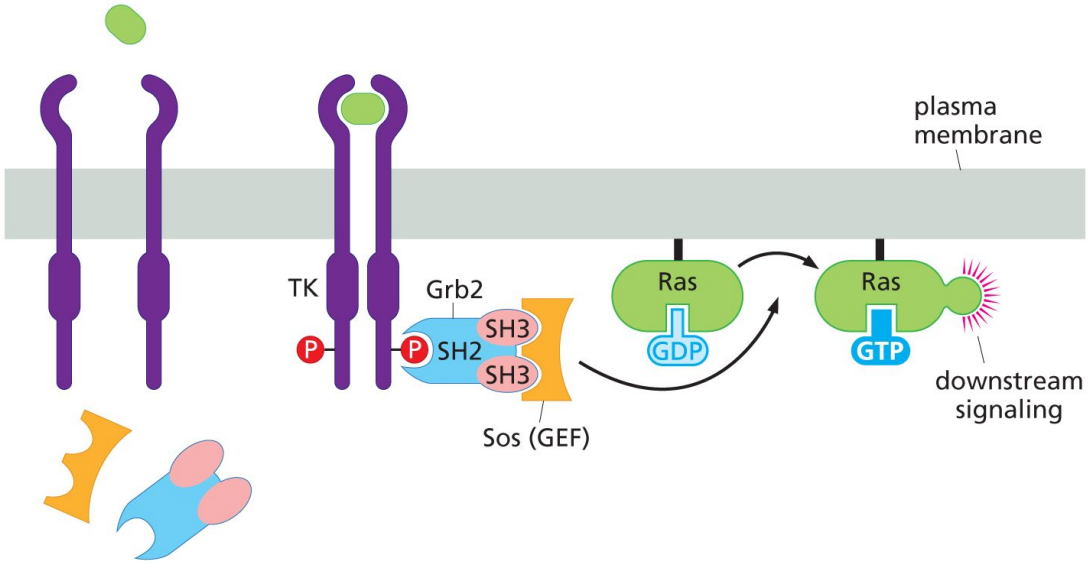
6.4 SH2 and SH3 groups explain how growth factor receptors activate Ras and acquire signaling specificity

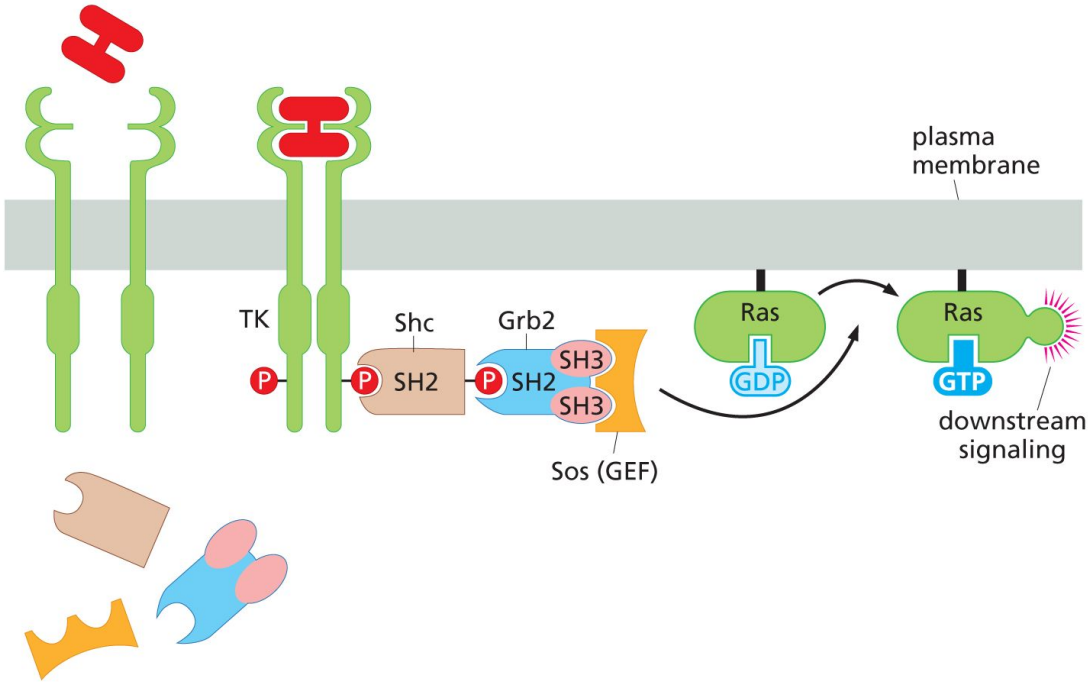
The discovery of SH2 and SH3 groups and their mechanisms of action made it possible to solve several important problems. The biochemical clues were now in place to explain precisely how the receptor → Sos → Ras cascade operates.

The final clues came from analyzing the structure of Grb2. It contains two SH3 groups and one SH2 group (Figure 6.5C). Its SH3 domains have an affinity for two distinct proline-rich sequences present in Sos, while its SH2 sequence associates with a phosphotyrosine present on the C-terminus of many growth factor–activated receptors. Consequently, Sos, which seems usually to float freely in the cytoplasm, now becomes tethered via the Grb2 linker molecule to the receptor (**Figure 6.7A**).



A diagram shows one way of achieving the association of S o s with ligand-activated growth factor receptors. A receptor is activated by a ligand. Simultaneously, two S H 3 domains of a G r b 2 bind to an S o s while the G r b twos S H 2 domain binds to a phosphotyrosine located on the receptor’s C-terminal tail, below the tyrosine kinase domain. The complex the converts an R a s with G D P to one with G T P, which begins downstream signaling.

(A)



A diagram shows another way of achieving the association of S o s with ligand-activated growth factor receptors. A receptor is activated by a ligand. Simultaneously, two S H 3 domains of a G r b 2 bind to an S o s while the G r b twos S H 2 domain binds to a phosphotyrosine located on S h c. The S h cees S H 2 domain, in turn, binds to a phosphotyrosine located on the receptor's C-terminal tail, below the tyrosine kinase domain. The complex then converts an R a s with G D P to one with G T P, which begins downstream signaling.

(B)

Figure 6.7 Intermolecular links forged by the Grb2 and Shc bridging proteins (A) The association of Sos, the Ras guanine nucleotide exchange factor (GEF), with ligand-activated growth factor receptors is achieved by bridging proteins, such as Grb2, shown here. The two SH3 domains of Grb2 (*pink*) bind to proline-rich domains of Sos (*orange*), while its SH2 domain (*light blue*) binds to a phosphotyrosine located on the C-terminal tail of a receptor. (B) An alternative mode of association can be achieved through a collaboration between two bridging proteins, Grb2 and Shc. Grb2 uses its SH3 domains to bind Sos and its SH2 domain to bind a phosphotyrosine on Shc (*beige*); the latter uses its own SH2 domain to bind a phosphotyrosine on a ligand-activated receptor. (Phosphorylation of Shc is achieved by Src-like tyrosine kinases.) (Adapted from G.M. Cooper,

Oncogenes, 2nd ed. Sudbury, MA: Jones and Bartlett, 1995. www.jblearning.com. Reprinted with permission from Jones and Bartlett.)

Detailed analysis of the structures of Grb2 and similarly configured proteins (for example, Crk) indicates that they carry no other functional domains beyond their SH2 and SH3 domains. Apparently, these adaptor proteins are nothing more than bridge builders designed specifically to link other proteins to one another. (An alternative bridging, also shown in Figure 6.7B, can be achieved when a growth factor receptor associates with Sos via Grb2 and Shc.)

Once Sos becomes anchored via Grb2 (or via Grb2 + Shc) to a receptor, it is brought into close proximity with Ras proteins, most of which seem to be permanently tethered to the inner face of the plasma membrane. Sos is then physically well positioned to interact directly with these Ras molecules, inducing them to release GDPs and bind instead GTPs. This guanine nucleotide exchange causes the activation of Ras protein signaling. Hence, the biochemically defined pathway could now be drawn like this:

Receptor → Grb2 → Sos → Ras or Receptor → Shc → Grb2 → Sos → Ras

Because a diverse group of signaling proteins become attracted to ligand-activated receptors (see, for example, Figure 6.5A and B), the Sos–Ras pathway represents only one of a number of signaling cascades radiating from growth factor receptors. Moreover, the SH2 and SH3 groups, as described here, represent only a small subset of the domains within intracellular proteins that are responsible for protein:protein interactions (**Supplementary Sidebar 6.3**).

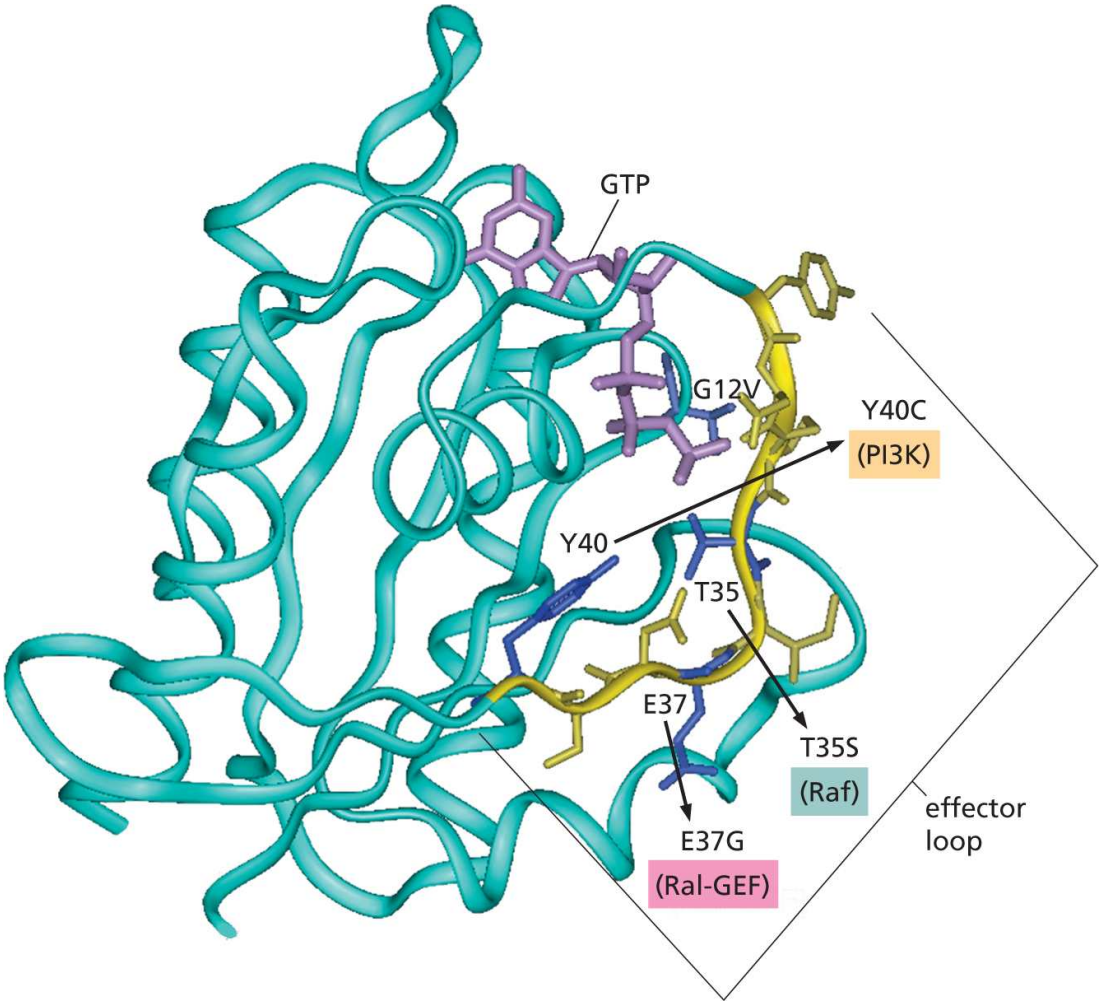
6.5 Ras-regulated signaling pathways: A cascade of kinases forms one of three important signaling pathways downstream of Ras

The multiple cellular responses that a growth factor elicits could now be explained by the fact that its *cognate* receptor (that is, the receptor that specifically binds it) is able to activate a specific combination of downstream signaling pathways. Each of these pathways might be responsible for inducing, in turn, one or another of the multiple biological changes occurring after cells are stimulated by this particular growth factor. Moreover, exaggerated forms of this signaling might well be operating in cancer cells that experience continuous growth factor stimulation because of a mutant, constitutively activated receptor or an autocrine signaling loop (see Figure 5.8A and C).

This branching of downstream pathways did not, however, explain precisely how the mutant Ras oncoprotein (which itself represents only one of the multiple pathways downstream of growth factor receptors) is able to evoke a number of distinct changes in cells. Here, once again, signal transduction biochemistry provided critical insights. We now know that at least three major downstream signaling cascades radiate from the Ras protein. (Precisely where within a cell these signals are transmitted remains unclear; see **Supplementary Sidebar 6.4**.). Their diverse actions help to explain how the Ras oncoprotein causes so many distinct changes in cell behavior.

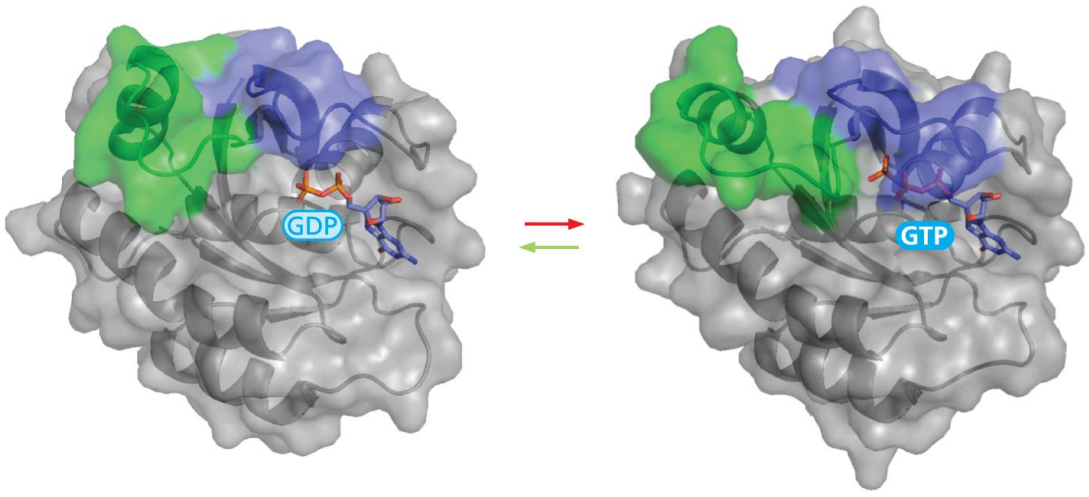
The layout of these downstream signaling pathways was mapped through a combination of yeast genetics and biochemical analyses of mammalian cells. These approaches made it clear that when Ras binds GTP, two of its “switch domains” shift (see Figure 5.25B), enabling its effector loop (**Figure 6.8**) to interact physically with several alternative downstream signaling partners that are known collectively as Ras *effectors*, that is, the proteins that carry out the actual work of Ras. Each of these effectors binds quite tightly to the effector loop of the GTP-bound form of Ras protein while having little affinity for the loop presented by its GDP-bound form. The first of these Ras effectors to be discovered was the Raf kinase (**Figure 6.9A**). Like the great majority of protein kinases in the cell, Raf phosphorylates substrate proteins on their serine and threonine residues. Long before its association with Ras was uncovered, the

Raf kinase had already been encountered as the oncoprotein specified by both a rapidly transforming murine retrovirus and, in homologous form, a chicken retrovirus.



A ribbon diagram of the R a s protein, with the effector loop on the right. Near by, G T P is shown with a G 12 V at one end. On the effector loop, three residues are shown, along with the effects of substitutions. Replacing the Y40 residue with Y40C leads to interaction with P I 3 K. Replacing T 35 with T 35 S leads to interaction with R a f. And replacing E 37 with E 37 G leads to interaction with R a l G E F.

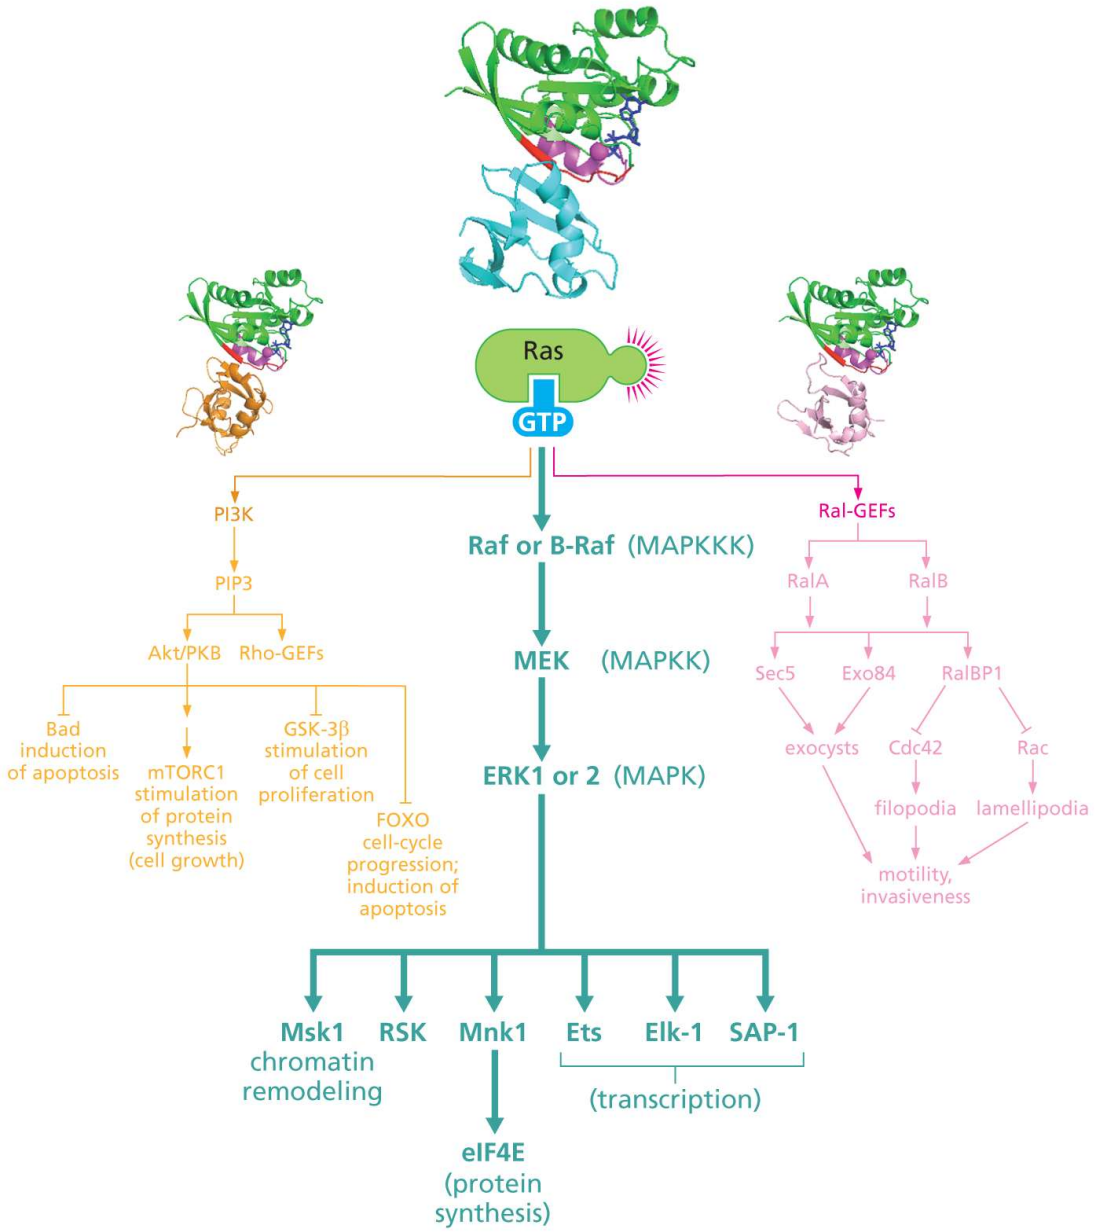
(A)



A diagram of transitions back and forth between two space filling models of R a s: inactive G D P-bound on the left and active G T P-bound on the right. With the transition, the conformation of the protein changes slightly.

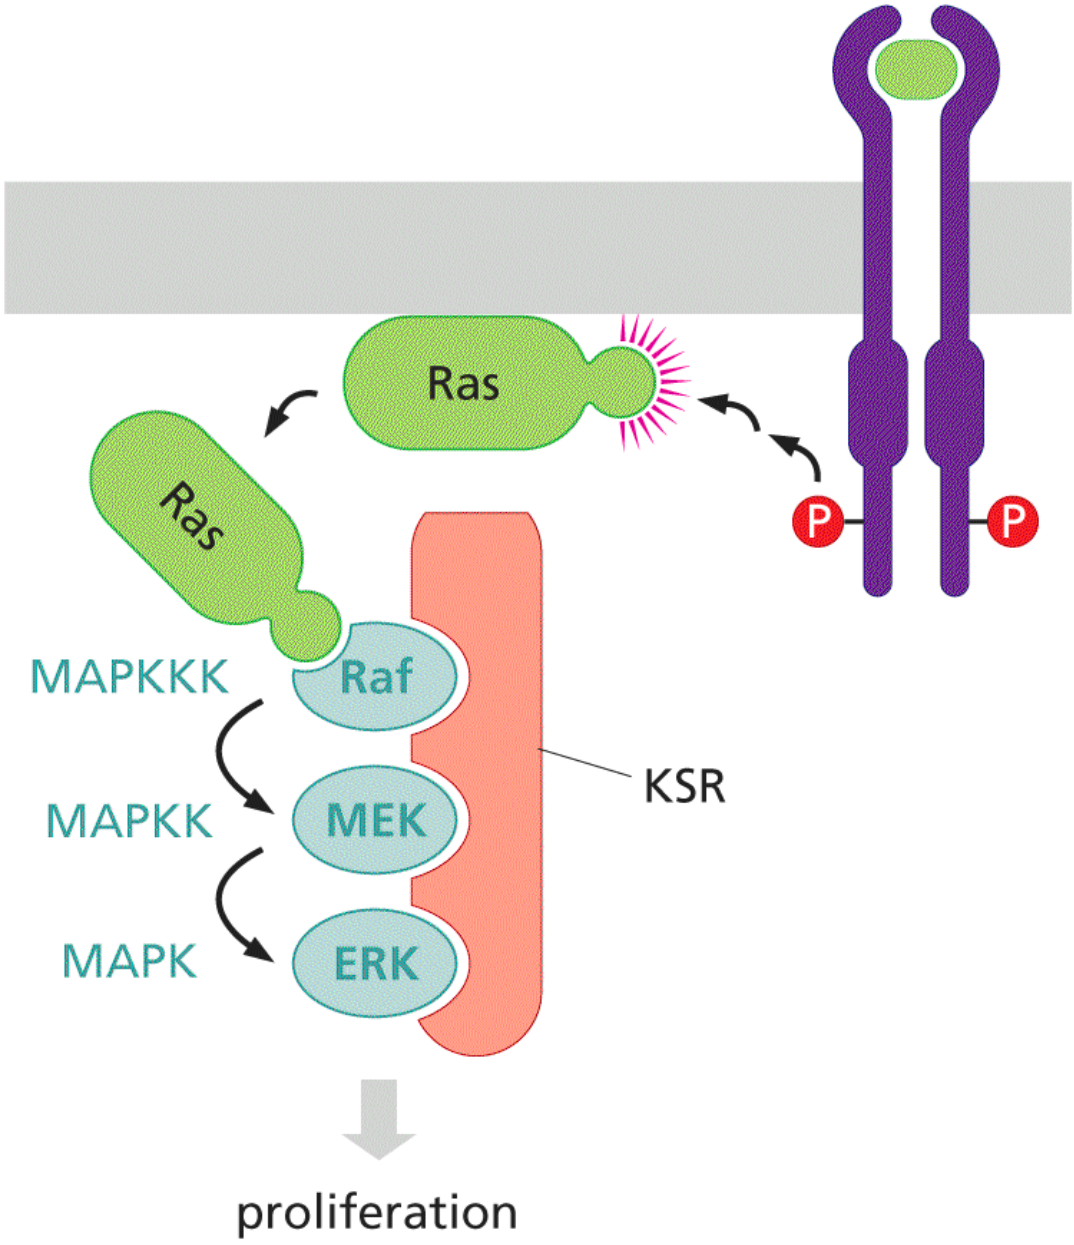
(B)

Figure 6.8 The Ras effector loop (A) The crystallographic structure of the Ras protein, viewed from a different angle than those illustrated in Figure 5.25, is depicted here in a ribbon diagram (*largely aquamarine*). The guanine nucleotide (*light purple stick figure*) is shown together with the nearby glycine residue, which, upon replacement by a valine in oncogenic Ras, causes inactivation of the GTPase activity (G12V). The effector loop (*yellow*) interacts with at least three important downstream effectors of Ras. Experimentally introduced amino acid substitutions (*arrows*) affecting three residues in the effector loop create three alternative forms of the Ras protein that interact preferentially with either PI3 kinase, Raf/B-Raf, or Ral-GEF. (B) In these space-filling models, the stereochemical shift of the effector domain of Ras (*green*, *purple*) enables Ras to interact physically with at least three of its downstream effectors listed in panel A. (A, Courtesy of R. Latek and A. Rangarajan, adapted from data in U. Krengel et al., *Cell* 62:539–548, 1990. B, Courtesy of P. Marinec and F. McCormick.)



A diagram shows three pathways which all begin with a G T P activated R a s. In the middle one, which is emphasized, R a s activates R a f or B R a f (an M A P K K K). The latter activates M E K (an M A P K K), which in turn activates E R K 1 or E R K 2 (an M A P K). E R K 1 or 2 then activates one or more of the following: M s k 1, R S K, M n k 1, E t s, E l k-1, and S A P-1. M s k 1 is labeled chromatin remodeling. E t s, E l k-1, and S A P-1 are labeled transcription. M n k 1 activates e I F 4 E, which is labeled protein synthesis. Ir another pathway, G T P activated R a s activates P I 3 K. The signal cascade passes through several other molecules that may result in induction of apoptosis, cell growth, cell proliferation, and or cell cyle progression. In the third pathway, G T P activated R a s activates R a l-G E effs. The signal

cascade passes through several molecules ulitimately causing motility and invasiveness.
(A)



A diagram shows phosphotyrosine from the C-terminal tail of a receptor activating R a s. The pathway featured in Part A then unfolds, with the R a s activating a cascade between R a f, M E K and E R K which are all attached tc a K S R, a vertically elongated molecule. Proliferation follows.

(B)

Figure 6.9 The Ras → Raf → MAP kinase pathway (A) This multi-kinase signaling cascade (*aquamarine*, *center*) is one of a series of similarly organized pathways in mammalian cells that have the overall plan MAPKKK → MAPKK → MAPK. In this particular case, Ras activates the Raf kinase (a MAPKKK), the latter proceeds to phosphorylate and activate MEK (a MAPKK), and MEK then phosphorylates and activates ERK1 and ERK2 (MAPKs). (The two other key effector pathways of Ras shown here will be analyzed further in Figures 6.10 and 6.15.) ERK1/2 can then phosphorylate kinases in the cytoplasm that regulate translation as well as transcription factors in the nucleus. The bimolecular complex, portrayed as a ribbon structure (*above*), illustrates the interaction of the effector domain of Ras (*red*, *purple*) with the Ras-binding domain of Raf (*aquamarine*). (B) Multi-kinase signaling cascades in eukaryotic cells are often assembled by scaffolding proteins that ensure the direct physical juxtaposition of one kinase to its downstream kinase substrate. The KSR scaffold shown here organizes the highly efficient signal transduction of Raf to ERK. (A, adapted from M.E. Pacold et al., *Cell* 103:931–943, 2000; N. Nassar et al., *Nature* 375:554–560, 1995; and L. Huang et al., *Nat. Struct. Biol*. 5:422–426, 1998. B, adapted from M.C. Good, J.G. Zalatan and W.A. Lim, *Science* 332, 680–686, 2011.)

The activation of Raf by Ras depends upon the relocalization of Raf within the cytoplasm. Recall that Ras proteins are always anchored to a membrane, usually the inner surface of the plasma membrane, through their C-terminal hydrophobic tails. Once it has bound GTP (see Figure 6.9A), the affinity of Ras for Raf increases by three orders of magnitude, enabling Ras to bind Raf relatively tightly, doing so via the Ras effector loop. Before this association, Raf is found in the cytosol; thereafter, Raf becomes tethered via Ras to the plasma membrane (or, in certain cases, to another cytoplasmic membrane). Moreover, as has recently been determined, both Ras and Raf function as dimeric proteins, and the dimerization of Raf may even depend on the prior dimerization of Ras molecules (**Supplementary Sidebar 6.5**). These interactions are further influenced by the fact that the intracellular localization of Ras is affected by whether it has bound GDP or GTP (see **Supplementary Sidebar 6.4**).

The physical association of Raf with Ras appears to be facilitated by additional proteins that act as scaffolds to hold them together (Figure 6.9B); yet others trigger the phosphorylation and dephosphorylation of key amino acid residues on Raf, altering its three-dimensional configuration. Raf now acquires active signaling powers and proceeds to phosphorylate and thereby activate a second kinase known as MEK. (MEK is actually a “dual-specificity kinase,” that is, one that can phosphorylate serine/threonine residues as well as tyrosine residues.) MEK uses these powers to phosphorylate two other kinases, the *e*xtracellular signal–*r*egulated *k*inases 1 and 2, commonly referred to as ERK1 and ERK2. Once phosphorylated and activated, each of these ERKs then phosphorylates substrates that, in turn, regulate various cellular

processes including transcription of genes promoting cell proliferation as described below (see Figure 6.9A). Much of the rapidity of activation of the Raf-MEK-ERK signaling cascade is due to the fact that scaffolding proteins hold these kinase components together, ensuring essentially instantaneous access to a downstream kinase substrate by its upstream kinase activator (see Figure 6.9B).

This type of kinase signaling cascade has been given the generic name of a MAPK (mitogen-activated protein kinase) pathway. In fact, there are at least four other signaling cascades in mammalian cells organized in a manner similar to the one described here. In the present case, ERK1 and ERK2 at the bottom of the Raf-initiated cascade are considered MAPKs. The kinase responsible for phosphorylating a MAPK is termed generically a MAPKK; in the case of the particular cascade studied here, this role is played by MEK. The kinase responsible for phosphorylating a MAPKK is therefore called generically a MAPKKK (see Figure 6.9A); in this scheme, Raf is classified as a MAPKKK.

Note that in these various kinase cascades, phosphorylation of kinase B by kinase A always results in the functional activation of kinase B. For example, when MEK is phosphorylated by Raf, MEK becomes activated as a signal-emitting kinase. Such serine/threonine phosphorylation therefore has a very different consequence from the phosphorylation of tyrosine residues carried by the cytoplasmic tails of growth factor receptors. The phosphotyrosines on these receptors attract signaling partners and are therefore responsible for the *relocalization* of partner proteins; in contrast, the phosphate groups attached to MEK by Raf cause a stereochemical shift in its structure that results in its *functional activation* as a kinase.

Once activated, an ERK kinase at the bottom of this cascade not only phosphorylates cytoplasmic substrates, but can also translocate to the nucleus, where it causes the phosphorylation of transcription factors; some of the latter then initiate the immediate and delayed early gene responses. For example, as indicated in Figure 6.9A, ERK can phosphorylate several transcription factors (as examples, Ets, Elk-1, and SAP-1) directly and, in addition, phosphorylate and thereby activate other kinases, which proceed to phosphorylate and activate yet other transcription factors. These downstream kinases phosphorylate two chromatin-associated proteins (HMG-14 and histone H3), creating modifications that place the chromatin in a configuration that is more hospitable to transcription (see Section 1.8). In the cytoplasm, the Mnk1 kinase, a cytoplasmic substrate of ERK1 and ERK2, phosphorylates the translation initiation factor eIF4E, thereby helping to activate the cellular machinery responsible for protein synthesis.

Once the ERKs phosphorylate the Ets transcription factor, the latter can then proceed to stimulate the expression of important growth-regulating genes, such as those specifying heparin-binding EGF (HB-EGF), cyclin D1, Fos, and $p21^{Waf1}$. (The

functions of the last three are described in detail in Chapter 8.) The actual number of distinct ERK substrates is vastly larger: a 2017 study undertook to enumerate those for which there was reasonably compelling biochemical evidence and came up with 2507 protein targets!

Especially important among the genes induced by the Raf → MEK → ERK pathway are the two immediate early genes encoding the Fos and Jun transcription factors. Once synthesized, these two proteins can associate with one another to form AP-1, a widely acting heterodimeric transcription factor that is often found in hyperactivated form in cancer cells. The special importance and influence of Fos and Jun is indicated by the fact that each was originally identified as the product of a retrovirus-associated oncogene (see Table 3.3).

The Ras → Raf → MEK → ERK pathway is only one of several downstream signaling cascades that are activated by the GTP-bound Ras proteins (see Figures 6.9, 6.10, and 6.15). The central importance of this kinase cascade is indicated by the fact that in a number of cell types, the Raf protein kinase, when introduced into cells in mutant, oncogenic form, can evoke most of the transformation phenotypes that are induced by the Ras oncoprotein itself. Hence, in such cells, the pathway downstream of Raf is responsible for the lion's share of the transforming powers of Ras oncoproteins. In addition to activating a number of growth-promoting genes, as described above, this pathway confers anchorage independence and loss of contact inhibition. It also contributes to the profound change in cell shape that is associated with transformation by a *ras* oncogene.

In certain cancers, the signaling pathway lying downstream of Raf may be strongly activated without any prior stimulation by Ras. Thus in ~50% of human melanomas a mutant form of B-Raf, a close cousin and functional analog of Raf, is found to carry an amino acid substitution causing a ~500-fold increase in kinase activity. [The mutation commonly occurring in melanomas causes B-Raf's activation loop, which usually obstructs access to the catalytic cleft of this enzyme (as seen in other kinases, see **Supplementary Sidebar 5.6**), to swing out of the way.] In about one-third of the remaining melanomas, mutant alleles encoding activated N-Ras oncoproteins can be found. In human tumors overall, a *ras* oncogene is rarely found to coexist with mutant alleles of *B-raf*, providing evidence that these two oncogenes have overlapping functions and thus are partially redundant with one another.

Various explanations have been proposed to rationalize why multi-kinase cascades like this one are used in a variety of signaling circuits throughout the cell. In fact, versions of these cascades are already apparent in single-cell eukaryotes, such as yeast, in which they are employed to regulate a variety of cell-biological processes. These kinase cascades—all exhibiting the MAPKKK–MAPKK–MAPK organization—share in common another striking feature that ensures their rapid and efficient firing: the

participating kinases are physically held together by scaffolding proteins (see Figure 6.9B). These proteins, such as the KSR featured in this figure, ensure that the signals flowing through the kinase cascades do so rapidly, and that the participating kinases are able to find their substrates instantaneously rather than depending on diffusion-dependent processes to do so. (A second aspect of kinase firing involving dimerization is discussed in **Supplementary Sidebar 6.5**.)

Of note, versions of ERK that are unable to dimerize and associate with the cytoplasmic scaffolding proteins in response to Ras or Raf signaling cripple the cell transformation usually induced by these oncoproteins; similarly, ERK proteins that are unable to translocate as monomers to the nucleus following their activation in the cytoplasm also preclude transformation by these oncogene-encoded proteins

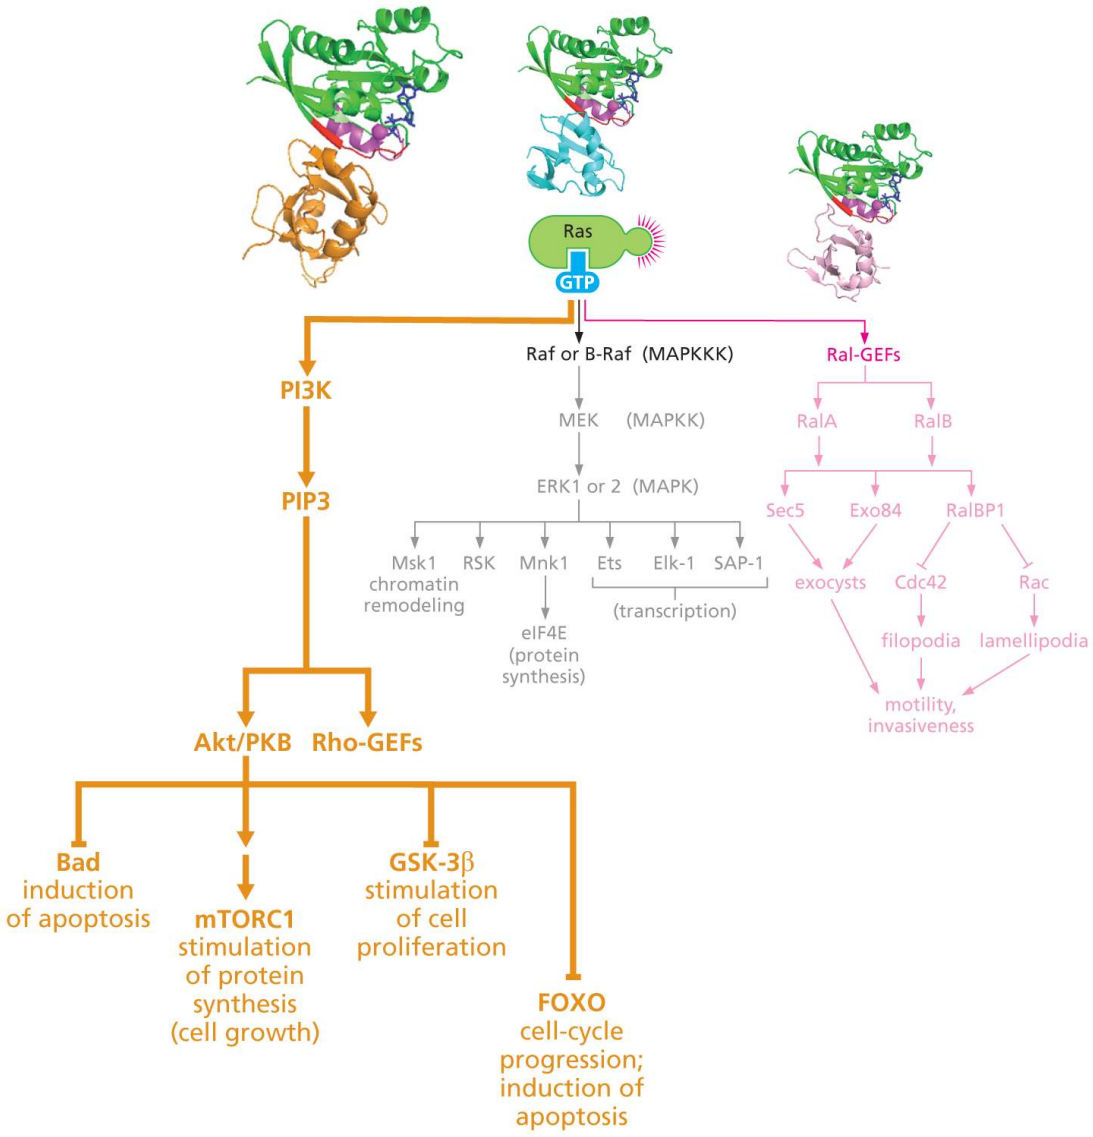
6.6 Ras-regulated signaling pathways: a second downstream pathway controls inositol lipids and the Akt/PKB kinase

A second important downstream effector of the Ras protein enables Ras to evoke other, quite distinct cellular responses (**Figure 6.10**). In the context of cancer, the most important of these is a suppression of apoptosis. This anti-apoptotic effect is especially critical for cancer cells, since many of them are poised on the brink of activating this cell suicide program, a subject covered in detail in Chapter 9.

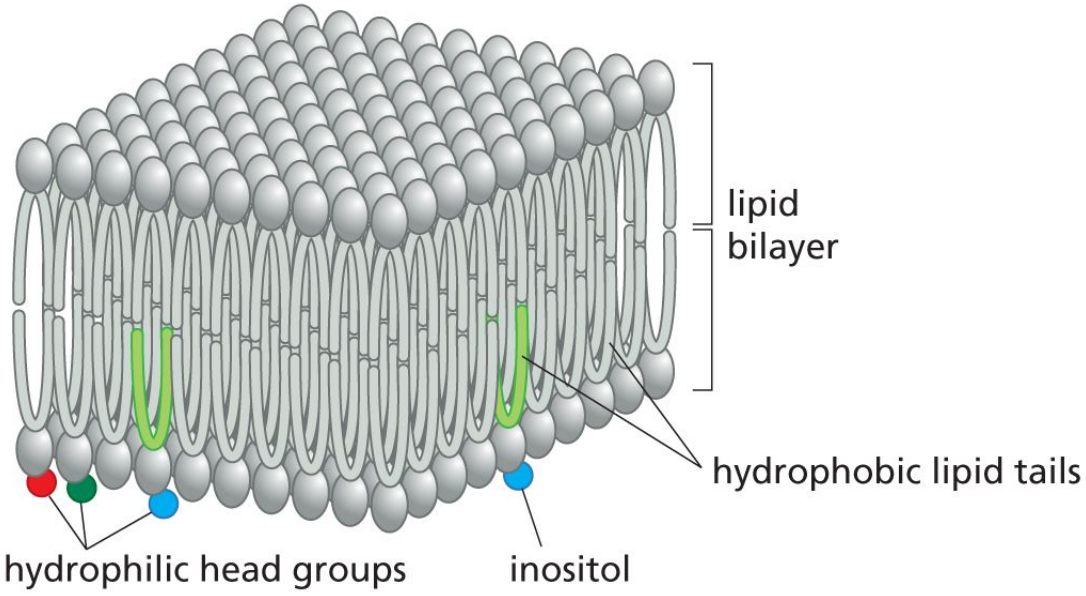


Three pathways all begin with a G T P activated R a s. In the left one, which is emphasized, R a s activates P I 3 K, which leads to the formation of PIP 3. This leads in turn to A k t (also called P K B) and Rho-G E effs. A k t inhibits Bads induction of apoptosis, it promotes m T O R C ones stimulation of protein synthesis (cell growth), it inhibits G S K - betas stimulation of cell proliferation, and it inhibits F O X O cell-cycle progression and induction of apoptosis. In another pathway, G T P activated R a s activates R a f or B R a f. In the third pathway, G T P activated R a s activate R a l-G E effs.

Figure 6.10 The PI3 kinase pathway A second effector pathway of Ras (*dark orange*, *left*) derives from its ability to associate with and activate phosphatidylinositol 3-kinase (PI3K), with the resulting formation of phosphatidylinositol (3,4,5)-triphosphate (PIP3). This leads in turn to the tethering

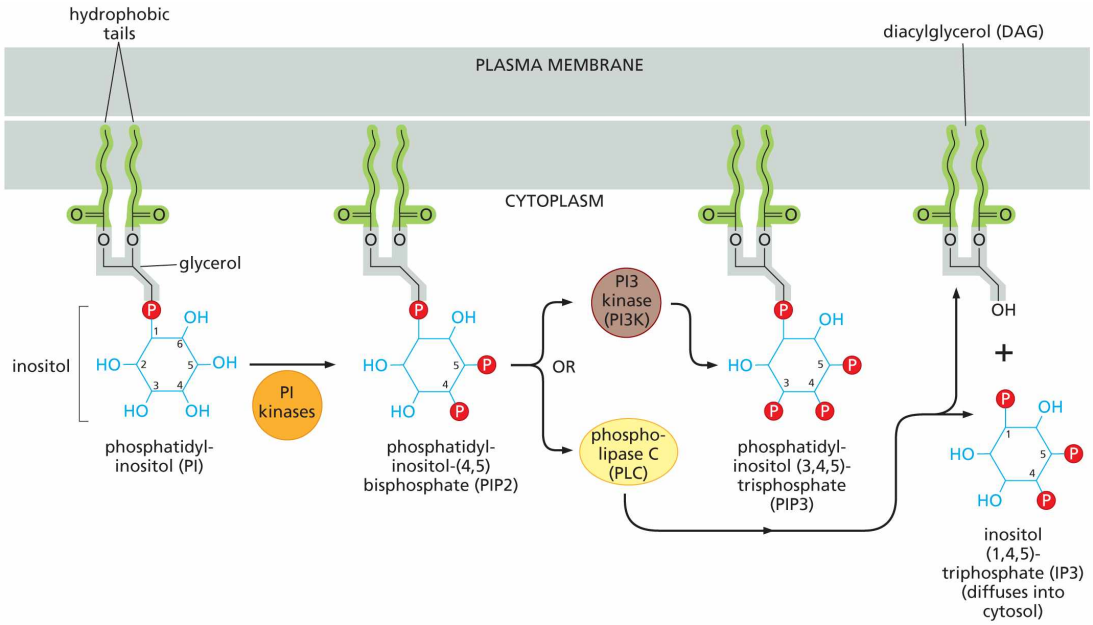
of PH-containing molecules, such as Akt (also called PKB) and Rho guanine nucleotide exchange proteins (Rho-GEFs), to the plasma membrane. Akt/PKB is able to inactivate Bad (a pro-apoptotic protein); inactivate GSK-3β, an antagonist of growth-promoting proteins such as β-catenin, cyclin D1, and Myc; and activate mTOR. (The latter is a kinase that stimulates protein synthesis and cell growth and also acts reciprocally to phosphorylate and activate Akt/PKB.) The bimolecular complex, seen as a ribbon structure (*above*), illustrates the interaction of the effector domain of Ras (*red, purple*) with the Ras-binding domain of PI3K (*orange*). (Adapted from M.E. Pacold et al., *Cell* 103:931–943, 2000; N. Nassar et al., *Nature* 375:554–560, 1995; and L. Huang et al., *Nat. Struct. Biol*. 5:422–426, 1998.)

Early studies of the biochemistry of the plasma membrane suggested that its phospholipids serve simply as a structural barrier between the aqueous environments in the cell exterior and interior. The biochemistry of these phospholipid molecules showed that they are amphipathic—that is, each possesses a hydrophilic head, which likes to be immersed in water, and a hydrophobic tail, which prefers nonaqueous environments (**Figure 6.11A**). This polarity explains the structure of lipid bilayers throughout the cell, in which the hydrophilic groups face and protrude into the extracellular or cytosolic aqueous environments while the hydrophobic tails are buried in the middle of the membrane, from which water is excluded. (The transmembrane domains of growth factor receptors discussed in Chapter 5 consist of hydrophobic acids that permit these domains to be buried stably in this hydrophobic environment.)



A lipid bilayer in cross section, consisting of many phospholipid molecules with hydrophilic heads on the upper and lower surfaces of the layer and hydrophobic tails oriented toward the middle of the layer. A few of the hydrophilic heads on the underside have hydrophilic head groups of different types attached. One type is inositol.

(A)



A phospholipid molecule with an inositol head group in greater detail. This is labeled phosphatidylinositol, or P I for short. It has two hydrophobic tails extending up into the plasma membrane. At the base of each tail is a double-bonded oxygen. Each tail attaches to one of two oxygens that are part of a glycerol structure. The other end of the glycerol attaches to a phosphorus, which in turn attaches to the 1-carbon in a six-carbon inositol ring. The other five carbons in the ring each carry an O H group. P I kinases cause phosphorylation on the 4 and 5 carbons, forming phosphatidylinositol (4,5) bisphosphate (PIP 2). From here, one of two things can happen. P I 3 kinase can cause phosphorylation on the 3 carbon, forming phosphatidylinositol (3,4,5) trisphosphate (PIP 3). Or phospholipase C (P L C) can cause the inositol to break away, along with the phosphotyrosine linking it to the rest of the structure, as inositol (1,4,5) triphosphate (I P 3), which diffuses into the cytosol. What remains behind is diacylglycerol (D A G), consisting of the glycerol and the two tails, with an O H group where the phosphorus had been.

(B)

Figure 6.11 Biochemistry of lipid bilayers (A) All cellular membranes are assembled as phospholipid bilayers, in which the hydrophilic head groups (*gray ovals*) protrude into the aqueous solvent above and below the membrane, while the hydrophobic tails (*green*, *gray*) are confined to the nonaqueous space within the lipid bilayer. A small minority of the various types of hydrophilic head groups (*red, green, blue*) contain inositol sugars (*blue*). (B) Phosphatidylinositol (PI; *left*) is composed of three parts—two fatty acids with long hydrocarbon tails (*green*) inserted into the plasma membrane, glycerol (*gray*), and inositol (*light blue*) attached to the glycerol via a phosphodiester linkage. PI kinases can add phosphate groups to the various hydroxyls of inositol, yielding, for example, the PI (4,5)-diphosphate (PIP2) shown here. Cleavage of PIP2 by phospholipase C yields diacylglycerol (DAG), which can activate protein kinase C (PKC); and inositol (1,4,5)-triphosphate (IP3), which induces release of calcium ions from intracellular stores. Alternatively, PIP2 can be further phosphorylated by PI3 kinase (PI3K) to yield phosphatidylinositol (3,4,5)-triphosphate (PIP3). Once formed, the phosphorylated head group of PIP3 serves to attract proteins carrying PH domains, which thereby become tethered to the inner surface of the plasma membrane.

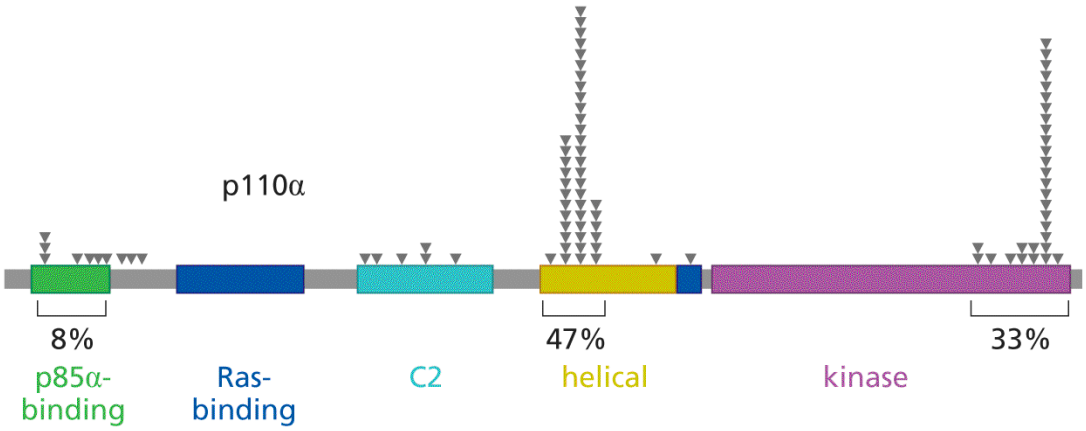
In the 1970s, it became apparent that eukaryotic cells exploit some of the membrane-associated phospholipids for purposes that are fully unrelated to the maintenance of membrane structure. Some phospholipids contain, at their hydrophilic heads, an inositol group. Inositol is a water-soluble carbohydrate molecule (termed more properly a polyalcohol). The inositol moiety of such phospholipids can be modified by the addition of phosphate groups. In some situations, the resulting phosphoinositol may then be cleaved by the phospholipase C (PLC) from the remaining, largely hydrophobic portions of a phospholipid molecule. Since it is purely hydrophilic, this liberated phosphoinositol, termed IP3 or IP_3, can then diffuse away from the membrane (Figure 6.11B), thereby serving as an *intracellular hormone* to dispatch signals from the plasma membrane to distant parts of the cell; such intracellular hormones are often called second messengers. The second product of this cleavage, termed diacylglycerol (DAG), which remains tethered to the plasma membrane, can serve to activate key signaling kinases in the cell—certain serine/threonine kinases belonging to the class known generically as protein kinase C (PKC). In other situations, a phosphorylated inositol avoids cleavage, can remain intact, and therefore can remain attached to the remainder of the phospholipid and thus can remain tethered to the plasma membrane; there, it can serve as an anchoring point to which certain cytosolic proteins can become attached, as discussed below.

We now know that the inositol moiety can be modified by several distinct kinases, each of which shows specificity for phosphorylating a particular hydroxyl of inositol.

Phosphatidylinositol 3-kinase (PI3K), for example, is responsible for attaching a phosphate group to the 3′ hydroxyl of the inositol moiety of membrane-embedded phosphatidylinositol (PI). While several distinct PI3 kinases have been discovered, the most important of these may well be the PI3K that phosphorylates PI(4,5)P_2 (or, more simply, PIP2). Prior to modification by PI3K, PIP2 already has phosphates attached to the 4′ and 5′ hydroxyl groups of inositol (in addition to the phosphodiester bond that links its 1′ hydroxyl to the membrane-embedded diacyglycerol-lipid moiety and gives these various forms their "PI" name); after this modification, this inositol acquires yet another phosphate group, and PIP2 is converted into PI(3,4,5)P_3, that is, PIP3 (see Figure 6.11B).

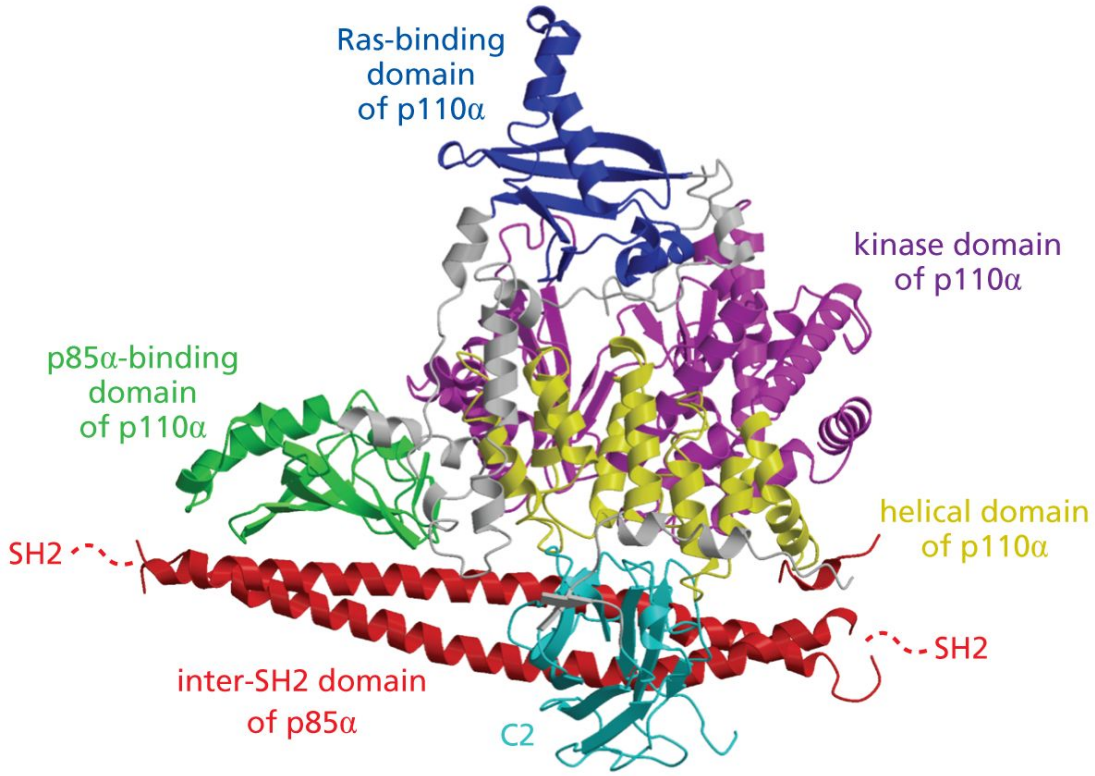
Note an important difference between the organization of this pathway and the Ras → Raf → MEK → ERK cascade that was described in the previous section. In the present case, one of the critical kinases (that is, PI3K) attaches phosphates to a phospholipid, rather than phosphorylating the side chain of an amino acid residue within a protein.

We first encountered PI3K, in passing, at an earlier point in this chapter (see Section 6.3, Figure 6.5A). There, we described the attraction of the PI3Kγ enzyme to a ligand-activated PDGF receptor via the SH2 groups of its regulatory subunit (resulting, as we now realize, in the phosphorylation of inositol-containing phospholipids already present in the nearby plasma membrane). It turns out that GTP-activated Ras is also able to bind PI3K directly and thereby enhance its functional activation (**Figure 6.12**). (Indeed, there is strong evidence that the H-Ras protein can effectively activate PI3K only when the p85 regulatory subunit of PI3K is bound to a phosphotyrosine on a ligand-activated growth factor receptor.) Hence, PI3K can function as a direct downstream effector of Ras. As is the case when Raf binds Ras, the binding of PI3K to Ras causes PI3K to become closely associated with the plasma membrane, where its PI substrates are located.



A schematic diagram showing five domains. From left to right, they are the p85 alpha binding, R a s binding, C 2, helical, and kinase domains. 8 percent of the mutations that led to P I 3 K activation occur on the p85 binding domain, 47 percent occur on the helical domain, and 33 percent occur on the kinase domain.

(A)



A ribbon diagram. It includes the five domains in Part A and also the inter-S H 2 domain of p85 alpha.

(B)

Figure 6.12 Activation of PI3K by Ras, growth factor receptors, and somatic mutation PI3K is a key enzyme in the control of cell growth and proliferation. The most important form of this enzyme, assembled as a complex of a catalytic subunit, termed p110, and a regulatory subunit, termed p85, is activated by the actions of the Ras oncoprotein and by tyrosine-phosphorylated growth factor receptors (RTKs). Three alternative forms of the catalytic subunit and five alternative regulatory subunits associate in various heterodimeric combinations. (A) The multidomain structure of p110α is depicted here schematically. The *gray* arrowheads indicate the locations of the somatic mutations that led to PI3K

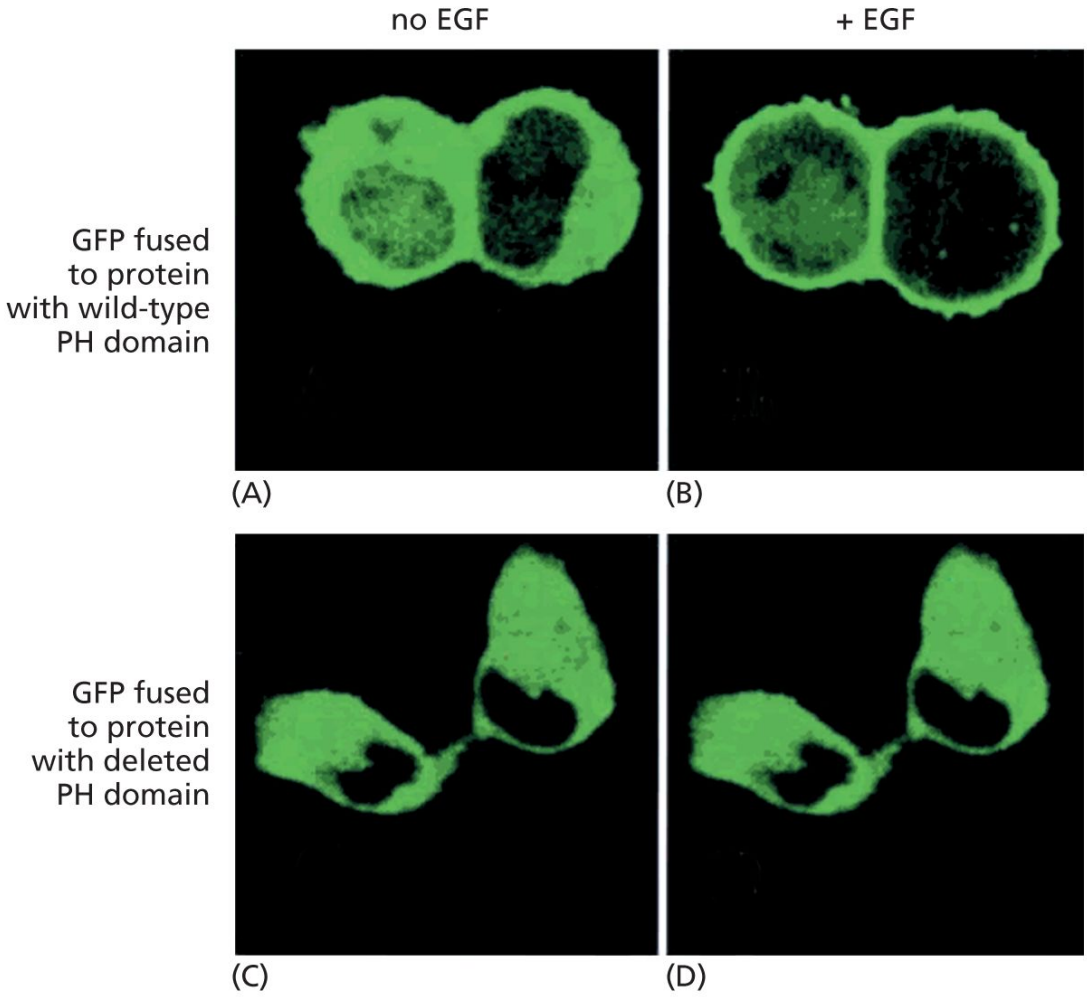
activation, as reported in an initial survey of PI3K sequences in human tumor cell genomes; like many activating mutations, these affected a limited number of nucleotides in the encoding gene. (B) A ribbon model of p110α with the inter-SH2 domain of p85α is shown here. The Ras-binding domain of p110α (*dark purple*) enables its tethering via Ras to the plasma membrane (*not shown*). The p85α subunit uses its two SH2 groups, which are located at the opposite ends of the inter-SH2 domain of p85 (*dark red*), to bind to phosphotyrosine residues in the cytoplasmic tails of ligand-activated growth factor receptors. The catalytic domain of p110α is shown in *light purple*. It remains unclear whether simultaneous interactions between p85, p110, Ras, and a ligand-activated RTK are required for activation of p110 or, alternatively, whether interactions of p85 with either a ligand-activated RTK or with Ras suffice for this activation. The inter-SH2 domain seems to have an affinity for binding lipid membranes. (A, from Y. Samuels et al., *Science* 304:554, 2004. B, from C.-H. Huang et al., *Science* 318:1744–1748, 2007. Both with permission from AAAS.)

Once activated by one or both of these associations, PI3K plays a central role in a number of signaling pathways, as described below. This is indicated by the fact that this enzyme is activated by a diverse array of signaling agents, including PDGF, nerve growth factor (NGF), insulin-like growth factor-1 (IGF-1), interleukin-3, and the extracellular matrix (ECM) attachment achieved by certain integrins (see Section 6.9).

The formation of the phosphorylated inositol head groups of phosphatidylinositol has little if any effect on the overall structure and function of the plasma membrane. (The inositol phospholipids are minor constituents of the plasma membrane.) However, a phosphorylated inositol head group protruding from the plasma membrane may be recognized and bound by certain proteins that are usually floating freely in the cytosol. Once anchored via a phosphoinositol to the plasma membrane, these proteins are then well positioned to release certain types of signals.

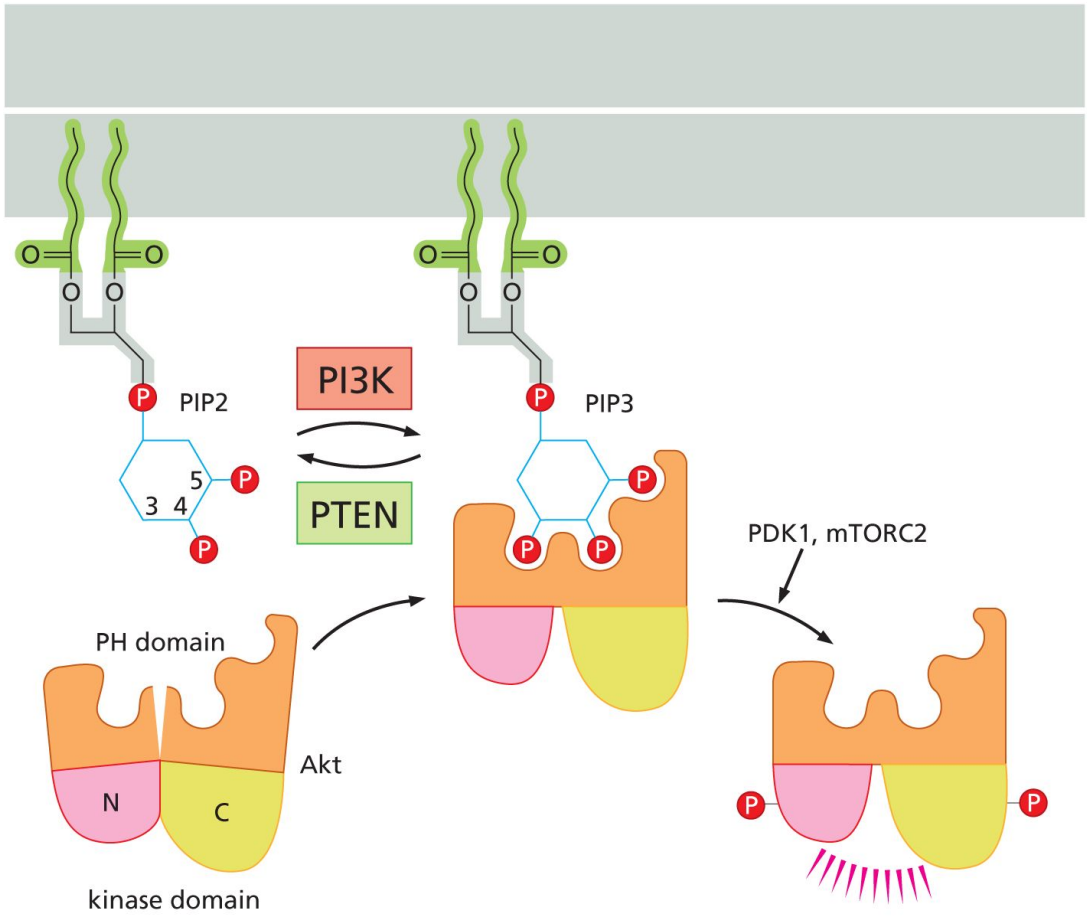
The most important of the phosphorylated inositol head groups appears to be PIP3, whose inositol, as mentioned above, carries phosphates at its 3′, 4′, and 5′ positions (see Figure 6.11B). Many of the cytosolic proteins that are attracted to PIP3 carry pleckstrin homology (PH) domains (see Table 6.2) that have strong affinity for this triply phosphorylated inositol head group (**Figures 6.13 and 6.14**). Arguably the most important PH domain–containing protein is the serine/threonine kinase named Akt/PKB, hereafter simply Akt. Thus, once PIP3 is formed by PI3K, an Akt kinase molecule can become tethered via its PH domain to the inositol head group of PIP3 that protrudes from the plasma membrane into the cytosol (Figure 6.14A). This association of Akt with the plasma membrane (together with phosphorylations of Akt that soon follow) results in the functional activation of Akt as a kinase. (In the absence of PIP3 binding, the PH domain of an Akt molecule obstructs its kinase domain,

explaining the inactivity of the cytosolic pool of Akt; see Figure 6.14B.) Once activated, Akt proceeds to phosphorylate a series of protein substrates that have multiple effects on the cell (see Figure 5.4B), including (1) aiding in cell survival by reducing the possibility that the cell apoptotic suicide program will become activated; (2) stimulating cell proliferation; and (3) stimulating cell growth, in the most literal sense of the term, that is, stimulating increases in cell size by increasing protein synthesis (**Supplementary Sidebar 6.6**). In addition, it also exerts an influence, still poorly understood, on cell motility and on angiogenesis—the production of new blood vessels (to be discussed in Chapter 13).



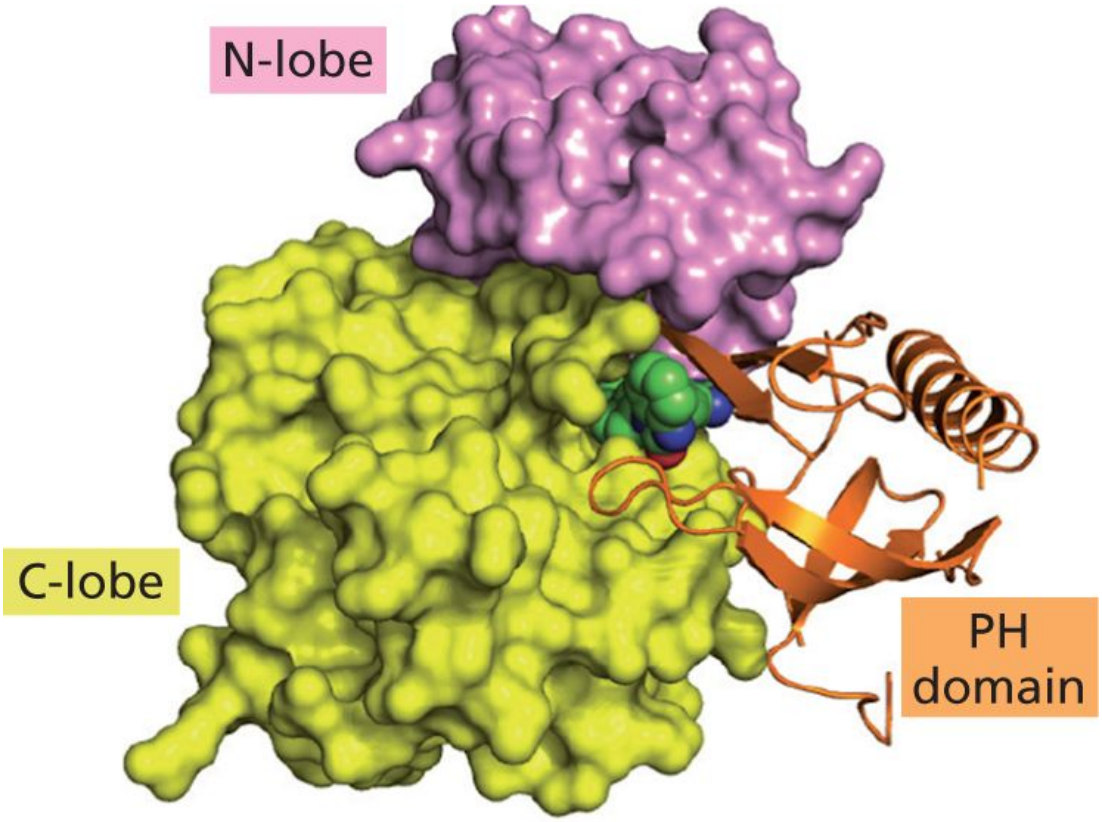
A four-part figure showing the effects of adding epidermal growth factor, E G F, to cells. Part A shows two connected cells, each roughly spherical, containing green fluorescent protein, G F P, fused to a protein with a wild-type P H domain. Each cell has large regions of bright green within the cytoplasm. Part B shows the effect of adding E G F to the wild type cells. The interior of each cell is now uniformly darker. Part C shows two cells, each irregularly shaped and connected by a short filament, containing G F P, fused to a protein with the P H domain removed.

Again, each cell has large regions of bright green within the cytoplasm. Part D looks the same as Part C indicating that adding the E G F has had no effect.
Figure 6.13 Migration of PH-containing proteins to PIP3 in the plasma membrane After PIP3 head groups are formed by PI3 kinase (see Figure 6.11B), they become attractive docking sites for PH (pleckstrin homology) domain–containing proteins. This phosphorylation and homing occurs within seconds of the activation of PI3 kinase, as revealed by these micrographs, in which green fluorescent protein (GFP) has been fused to a protein carrying a PH domain. This hybrid protein moves from a diffuse distribution throughout the cytoplasm (A) to the inner surface of the plasma membrane (B) within a minute after EGF (epidermal growth factor) has been added to cells. However, if the PH domain of the fusion protein is deleted (C), addition of EGF has no effect on its intracellular distribution (D) and it remains diffusely distributed throughout the cytoplasm. (From K. Venkateswarlu et al., *J. Cell Sci*. 112:1957–1965, 1999. With permission from The Company of Biologists.)



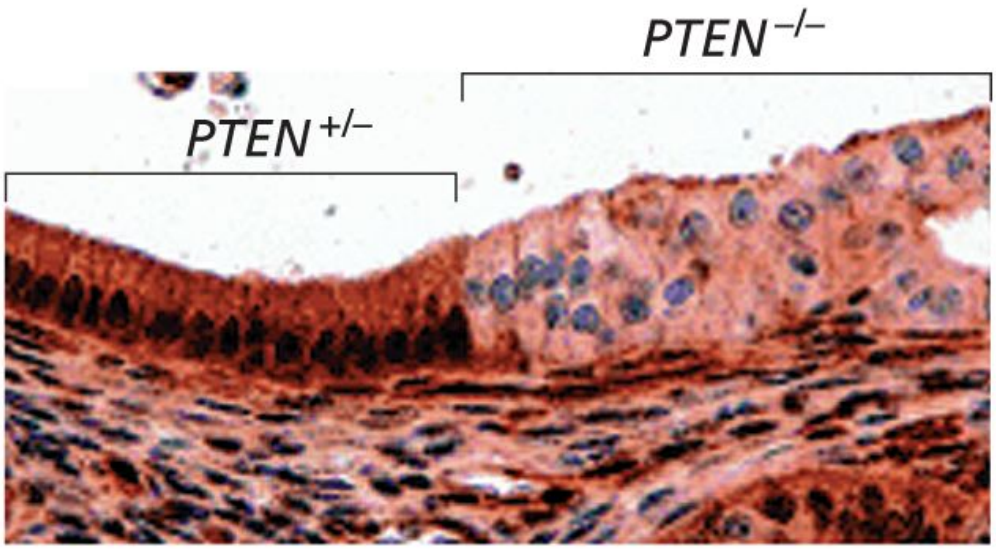
A sequence that begins with PIP 2, with its hydrophobic tails inside a plasma membrane and the head consisting of a glycerol and an inositol ring in which carbons 4 and 5 are phosphorylated. P I 3 K phosphorylates the number 3 carbon, producing PIP 3. The reverse process, from PIP 3 to PIP 2, would be via P T E N. A k t kinase has an N lobe and a C lobe on the kinase domain end and a complex P H domain at the other end that binds to the three exposed phosphotyrosines on the PIP 3 head. When the N and C lobes are each phosphorylated by P D K 1 and m T O R C 2, A k t kinase, now activated, detaches from PIP 3.

(A)



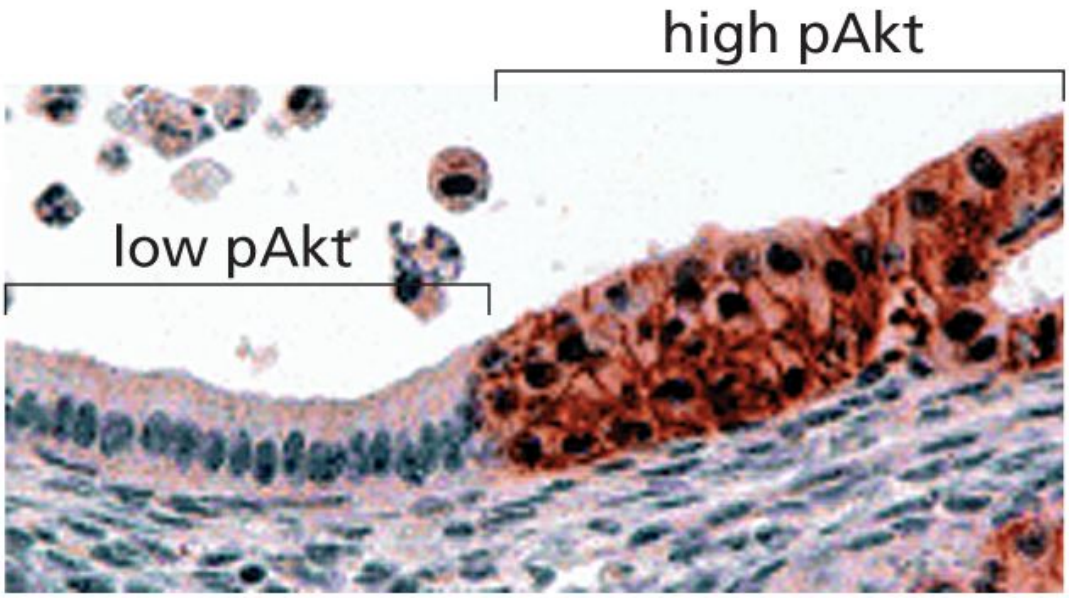
A model of A k t kinase, showing the large N lobe and the smaller C love as space-filling models and the P H domain as a ribbon structure. At the point where it connects to the N and C lobes there is a dark green structure.

(B)



A histology image of uterine epithelial cells, with P T E N plus minus cells on the left that look normal and P T E N minus minus cells on the right that are unnaturally thickened and irregular.

(C)



The same tissue and same pattern of normal and abnormal cell growth as in Part C, but with low p A k t activity on the left and high p A k t activity on the right.

(D)

Figure 6.14 Docking of PH domains to PIP3 By forming the triply phosphorylated inositol "head group" (*blue lines*) of PIP3 (see Figure 6.11B), PI3K creates a docking site for cytoplasmic proteins that carry PH domains. The most important of these is the Akt kinase. Once docked to the inner surface of the plasma membrane via its PH domain, the Akt kinase (sometimes termed PKB) becomes doubly phosphorylated at its two lobes (N, C) by two other kinases (PDK1 and mTORC2, respectively) and thereby activated (*lower right*). (Recent evidence indicates that PDK1, which has its own PH domain, can transduce oncogenic signals that do not depend on Akt activation.) Akt then proceeds to phosphorylate a variety of substrates throughout the cell regulating cell proliferation, survival, and size. However, if PTEN is also present and active, it dephosphorylates PIP3 to PIP2, thereby depriving Akt/PKB of a docking site at the plasma membrane. (The size of the PH domain of Akt/PKB relative to the size of its kinase domain has been greatly exaggerated in this drawing.) (B) The crystal structure of Akt reveals that the protein is formed from a kinase domain (*left*), shown here in a space-filling structure with the N- and C-lobes (*pink, yellow*) typical of most kinases (see Figure 6.6), which are connected via a flexible linker to the PH domain, shown as a ribbon diagram (*right, orange brown*). The catalytic cleft of the kinase domain sandwiched between its N- and C-lobes is usually inhibited by the PH domain. Upon binding to PIP3, the PH domain shifts away, disinhibiting the kinase domain. A drug molecule that inhibits the kinase and is bound near the catalytic cleft of the kinase is shown in *green*. (C) The dynamics of this interaction are seen in genetically altered mice having a *Pten*$^{+/-}$ genotype. Uterine epithelial cells in these mice often lose the remaining *Pten* wild-type allele, yielding *Pten*$^{-/-}$ cells, which form localized hyperplasias and cysts. Immunostaining with anti-PTEN antiserum shows that the epithelial cells on the right have lost PTEN expression and become larger, indicating the effects of the PIP3 pathway on cell size. (D) When the same lesion is stained with an anti-phospho-Akt antibody (which detects activated Akt), the cells on the right show high pAkt activity, while those on the left show very low activity, illustrating how even half the normal dose of PTEN present in the heterozygous cells suffices to shut down Akt function. (B, from W.-I. Wu et al., *PLoS One* 5:e12913, 2010. © 2010 Wu et al. This is an open-access article distributed under the terms of the Creative Commons Attribution License. C and D, from K. Podsypanina et al., *Proc. Natl. Acad. Sci*. USA 98:10320–10325, 2001. With permission from National Academy of Sciences, U.S.A.)

Interestingly, functionally active Akt seems to elicit many of its effects while still anchored via its PH domain to the plasma membrane. In addition, once released from this tethering into the cytosol, Akt persists for some time in its activated state, ostensibly sustained by its pair of phosphorylated residues (see Figure 6.14A); indeed,

a portion of activated Akt succeeds in migrating into the nucleus, where it phosphorylates and thereby activates certain transcription factors. Eventually, however, Akt signaling is reversed by phosphatases that remove its activating phosphate groups.

The activation of PI3K, and thus of Akt, is under very tight control. In a quiescent, nongrowing cell lacking growth factor stimulation, the intracellular levels of PIP3 are extremely low. Once such a cell encounters mitogens, the levels of PIP3 in this cell increase rapidly (see Figure 6.13). The normally low levels of PIP3 and other phosphorylated PI molecules are the work of a series of phosphatases that reverse the actions of the activating kinases such as PI3K. The best characterized of these phosphatases, PTEN, removes the 3′ phosphate group from PIP3 that has previously been attached by PI3K (Figure 6.14A and C). This removal suggests two distinct mechanisms by which the Akt/PKB signaling pathway can become deregulated in cancer cells—hyperactivity of PI3K or inactivity of PTEN.

The portfolio of diverse biological functions assigned to Akt and described above requires that this kinase be able to phosphorylate a variety of substrates, each involved in a distinct downstream signaling pathway (**Table 6.3**). The first of these functions—facilitating cell survival—depends on the ability of Akt to suppress any tendencies the cell may have to activate its own built-in suicide program of apoptosis, as discussed in Chapter 9. For the moment, suffice it to say that phosphorylation by Akt results in the inhibition of several proteins that play prominent roles favoring the entrance of a cell into apoptosis.

Table 6.3 Effects of Akt/PKB on survival, proliferation, and cell growth[a]

Biological effect	**Substrate of Akt/PKB**	**Description**	**Functional consequence**
Anti-apoptotic			
	Bad (pro-apoptotic)	Bcl-X antagonist; like Bad, belongs to Bcl-2 protein family controlling mitochondrial membrane pores (Section 9.13).	inhibition

Biological effect	Substrate of Akt/PKB	Description	Functional consequence
Anti-apoptotic			
	caspase-9 (pro-apoptotic)	Component of the protease cascade that affects the apoptotic program (Section 9.13).	inhibition
	IκB kinase, abbreviated IKK (anti-apoptotic)	Activated by Akt/PKB phosphorylation (Section 6.12).	activation
	FOXO1 TF, formerly called FKHR TF (pro-apoptotic)	Phosphorylation prevents its nuclear translocation and activation of pro-apoptotic genes.	inhibition
	Mdm2 (anti-apoptotic)	Activated via phosphorylation by Akt/PKB; it triggers destruction of p53 (Section 9.8).	activation
Proliferative			
	GSK-3β (anti-proliferative)	Phosphorylates β-catenin, cyclin D1, and Myc (Sections 7.10, 8.3, 8.9), causing their degradation; inactivated via phosphorylation by Akt/PKB.	inhibition

Biological effect	Substrate of Akt/PKB	Description	Functional consequence
Anti-apoptotic			
	FOXO4, formerly called AFX (anti-proliferative)	Induces expression of the CDK inhibitor $p27^{Kip1}$ (Section 8.4) gene and some pro-apoptotic genes; exported from the nucleus when phosphorylated by Akt/PKB.	inhibition
	$p21^{Cip1}$ (anti-proliferative)	CDK inhibitor, like $p27^{Kip1}$ (Section 8.4). Exits the nucleus upon phosphorylation by Akt/PKB.	inhibition
Growth			
	Tsc2 (anti-growth)	Phosphorylation by Akt/PKB causes Tsc1/Tsc2 complex to dissociate, allowing activation of mTOR, which then up-regulates protein synthesis.	inhibition
Metabolism			
	GSK-3β	glycogen formation	activation
	ATP citrate lyase	fatty acid synthesis	activation
	mTOR	activator of glycolysis	activation

Biological effect	Substrate of Akt/PKB	Description	Functional consequence
Anti-apoptotic			
	GLUT4	glucose transporter	activation

The proliferative functions of Akt depend on its ability to perturb proteins that are important for regulating the advance of a cell through its cycle of growth and division, often termed the "cell cycle." We will learn more about this complex program in Chapter 8.

Independent of these effects on proliferation, Akt is able to induce dramatic changes in the proteins that control the rate of protein synthesis in the cell. Akt acts through intermediaries to trigger activation of mTOR kinase; the latter, when acting as a subunit of the mTORC1 complex, proceeds to phosphorylate and inactivate 4E-BP, a potent inhibitor of translation and, at the same time, phosphorylates and thereby activates p70S6 kinase, an activator of translation. These changes allow Akt to increase the efficiency with which the translation of a class of mRNAs is initiated; the resulting elevated rate of protein synthesis favors the accumulation of many cellular proteins and is manifested in the growth (rather than the proliferation) of cells. An illustration of the growth-inducing powers of Akt is provided by transgenic mice that express a mutant, constitutively active Akt in the β cells of the pancreatic islets (see **Supplementary Sidebar 6.6**); in such mice, these particular cells grow to a size more than twice the cross-sectional area (and almost 4 times the volume) of normal β cells!

There is evidence that yet other cytoplasmic proteins use their PH domains to associate with PIP3, and that this association also favors their functional activation. Among the PH-bearing cellular proteins are a group of guanine nucleotide exchange factors (GEFs) that function analogously to Sos (see Figure 5.24), being responsible for activating various small GTPases that are distant relatives of the Ras proteins. These other GTPases belong to the Rho family of signaling proteins, which includes Rho proper and its two cousins, Rac and Cdc42. Like Ras, these Rho proteins operate as binary switches, cycling between a GTP-bound actively signaling state and a GDP-bound inactive state (**Sidebar 6.4**). The Rho-GEFs, once activated by binding to PIP3, act on Rho proteins in the same way that Sos acts on Ras. In particular, the Rho-GEFs induce Rho proteins to jettison their bound GDPs, allowing GTP to jump aboard and activate the Rho's.

Sidebar 6.4 Ras is the prototype of a large family of similar proteins

Ras is only one of a large superfamily of at least 151 similarly structured mammalian proteins that together are called “small G proteins” to distinguish them from the other class of larger, heterotrimeric guanine nucleotide–binding G proteins that are activated by association with seven-membrane-spanning (serpentine) cell surface receptors (see Figure 5.19A). Most of these small G proteins have been given three-letter names, each derived in some way from the initially named and discovered Ras proteins—for example, Ral, Rac, Ran, Rho, Rheb, and so forth. (The Cdc42 protein is a member of the Rho family that has kept its own unique name because of its initial discovery through yeast genetics.)

Much of the sequence similarity shared among these otherwise diverse proteins is found in the cavities in each that bind and hydrolyze guanine nucleotides. Virtually all of the small G proteins operate like a binary switch, using a GTP–GDP–GTP cycle to flip back and forth between an on and an off state (see Figure 5.24). Like Ras, each of these proteins is thought to have its own specialized guanine nucleotide exchange factors (GEFs) to activate it (by promoting replacement of GDP by GTP) and its own GTPase-activating proteins (GAPs) to trigger its GTPase activity, thereby inactivating it.

Each of these small G proteins is specialized to associate with its own group of effector proteins and control a distinct cell-physiologic or biochemical process, including regulation of the structure of the cytoskeleton, trafficking of intracellular vesicles, and apoptosis. One is even used to regulate the transport of proteins through pores in the nuclear membrane. The only trait shared in common by these diverse cell-biological processes is a need to be regulated by some type of binary switching mechanism—an operation for which the small G proteins are ideally suited.

Activated Rho proteins have functions that differ strongly from those of Ras: they participate in reconfiguring the structure of the cytoskeleton and the attachments that the cell makes with its physical surroundings. (While Ras and Rho proteins retain many commonalities in structure and guanine nucleotide binding, they seem to have diverged from one another at least 1.5 billion years ago during the early evolution of eukaryotic cells.) The Rho-like proteins control cell shape, motility, and, in the case of cancer cells, invasiveness. For example, Cdc42 is involved in reorganizing the actin cytoskeleton of the cell as well as controlling filopodia, small, fingerlike extensions from the plasma membrane that the cell uses to explore its environment and form adhesions to the extracellular matrix. Rac, in contrast, is involved in the formation of lamellipodia, broad ruffles extending from the plasma membrane that are found at the leading edges of motile cells. Because these structures are so intimately tied to the

steps of tumor cell invasion and metastasis, we will defer further discussion of these structures and their mechanisms of action until Chapter 14.

The pathway involving PI metabolites and Akt is deregulated in a number of human cancer cell types through changes that are often quite independent of Ras oncoprotein action (**Table 6.4**). In advanced ovarian carcinomas, elevated levels of one form of PI3K are associated with increased proliferation and invasiveness as well as decreased levels of apoptosis. In yet other tumors, such as lymphomas, cancers of the head and neck, and colon carcinomas, the Akt enzyme is overexpressed and presumably hyperactivated.

Table 6.4 Alteration of the PI3K pathway in human tumors[a]

Cancer type	***Akt/PKB* hyperactive**	***PIKC3A* hyperactive**[b]	***p85α***[c]	***PTEN*-mutant or repressed** [d]
Glioblastoma		6–27%	8%	20%
Ovarian carcinoma	~2%	4–12%	4%	8%
Endometrial carcinoma		22%		42–54%
HeHepatocellular carcinoma		6–36%		5%
Melanoma	~80%	~9%		40–50%
Lung carcinoma		3–4%		9%
Renal cell carcinoma		3%		4%
Thyroid carcinoma		5%		5%

Cancer type	***Akt/PKB* hyperactive**	***PIKC3A* hyperactive**[b]	***p85α***[c]	***PTEN*-mutant or repressed** [d]
Lymphoid		3%		8%
Prostate carcinoma		2%		10%
Colon carcinoma	~6%	14–32%	2–8%	13–54%
Breast carcinoma	~8%	18–40%	2%	20–33%
Bladder		23%		8%
Pancreatic		25%	17%	
Gastric		8%

PI3K is hyperactivated in almost one-third of human colon carcinomas because of mutations affecting its p110α catalytic subunit (see Figure 6.12A and Table 6.4). In fact, these activating mutations make the *PIK3CA* gene, which encodes the α isoform of PI3K, the second most mutated oncogene in human cancers, appearing just below the K-*RAS* gene in the roster. Experimental inactivation of the gene encoding the p110α subunit effectively eliminates the ability of an activated K-*ras* oncogene to incite pancreatic cancer in mice, pointing to the critical role of this PI3K isoform in relaying signals from a Ras oncoprotein to a variety of downstream cellular targets. At the same time, the frequently observed hyperactivity of Akt seen in a diverse array of human cancers is due to elevation of PIP3 levels caused more often by loss of PTEN function rather than hyperactivity of PI3K (see Table 6.4).

In a number of distinct tumor types, including breast and prostate carcinomas as well as glioblastomas, this loss of PTEN activity arises because of mutations in the encoding *PTEN* gene, DNA methylation events that suppress transcription of the *PTEN* gene, or overexpression of a microRNA that suppresses translation of the PTEN mRNA. Altogether, PTEN activity is lost in 30 to 40% of all human cancers. The resulting accumulation of high levels of the PIP3 phosphorylated inositide results in the downstream consequences enumerated above. This normal behavior of *PTEN* in suppressing cell proliferation indicates that it functions as a tumor suppressor gene, a topic that we will explore in Chapter 7.

Since PI3K activation and PTEN loss lead to the same outcome—an increase in PIP3—we might expect that human tumors generally have one but not the other alteration, and this is indeed the case. Hence, PI3K activation makes PTEN inactivation unnecessary, and vice versa.

Glossary

amphipathic
: Describing a molecule containing distinct hydrophobic and hydrophilic domains.

second messenger
: A low–molecular-weight molecule that functions as an intracellular hormone, conveying signals from one part of a cell to another.

filopodium
: Filamentous, spikelike protrusion from the surface of a cell, usually extending from the leading edge of a lamellipodium, that may be used by the cell to explore territory that lies ahead in its path and to forge focal adhesions with the extracellular matrix lying in this path. *See also* **lamellipodium**.

lamellipodium
: (pl., **- ia**) A broad, sheetlike ruffle extending from the plasma membrane into the extracellular space that is typically found at the leading edge of a motile cell.

angiogenesis
: Process by which new blood vessels are formed by sprouting from existing vessels; *also called* **neoangiogenesis** in certain circumstances. *Compare* **vasculogenesis**.

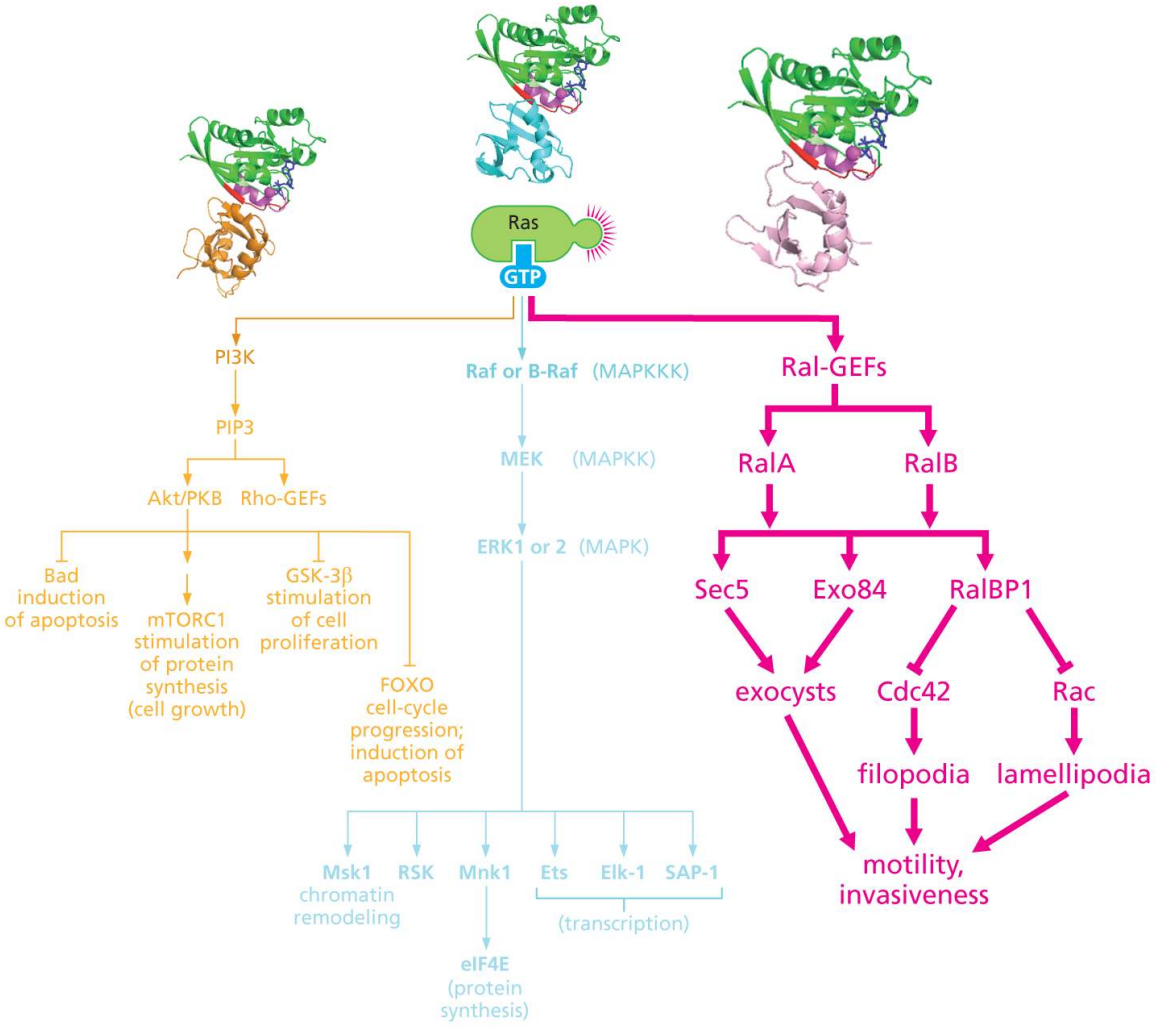
6.7 Ras-regulated signaling pathways: a third downstream pathway acts through Ral, a distant cousin of Ras

The third of the three major effector pathways downstream of Ras involves a pair of Ras-like proteins termed Ral-A and Ral-B, which share 58% sequence identity with Ras (see Sidebar 6.4). As is the case with Ras and the Rho proteins, functional activation of these Ral proteins involves the replacement of bound GDP with GTP (see Figure 5.24).

The communication between Ras and Ral is mediated by Ral guanine nucleotide exchange factors (Ral-GEFs), which can stimulate a Ral protein to shed its GDP and bind GTP, thereby echoing the effects of Sos on Ras. In addition to its GEF (guanine nucleotide exchange factor) domain, each Ral-GEF has a pocket that can bind activated Ras. This association with Ras has two consequences for the Ral-GEF: Ras causes the relocalization of the Ral-GEFs near the inner surface of the plasma membrane or another cytoplasmic membrane; in addition, binding to Ras seems to cause a conformational shift in Ral-GEFs that activates their intrinsic guanine nucleotide exchange factor activity.

The resulting activation of RalA and RalB proteins allows them to regulate targets further downstream in the signaling circuitry (**Figure 6.15**). For example, the Ral pathway can activate two proteins—Sec5 and Exo84—that contribute to Ras-mediated anchorage-independent growth, ostensibly by regulating exocysts that control the display of various proteins on the cell surface via the process of exocytosis; in addition, RalA/B signaling, acting via RalBP1, causes inactivation of the two Rho proteins cited in the last section—Cdc42 and Rac. RalA phosphorylation results in its functional inactivation, and its dephosphorylation (by PP2A phosphatase; see Section 11.9) can mimic much of the actions of an activated Ras oncoprotein in human cell transformation. Rac can also emit mitogenic signals and, by stimulating the production of reactive oxygen species, antagonize the actions of several Rho proteins. Though still poorly understood,

the Ral proteins are likely to play key roles in the motility that enables cancer cells to invade and metastasize.



Three pathways all begin with a G T P activated R a s. In the right one, which is emphasized, R a s activates R a l-G E effs. This leads to the activation of R a l A and R a l B. These in turn lead to S e c 5, E x o 84, and R a l B P 1. S e c 5 and E x o 84 together stimulate the development of exocysts, which enhance motility and invasiveness. R a l B P 1, meanwhile, inhibits C d c 4 2, which stimulates development of filopodia, which enhance motility and invasiveness, and R a l B P 1 also inhibits R a c, which stimulates development of lamellipodia, which again enhance motility and invasiveness. In another pathway, G T P activated R a s activates R a f or B R a f. In the third pathway, G T P activated R a s activates P I 3 K.

Figure 6.15 Ral and the control of the cytoskeleton The interaction of Ras with Ral-GEF (*pink, right*) enables the latter to activate the RalA and RalB GTPase proteins. The resulting GTP-bound Ral proteins proceed to activate a number of downstream pathways; prominent among them are those that activate Sec5, Exo84, and RalBP1. Sec5 and Exo84 contribute to the anchorage-independent growth of *Ras*-transformed cells *in vitro* and to their tumorigenicity *in vivo*; in addition, these two proteins together exert effects on the *exocyst*—a multiprotein complex involved in tethering cytoplasmic vesicles to the plasma membrane prior to exocytosis as well as other functions associated with vesicular trafficking. RalBP1, acting via Cdc42 and Rac, reorganizes the actin cytoskeleton and thereby affects cell motility and invasiveness. The bimolecular structural complex (*above*) illustrates the interaction of the effector domain of Ras (*red, purple*) with the Ras-binding domain of Ral-GEF, also known as Ral-GDS (*pink*). (Adapted from M.E. Pacold et al., *Cell* 103:931–943, 2000; N. Nassar et al., *Nature* 375:554–560, 1995; and L. Huang et al., *Nat. Struct. Biol*. 5:422–426, 1998.)

The functional description of Ras as a pleiotropically acting oncoprotein can now be explained at a biochemical level by the actions of the three downstream signaling cascades that radiate from Ras. It would be pleasing if each of the phenotypes that we have associated with Ras oncoprotein action (for example, anchorage independence, survival, proliferation, or biosynthetic rate) could be linked specifically to the actions of one of the three Ras effector arms. In fact, things are more complicated: most Ras-induced phenotypes seem to be achieved through the collaborative actions of several of these effectors with one another. However, to oversimplify, the pleiotropic actions of a Ras oncoprotein depend on its Raf effectors inducing cell proliferation, its PI3K effectors promoting cell survival and metabolic changes (for example, aerobic glycolysis), and its Ral-GEF effectors controlling membrane trafficking and adhesion.

There are also three other dimensions of complexity that we have not touched on. First, we have discussed Ras here as if it were a single protein, but there are indications that the four Ras proteins (one H-Ras, one N-Ras, and two K-Ras species) act in subtly different ways in distinct cytoplasmic locations. Thus, after Ras proteins become activated by Sos and its relatives near the plasma membrane, they may continue to emit signals from the membranes of endosomes generated by endocytosis and, thereafter, from other cytoplasmic membranes, notably those of the Golgi apparatus and the endoplasmic reticulum; at each of these locations, the various Ras proteins interact with greater or lesser efficiency

with their downstream effectors (see **Supplementary Sidebar 6.4**). Second, our list of three Ras effectors (Raf, PI3K, and Ral-GEF) is hardly an exhaustive one. It is clear that Ras can interact with at least half a dozen other, still poorly characterized effectors that enable it to evoke yet other changes within the cell (**Supplementary Sidebar 6.9**). And finally, the Raf kinase, and plausibly many other kinases, act as homodimers and heterodimers that control each other's catalytic activity (**Supplementary Sidebar 6.5**), echoing receptor tyrosine kinase dimerization described in the last chapter.

In any hierarchical organization, those individuals near the top exert far more power and influence than those lower down. By activating multiple control pathways concomitantly, a Ras oncoprotein (or a stimulatory signal emitted by one of its upstream controllers) induces many of the phenotypic changes acquired by a cell during the course of neoplastic transformation. In contrast, deregulation of one or another of the pathways downstream of Ras confers only a *subset* of these phenotypic changes and therefore yields far less proliferative advantage for a would-be cancer cell. This point is illustrated nicely by the mutant alleles of the gene encoding the B-Raf kinase, the close cousin of Raf cited above, which is also activated by interaction with Ras. These mutations, which are found in more than half of human melanomas, create oncogenic *BRAF* alleles whose products, in spite of their greatly enhanced kinase activity (also described in Section 6.5), have only about one-fiftieth of the transforming power of the glycine-to-valine–substituted, activated Ras oncoprotein. Presumably, signaling components located further downstream, when altered by mutation, confer even less benefit (that is, proliferative advantage) on evolving pre-neoplastic cells and therefore are rarely encountered in the genomes of human tumor cells. Moreover, human tumors often show concomitant genetic alterations of two of the effector pathways (for example, Raf and PI3K) rather than a mutation in the *Ras* gene itself; this apparently enables these downstream effectors, working in concert, to achieve cell-biological effects comparable to those elicited by a mutant Ras oncoprotein.

Glossary

exocyst

Multi-subunit cytoplasmic protein complex that enables the tethering to the inner surface of the plasma membrane of vesicles destined for exocytosis, thereby regulating the cell surface display and secretion of a broad range of signaling molecules. *See* **exocytosis**.

exocytosis

(1) Process by which cells secrete soluble products by storing them in the lumina of cytoplasmic exocytic vesicles that are caused to fuse with the plasma membrane, allowing the products carried within these vesicles to be released into the extracellular space. (2) Process by which cells achieve the display of proteins on the cell surface by embedding them in the membranes of exocytic vesicles prior to fusion of the latter with the plasma membrane. *Compare* **endocytosis**. *See also* **exocyst**.

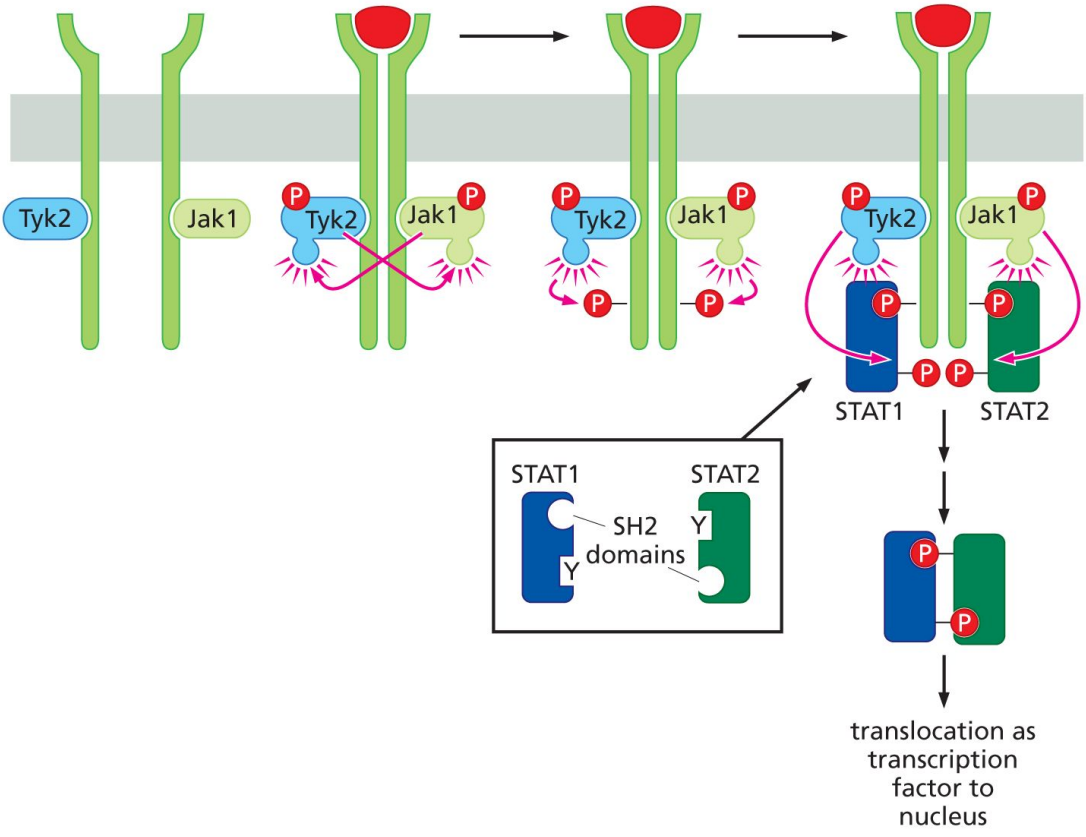
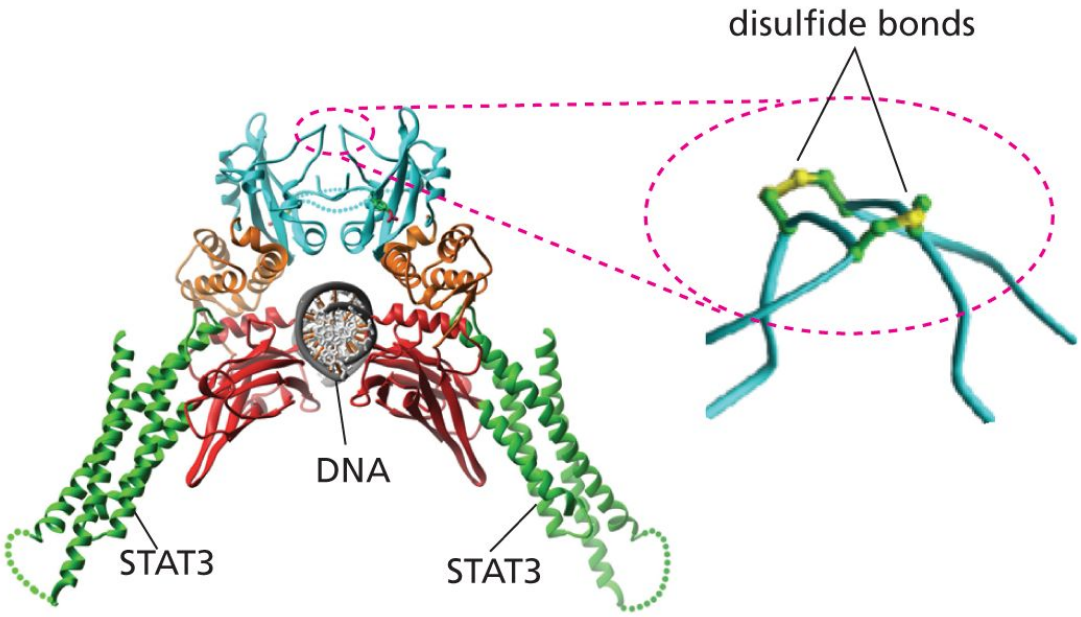
6.8 The JAK–STAT pathway allows signals to be transmitted from the plasma membrane directly to the nucleus

As mentioned in Section 5.7, study of a number of receptors for cytokines—growth factors that stimulate components of the hematopoietic system—has revealed receptor molecules that are constructed slightly differently from most of the growth factor receptors that were discussed in the last chapter. These particular receptor proteins do not carry covalently linked tyrosine kinase domains and instead form noncovalent complexes with tyrosine kinases of the JAK (Janus kinase) class (**Figure 6.16A**). Included among these are the receptors for interferon (IFN), erythropoietin (EPO), and thrombopoietin (TPO). Interferon is an important mediator of immune cell function, as we will learn in Chapter 15; the other two cytokines control erythropoiesis (red blood cell formation) and thrombopoiesis (platelet formation), respectively.



A diagram shows what happens after a ligand binds to a receptor with a T y k 2 domain on one subunit and a J a k 1 domain on the other subunit. The two domains transphosphorylate each other and then phosphorylate the C two terminal tails. The resulting complex attracts an STAT 1 to the T y k 2 side and an STAT 2 to the J a k 1 side. The two STATs then attach to each other, matching an S T 2 domain on each to a phosphotyrosine attached to the other. The dimerized STAT translocates to the nucleus as a transcription factor.

(A)



A symmetric ribbon diagram with two S T A threes flanking a central D N A. A close-up of the top of the molecule shows disulfide bonds.

(B)

Figure 6.16 The JAK–STAT pathway (A) The JAK–STAT pathway depends upon the actions of JAK tyrosine kinases, such as JAK1 and Tyk2 illustrated here. Both of these kinases are attached noncovalently to a number of cytokine receptors, including those for interferons, erythropoietin (EPO), and thrombopoietin (TPO). Once a ligand has activated one of these receptors via dimerization, the JAKs transphosphorylate one another as well as the C-terminal tails of the receptors. The resulting phosphotyrosines attract STAT proteins, such as the STAT1 and STAT2 shown here (*dark blue, dark green*), which bind via their SH2 domains and become phosphorylated on specific phosphotyrosines, indicated here as Y's (*inset*), by the JAKs. Thereafter, the STATs dimerize, each using its SH2 domain to bind to the phosphotyrosine of its partner, and then translocate to

the nucleus, where they operate as transcription factors to activate expression of key genes, for example, the gene encoding an interferon. Not shown here is the activation under certain conditions of JAKs that are bound to some G-protein–coupled receptors (GPCRs) and the phosphorylation of STATs directly by certain ligand-activated growth factor receptors (RTKs) as well as non-receptor tyrosine kinases. (B) As indicated above, the STAT3 proteins normally dimerize through the SH2 domains in their C-terminal regions (*aquamarine*) to form dimeric transcription factors that sit astride the DNA double helix (*gray and brown circular structure*). However, use of site-directed mutagenesis has allowed the insertion of two cysteine residues in the C-terminal domain of STAT3, leading to the formation of dimers that are held together covalently by disulfide bonds (*right*). Thus, the disulfide bonds (*yellow*) linking the two monomers are within the dashed oval (*left*). Thereafter, these two STAT3 proteins are held together constitutively without any physiological signal to stimulate their dimerization. (From J. Bromberg et al., *Cell* 98:295–303, 1999. With permission from Elsevier.)

Following ligand-mediated receptor dimerization, the JAK enzyme associated with each receptor molecule phosphorylates tyrosine residues on the cytoplasmic tails of the partner receptor molecule, much like the transphosphorylation occurring after ligand activation of receptors like the EGF-R and PDGF-R (see Figure 5.11A). The resulting phosphotyrosines attract and are bound by SH2-containing transcription factors termed STATs (signal transducers and activators of transcription), which then become phosphorylated by the JAKs. This creates individual STAT molecules that possess both SH2 groups and newly acquired phosphotyrosines. Importantly, the SH2 groups displayed by the STATs have a specificity for binding the phosphotyrosine residues that have just been created on the STATs. Consequently, STAT–STAT dimers form, in which each STAT uses its SH2 group to bind the phosphotyrosine of its partner. The resulting dimerized STATs migrate to the nucleus, where they function as transcription factors (see Figure 6.16A).

The STATs—seven of which have been documented—activate target genes that are important for cell proliferation and cell survival. Included among these genes are *myc*, the genes specifying cyclins D2 and D3 (which enable cells to advance through their growth-and-division cycles, as described in Chapter 8), and the gene encoding the strongly anti-apoptotic protein Bcl-X_L (described in Chapter 9). In addition to phosphorylating STATs, the JAKs can phosphorylate substrates that activate other mitogenic pathways, including the Ras–MAPK pathway described earlier.

Perhaps the most dramatic demonstration of the contribution of STATs to cancer development has come from a re-engineering of the STAT3 protein through the introduction of a pair of cysteine residues, which causes the resulting mutant STAT3 to

dimerize spontaneously, forming stable covalent disulfide cross-linking bonds (Figure 6.16B). These stabilized STAT3 dimers are structural and functional mimics of the dimers that are formed physiologically when STAT3 is phosphorylated by JAKs. This mutant STAT3 protein is now constitutively active as a nuclear transcription factor and can function as an oncoprotein that is capable of transforming NIH 3T3 and other immortalized mouse cells to a tumorigenic state.

STAT3 is also known to be constitutively activated in a number of human cancers. For example, in many melanomas, its activation is apparently attributable to Src, which is also constitutively active in these cancer cells; indeed, at least four other cousins of Src, all nonreceptor tyrosine kinases, can also phosphorylate and thereby activate STAT3. This highlights the fact that STATs can be activated in the cytoplasm by tyrosine kinases other than the receptor-associated JAKs. In the case of the melanoma cells, inhibition of Src, which leads to deactivation of STAT3, triggers apoptosis, pointing to the important contribution of STAT3 in ensuring the survival of these cancer cells.

In the majority of breast cancer cells, STAT3 has been found to be constitutively activated; in some of these, STAT3 is phosphorylated by Src and JAKs acting collaboratively. As is the case with melanoma cells, reversal of STAT3 activation in these breast cancer cells leads to growth inhibition and apoptosis. In almost all head-and-neck cancers, STAT3 is also constitutively activated, possibly through the actions of the EGF receptor. Alternatively, in many glioblastomas, activation of STAT3 is favored by the loss of a phosphatase responsible for removing its phosphotyrosine. STAT3 activation in lung and gastric cancers also appears to be critical to their neoplastic phenotype.

After reaching the nucleus, dimerized activated STAT proteins induce the expression of several hundred genes, many of which favor cell proliferation and protect against apoptosis. Taken together, these various threads of evidence converge on the notion that STATs represent important mediators of transformation in a variety of human cancer cell types. This depiction of the STATs as being invariably tumor-promoting must be tempered by the fact that certain STATs, such as STAT1, can antagonize cell proliferation and survival and therefore act as tumor-suppressing proteins. For example, this particular STAT can act to promote cell cycle arrest and even induce cell death via apoptosis, which we will encounter in Chapter 9.

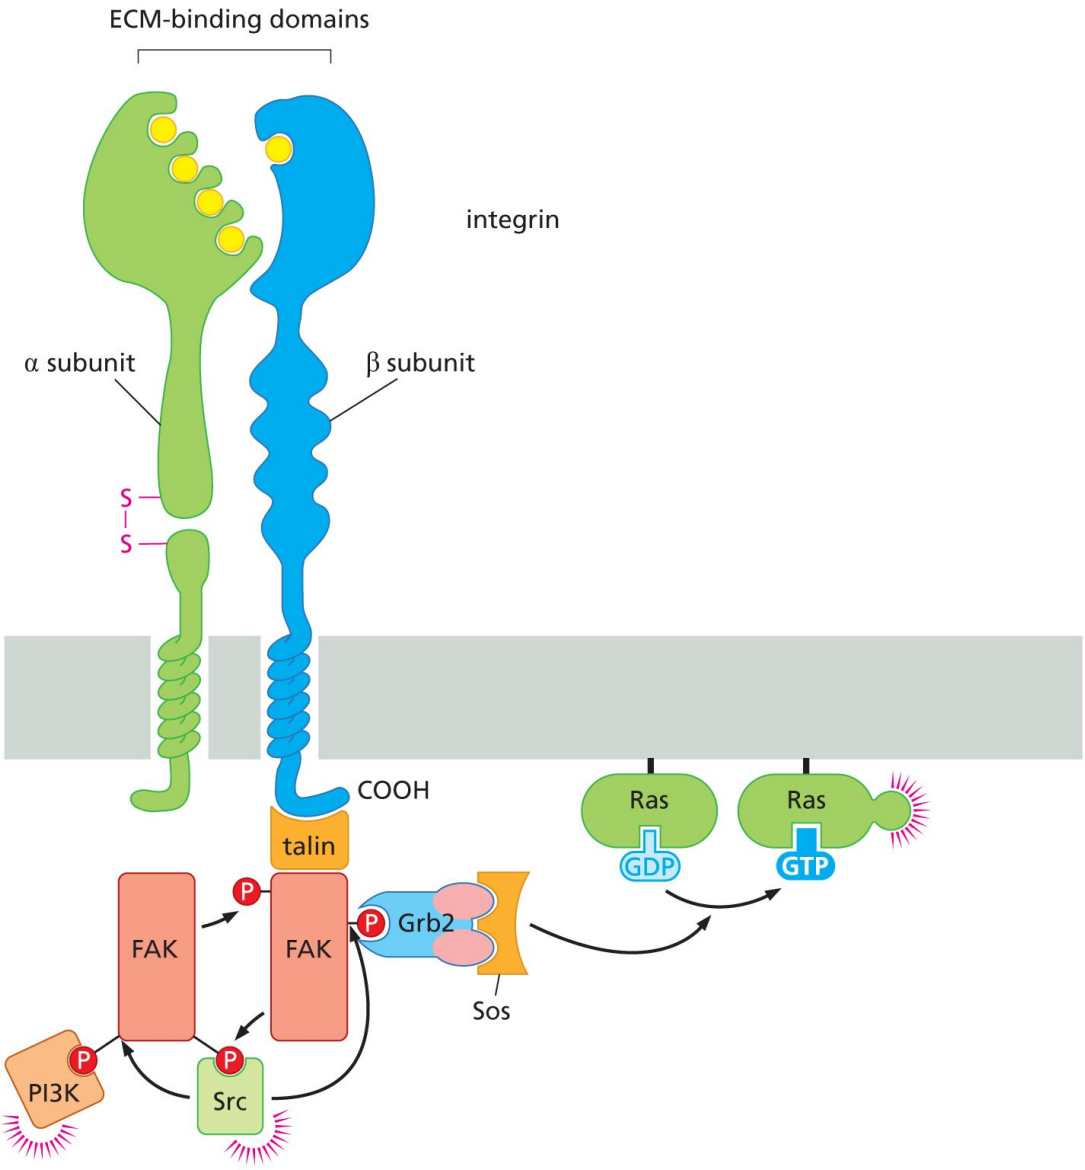
6.9 Cell adhesion receptors emit signals that converge with those released by growth factor receptors

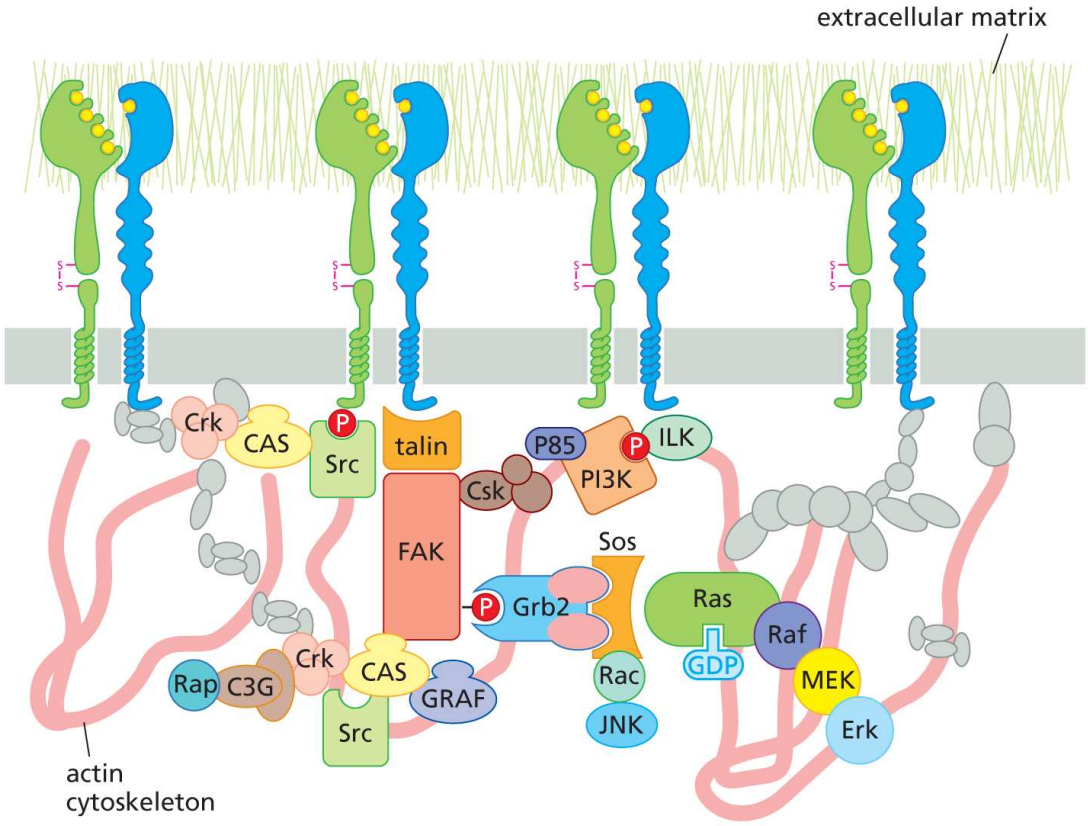
In the last chapter, we read that cells continuously monitor their attachment to components of the extracellular matrix (ECM; Section 5.9). Successful tethering to the molecules forming the ECM, achieved via integrins, causes survival signals to be released into the cytoplasm that decrease the likelihood that a cell will enter into the form of apoptosis termed anoikis. At the same time, integrin activation, provoked by signals originating inside the cell, can promote cell motility by stimulating integrin molecules located at specific sites on the plasma membrane to forge new linkages with the ECM. Consequently, integrins serve the three functions of (1) physically linking cells to the ECM, (2) informing cells whether or not tethering to certain ECM components has been achieved, and (3) facilitating motility by making and breaking contacts with the ECM. (In fact, there is a fourth but incompletely understood function: integrins and their cytoplasmic signaling partners serve as sensors of physical tension that arises between the ECM and the actin cytoskeleton. Cells respond in complex ways to this sensed tension.)

As described in the last chapter, integrins may cluster and form multiple links to the ECM in small, localized areas termed *focal adhesions* (see Figure 5.22A). Such clustering provokes strong activation of focal adhesion kinase (FAK), a nonreceptor tyrosine kinase like Src. FAK is associated with the cytoplasmic tails of the β subunits of certain integrin molecules and becomes phosphorylated, apparently by transphosphorylation, once integrins congregate in these focal adhesions. One of the resulting phosphotyrosine residues on FAK provides a docking site for various SH2-containing signaling molecules including notably Src, Shc, PI3K, and PLC-γ (**Figure 6.17A**). The binding of Src results in the phosphorylation of additional tyrosines on FAK, and the resulting phosphotyrosines serve as docking sites for yet other SH2-containing signaling molecules, including Grb2, Shc, and PLC-γ. There is also evidence that Grb2, once bound to tyrosine-phosphorylated FAK, can recruit Sos into this complex; Sos then proceeds to activate its normal downstream Ras target. In fact, the full complexity of signaling downstream of integrins still awaits resolution (Figure 6.17B).



A diagram of an integrin, with a green alpha subunit on the left and a blue beta subunit on the right. The domains that extend into the cytosol are hook-shaped, and on the beta subunit the carboxyl group at the end is shown. A talin attaches to the hooked portion, and a series of interactions occur with an F A K that has phosphorylated, activated P I 3 K and Sarc groups attached. The result is that a doubly phosphorylated F A K attaches to the talin, and a G r b 2 S o s complex attaches to one of the phosphotyrosines. An R a s attached to the cytoplasmic side of the plasma membrane has an attached G D P. The G r b 2 S o s complex converts the G D P to G T P, activating the R a s, which begins signaling.

(A)



Four integrins, side by side. Attached to the hook shaped ends on the cytoplasmic side is a complex arrangement of proteins and other molecules fixed within the actin cytoskeleton. These include the molecules shown in Par A, two copies each of C R S and C R K, and single copies of many other molecules.

(B)

Figure 6.17 Integrin signaling (A) The integrins are assembled as α + β heterodimers. In addition to physically linking the cytoskeleton to the extracellular matrix (ECM; see Figure 5.22B), the binding by the ectodomain of the heterodimer to components of the ECM (*not shown*) triggers the association of a series of cytoplasmic signal-transducing proteins, such as focal adhesion kinase (FAK), with the β subunit. Resulting transphosphorylation events and the attraction of SH2-containing signaling molecules release signals that activate many of the same pathways that are turned on by ligand-activated growth factor receptors. This signaling is amplified by clustering of multiple heterodimers following ECM binding (*not shown*). (B) As indicated here, the molecules shown in panel A represent only part of a complex, still-poorly understood collection of signal-transducing molecules that become physically associated with the cytoplasmic domains of various integrin β subunits following ECM binding. In

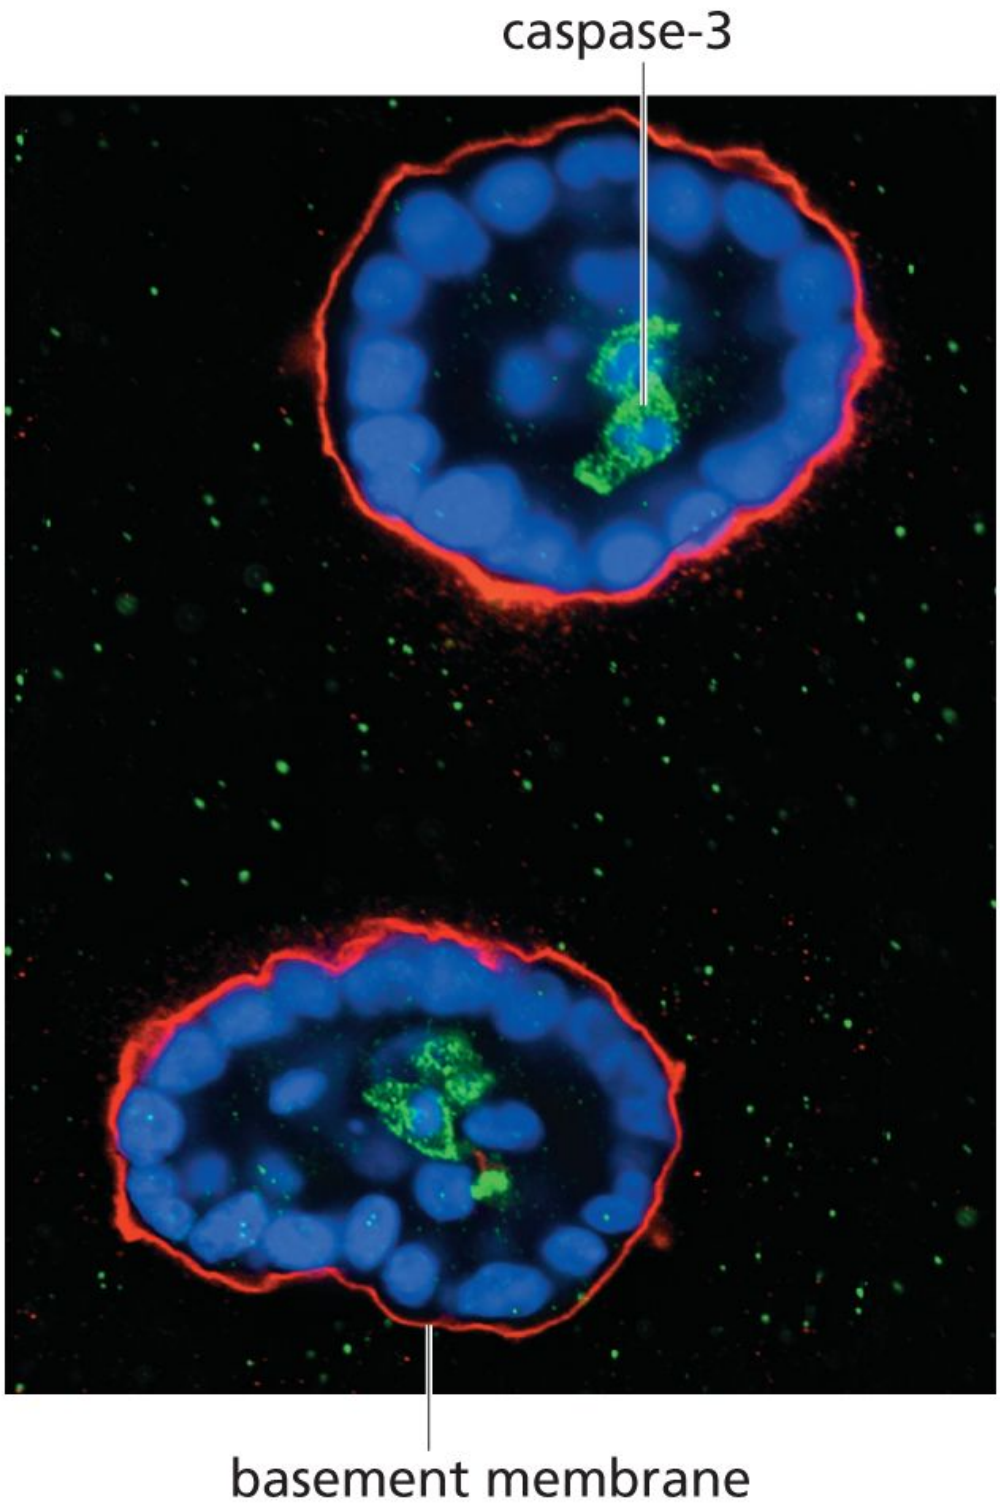
total, almost 180 distinct proteins have been found to be physically associated with focal adhesions. (Adapted from C. Miranti and J. Brugge, *Nat. Cell Biol*. 4:E83–E90, 2002. With permission from Nature.)

The accumulated evidence suggests a pathway that has, minimally, the following components:

ECM → integrins → Sos → Ras → Raf, PI3K, and Ral-GEF

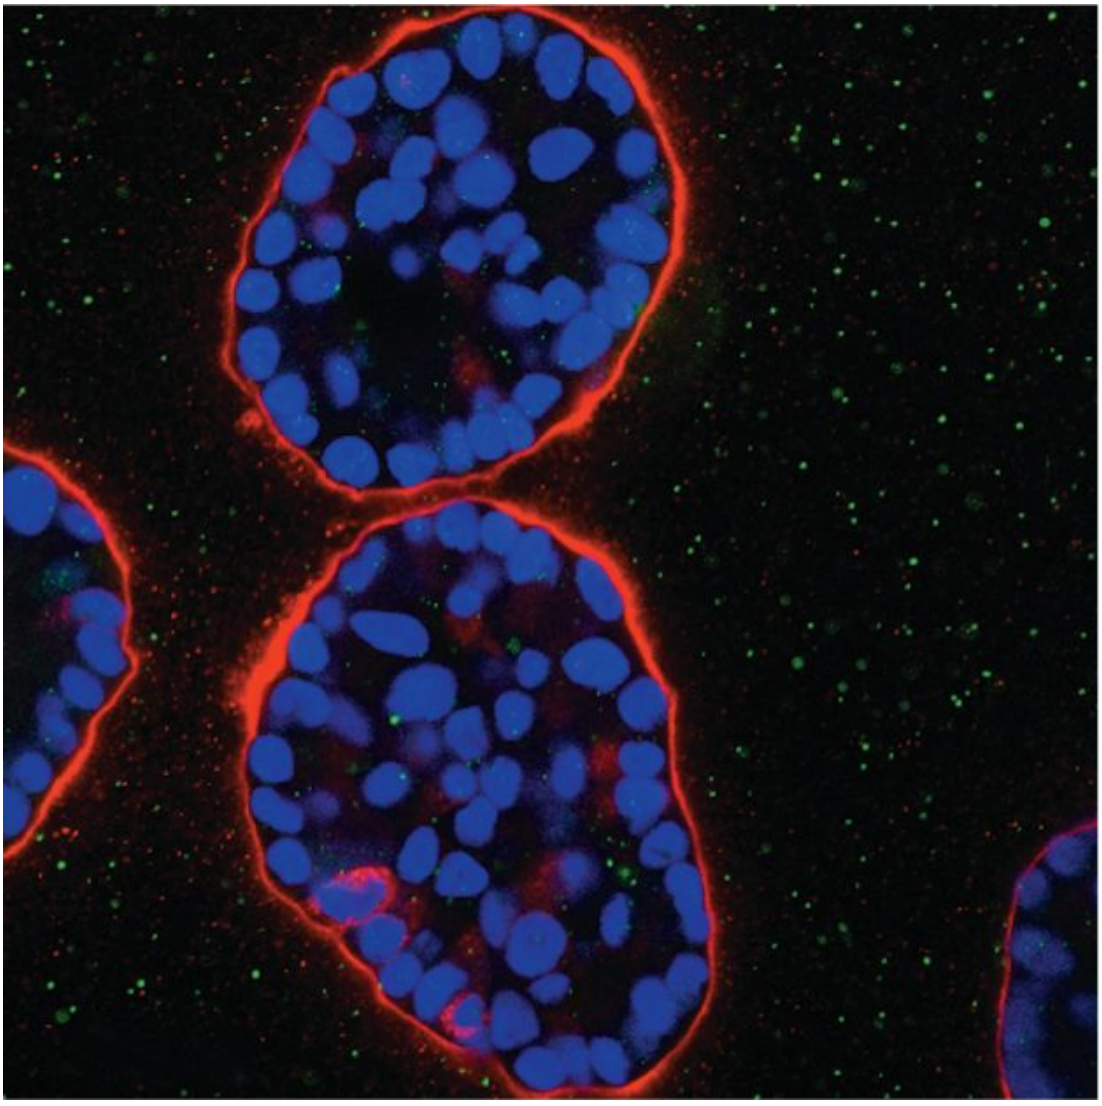
The parallels between integrin and receptor tyrosine kinase signaling are striking: tyrosine kinase receptors bind growth factor ligands in the extracellular space, while integrins bind extracellular matrix components as ligands. Once activated, these two classes of sensors release signals that converge on many of the same downstream signal transduction cascades. Moreover, some integrins co-localize on the plasma membrane with certain tyrosine kinase receptors; this lateral physical association appears to enhance the signaling by both types of cell surface proteins.

This convergence of signaling pathways appears to explain one of the important cell-biological effects of the Ras oncoprotein—its ability to enable cells to grow in an anchorage-independent fashion. It seems that cells normally depend on integrin signaling to provide a measure of activation of the normal Ras and Src proteins. In the absence of this signaling, cells come to believe that they have failed to associate with the extracellular matrix. This may block further advance of cells through their cell growth-and-division cycle or, more drastically, may cause cells to enter into anoikis as mentioned above. Avoidance of anoikis triggered by loss of normal attachment to the basement membrane seems to represent one of the first steps in the initiation of breast cancers (**Figure 6.18**).



Two normal acini formed in suspension culture. Each acinus features a red outer wall with cells attached to the inner surface in orderly fashion, as can be seen from the large blue nuclei. The center of each acinus contains blue and green cells that are in the process of withering to leave an empty lumen.

(A)



More acini formed in suspension culture, but here the attachment of cells to the red wall is less orderly, and within the center of each acinus there are many more cells, none of which are green to indicate that they are withering.

(B)

Figure 6.18 Anoikis and morphogenesis Anoikis serves during morphogenesis to excavate lumina (cavities) in the middle of cylindrical aggregates of cells, thereby creating hollow ducts. When placed into suspension culture, human mammary epithelial cells (MECs) form globular clusters that mimic, at least superficially, the acinar structures of mammary gland ducts. (A) An acinus is seen here in cross section surrounded by a layer of basement membrane containing

laminin-5 (*red*) that the cells have secreted (see Section 2.2). Cells that succeed in tethering to this basement membrane via their integrins are healthy and have large nuclei (*blue*), while those that are deprived of direct attachment to this basement membrane undergo anoikis, resulting in the formation of a protein (activated caspase-3; *green*) that is indicative of active apoptosis (see Chapter 9); these central cells also exhibit fragmented nuclei, another sign of apoptosis. The loss of these cells will yield a lumen in this acinus. Here the basement membrane serves as an analog of the substrate to which cells must adhere in the Petri dish in order to avoid anoikis. (B) In an early step of breast cancer development, normal anoikis and resulting excavation of the lumen of a mammary duct may be prevented by the actions of certain anti-apoptotic proteins described in Chapter 9. Here, experimentally induced expression of the anti-apoptotic Bcl-xL protein in MECs has resulted in the suppression of apoptosis, survival of luminal cells, and resulting luminal filling, echoing the appearance of certain ductal hyperplasias and *in situ* carcinomas often seen in the initial steps of human breast cancer development. Indeed, overexpressed EGF-R, which activates many of the same signaling pathways as integrins, also strongly reduces anoikis, once again favoring luminal filling (*not shown*). (Courtesy of J. Debnath and J. Brugge.)

Taken together, these diverse observations suggest that oncogenic Ras promotes anchorage-independent proliferation by mimicking one of the critical downstream signals that result following tethering by integrins to the extracellular matrix. In effect, oncogenic Ras may delude a cell into believing that its integrins have successfully bound certain ECM components, thereby permitting a *ras*-transformed cell to proliferate, even when no such attachment has actually occurred.

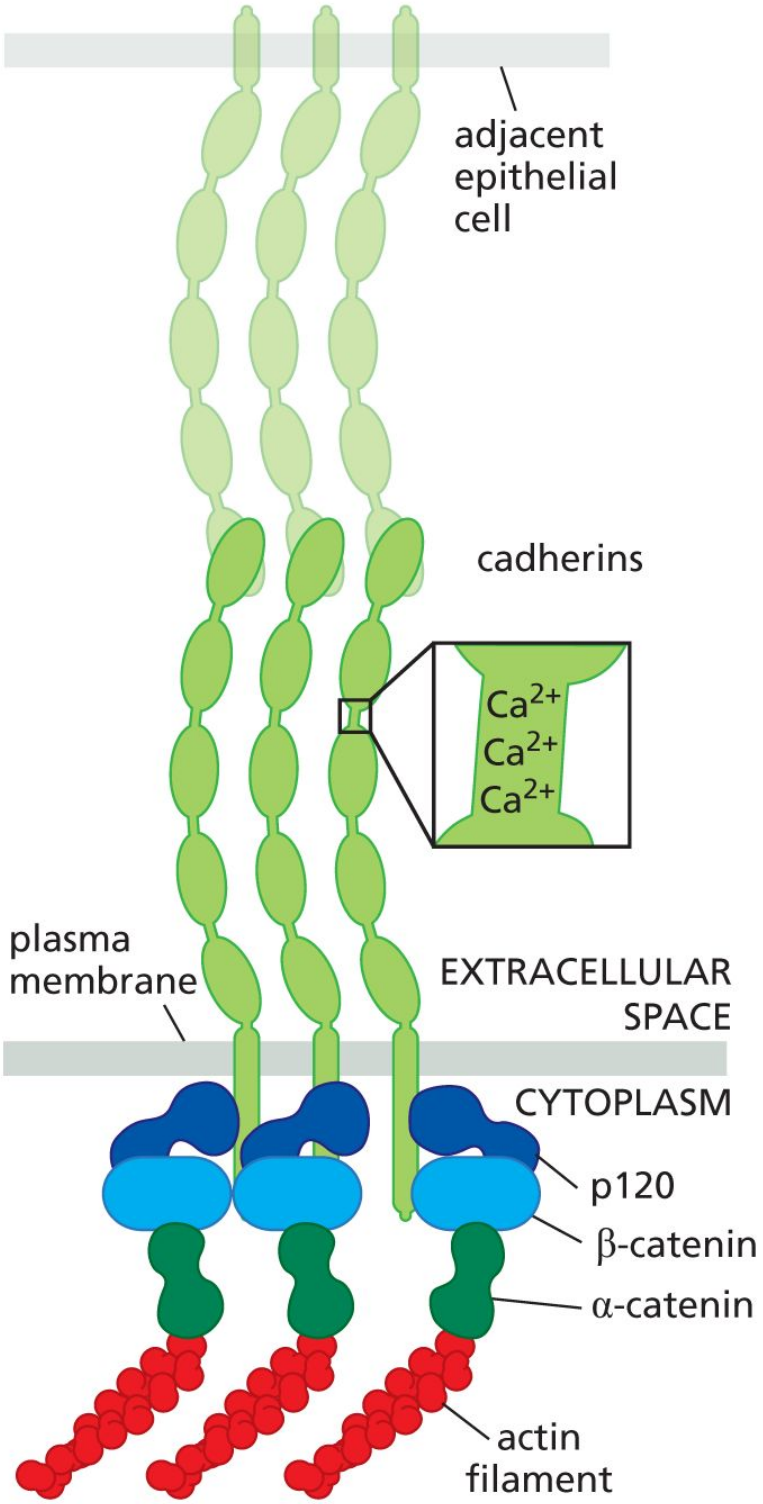
6.10 The canonical and non-canonical Wnt pathways control diverse cellular phenotypes

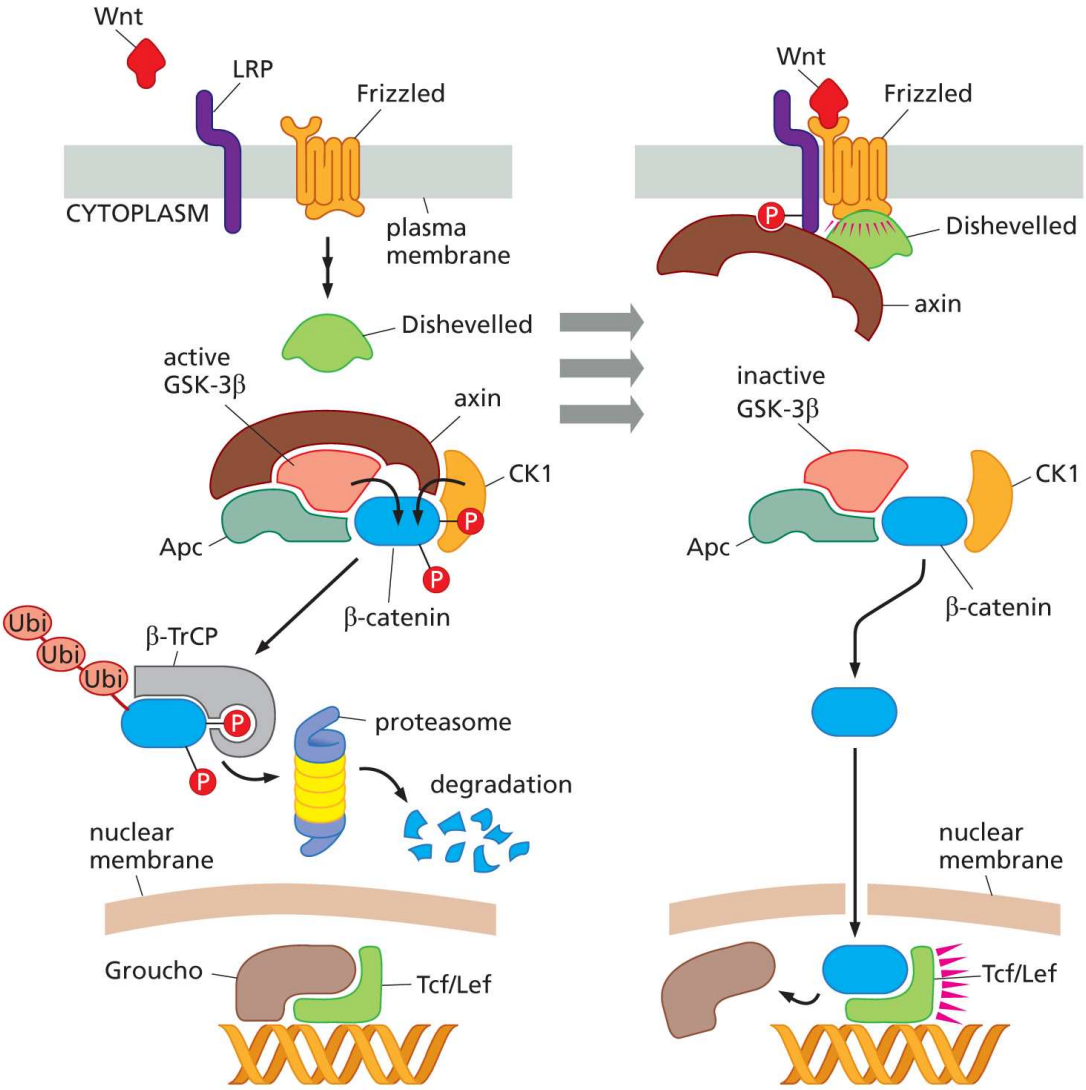
In most cell types, the RTK → Sos → Ras cascade appears to play a dominant role in mediating responses to extracellular mitogens, but it is hardly the only pathway having this result. Yet other, less studied pathways also confer responsiveness to mitogenic signals impinging on the cell surface. Prominent among these is the pathway controlled by Wnt factors, of which at least 19 can be found in various human tissues. In addition to transducing mitogenic signals, this pathway enables cells to remain in a relatively undifferentiated, stem cell-like state—an important attribute of certain subsets of the cancer cells in many tumors that will be discussed in more detail in Chapter 11.

As we learned in the last chapter (see Section 5.7), the molecular design of the Wnt pathway is totally different from that of the RTK → Sos → Ras → Raf → ERK pathway. Recall that canonical Wnt factors, acting through Frizzled receptors, suppress the activity of glycogen synthase kinase-3β (GSK-3β). In the absence of Wnts, GSK-3β phosphorylates several key substrate proteins, which are thereby tagged for destruction. The most important of these substrates is β-catenin, normally a cytoplasmic protein that exists in three states. It may be bound to the cytoplasmic domain of cell–cell adhesion receptors, notably the E-cadherin that is expressed on the surface of all epithelial cells and serves to knit together epithelial cell sheets (**Figure 6.19A**); E-cadherin molecules from adjacent cells may associate with one another to form adherens junctions involving cell-to-cell contacts together with associated cytoplasmic proteins that help to ensure the structural integrity of epithelial sheets and impede metastasis (as discussed in Chapter 14). Moreover, the cytoplasmic association of adherens complexes with the actin cytoskeleton, which depends on the involvement of β-catenin, creates physical coupling between the cytoskeletons of adjacent epithelial cells. Alternatively, in a fully unrelated role, β-catenin exists in a soluble pool in the cytosol, where it turns over very rapidly, having a lifetime of less than 20 minutes. And finally, β-catenin operates in the nucleus as an important component of a transcription factor complex (Figure 6.19B).



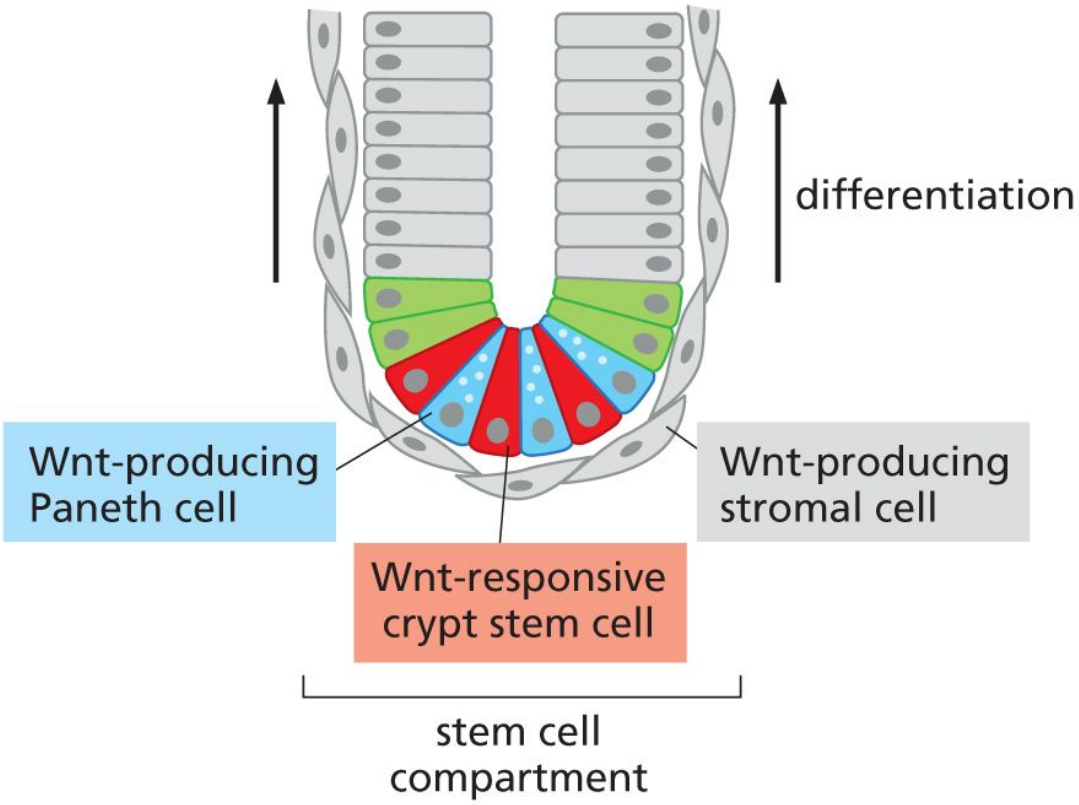
Long proteins called cadherins extend from one epithelial cell into the intracellular space and connect end-to-end with another cell's cadherins to bridge the space between the two cells. Each cadherin is a chain of five bulbous segments joined by thin segments made of C a plus 2 ions. The

cytoplasmic tails the cadherins connect to cytoplasmic actin filaments via a structure containing a p 120, a beta catenin, and an alpha catenin.
(A)



Two images show what happens to beta catenin in the absence and then in the presence of W n t binding. Without W n t binding, L R P and Frizzled remain apart within the plasma membrane. In the cytoplasm, Dishevelled remains separate from a complex consisting of C K 1, axin, active G S K 3 beta, A p c, and doubly phosphorylated beta catenin. This beta catenin detaches, while remaining doubly phosphorylated. A chain of three U b eyes attaches to it, and so does a beta T r C P. Degradation of the beta catenin is then mediated by a spiral-shaped proteasome. Meanwhile, within the cell nucleus, two proteins labeled Groucho and T c f / L e f are attached to a D N A double helix. This picture is changed by W n t binding. W n t, L R P and Frizzled come together

and activate, and Dishevelled and the axin from the complex attach on the cytoplasmic side. Also, the L R P is now singly phosphorylated. The G S K 3 beta in the complex is now inactive. Beta catenin remains unphosphorylated and does not undergo degradation. Instead, it passes through the nuclear membrane and binds to the T c f / L e f and the D N A double helix, displacing the Groucho protein. The T c f / L e f begins signaling.
(B)



A U-shaped structure of cells is shown. The bottom of the U is labeled stem cell compartment. Here, W n t-producing Paneth cells alternate with W n t-responsive crypt stem cells. The vertical arms of the U represent increasingly differentiated cells. The U is enclosed in a thin layer of W n t-producing stromal cells.

(C)

Figure 6.19 Canonical Wnt signaling: multiple roles of β-catenin (A) Like many integrins, the cadherins (*light green*) are transmembrane proteins that form attachments in the extracellular space and become linked, via intermediary proteins, to the actin cytoskeleton (*red*). The ectodomains of an epithelial cell's E-cadherin associate with E-cadherin molecules displayed by an adjacent epithelial

cell via *homophilic* interactions that form the core of adherens junctions displayed between adjacent epithelial cells in an epithelial cell sheet. Only the most distal, N-terminal subdomain among the five repeating subdomains of an individual E-cadherin ectodomain participate in associating with one displayed by an adjacent cell. Each of the four inter-subdomain linker regions binds three calcium ions whose presence is critical to preserve the rigidity and adhesive interactions of the protein. The cytoplasmic tail of E-cadherin, for its part, is known to associate directly with p120 and β-catenin (*dark blue, light blue*). These associate in turn with a monomer of α catenin (*dark green*). The precise molecular mechanisms of linkage of the cytoplasmic components are still poorly resolved. Breakdown of this multi-subunit complex, which includes comparable E-cadherin-associated proteins in the adjacent cell (*above, not shown*) often accompanies the acquisition of highly malignant properties by carcinoma cells. With the exception of actin (*red, below),* all of the proteins shown in this figure together with corresponding proteins in the adjacent cell (*not shown*) form, in aggregate, an adherens junction. (*continued*)

The relatively large number of E-cadherin molecules on the surface of epithelial cells serves as a major sink to absorb and stabilize a significant proportion of a cell's pools of β-catenin molecules; the latter are liberated when adherens junctions are dissolved, often achieved through the endocytosis of E-cadherin molecules. We focus here on the pools of these β-catenin molecules that are released into the cytosol following E-cadherin endocytosis. Such cytosolic β-catenin molecules may initially form multiprotein complexes with three other cellular proteins—Apc (the adenomatous polyposis coli protein), Wtx, and axin. These proteins help to bring β-catenin together with its GSK-3β executioner (see Figure 6.19B). By phosphorylating β-catenin, GSK-3β ensures that β-catenin will be tagged by ubiquitylation, a process that drives the rapid destruction of β-catenin; this explains the low steady-state concentrations of β-catenin normally present in the cytosol. We will encounter this degradation system later in more detail (see **Supplementary Sidebar 7.5**).

However, when canonical Wnt signaling is activated by the binding of canonical Wnt ligands to their cognate Frizzled (Fzd) receptors, GSK-3β firing is blocked and β-catenin is saved from rapid destruction; its half-life increases from less than 20 minutes to 1–2 hours, and its steady-state concentrations increase proportionately. Following appropriate changes in their phosphorylation, many of the accumulated β-catenin molecules move into the nucleus and bind to Tcf/Lef proteins (see Figure 6.19B). The resulting multi-subunit transcription factor complexes proceed to activate expression of a number of important genes, including those encoding critical proteins involved in cell growth and proliferation, such as cyclin D1 and Myc, that we will study later in Chapter 8.

In addition, GSK-3β can phosphorylate other crucial growth-regulating proteins besides cytoplasmic β-catenin. By phosphorylating cyclin D1 in the nucleus, GSK-3β also tags this growth-promoting protein for rapid degradation. Hence, the Wnt pathway actually modulates cyclin D1 expression at both the transcriptional and the post-translational levels. These various actions of Wnts indicate that, in addition to their originally discovered powers as morphogens, they can also act as potent mitogens, much like the ligands of many tyrosine kinase receptors. Moreover, as we will learn in Chapter 7, high levels of β-catenin in intestinal stem cells ensure that these cells remain in an undifferentiated, stem cell-like state, rather than developing into the specialized cells that line the wall of the intestine (Figure 6.19C). Indeed, there are multiple tissues throughout the body in which the stem cells seem to depend on Wnt signaling to enable their survival and drive their proliferation.

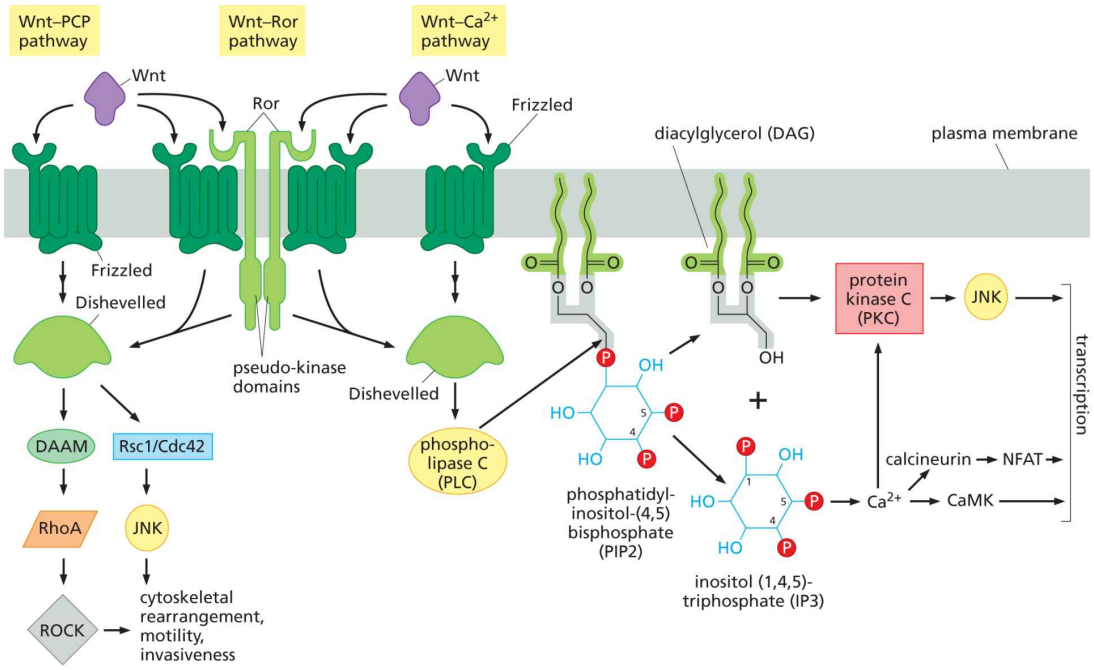
Then there is a major puzzle: Why has evolution invested two such unrelated functions in a single protein? (In worms, these two functions of β-catenin are carried out by distinct proteins encoded by separate genes.) According to one rationalization, the adherens junctions act as sensors of cell–cell contact in epithelial cell sheets, and once this contact is disrupted by various biological mechanisms, β-catenin can rapidly move into the nucleus to re-align the cell's transcriptional program to respond to this new biological state. This may explain how epithelial cells at the edge of a damaged cell sheet (which have lost adherens junctions with neighbors previously on one side) can activate the β-catenin–induced EMT (epithelial–mesenchymal transition) program, doing so in order to gain the motility that enables them to cover over and thereby heal the wound that generated this broken sheet, as described later in Chapter 14.

In many human breast cancers, expression of certain Wnts is increased four- to tenfold above normal, suggesting the operations of autocrine and paracrine growth-stimulatory pathways. There is clear evidence of nuclear translocation of β-catenin in approximately 20% of advanced prostate carcinomas. Moreover, in 5 to 7% of prostate carcinomas, mutations of the β-catenin gene have yielded a protein that can no longer be phosphorylated by GSK-3β, allowing it, in turn, to accumulate to high levels in the nucleus, where it can operate as a transcription factor. Such mutations have also been documented in carcinomas of the liver, colon, endometrium, and ovary, as well as in melanomas (**Supplementary Sidebar 6.7**). And as we will see in the next chapter, in virtually all colon carcinomas, β-catenin degradation is flawed, due to defects in one of the proteins—Apc—that usually facilitate its degradation (see Figure 6.19B). It is likely that this pathway is also deregulated in other human cancers by mechanisms that have not yet been uncovered.

The above descriptions do not begin to address the complexity of Wnt signaling. Thus, there are alternatives to the "canonical" Wnt signaling cascade described above. These alternative pathways tend to be triggered by a distinct subset of the Wnt ligands, operate independently of β-catenin signaling, and are grouped together under the

rubric of “non-canonical Wnt signaling.” Thus, Wnt3a is often used experimentally as a representative of canonical Wnt ligands whereas Wnt5a is used to study non-canonical signaling.

As seen in **Figure 6.20**, non-canonical Wnt signaling encompasses multiple signaling pathways. In the context of cancer, arguably the most important are a group of five tyrosine kinase receptors (RTKs), all of which appear to carry catalytically inactive kinase domains, much like HER3 (see Section 5.6). Among these pseudokinase receptors, Ror1 and Ror2 are best documented as important drivers of cancer-associated cellular phenotypes. These five receptors are clearly distant relatives of active RTKs whose kinase domains have lost catalytic activity through replacement of critical amino acid residues within the catalytic clefts of their respective tyrosine kinase domains. Indeed, like most RTKs, versions of these receptors are evolutionarily highly conserved, being clearly present in the cells of worms and flies.



Three non-canonical W n t signaling pathways. The W n t-P C P pathway involves W n t binding to Frizzled. The W n t-Ror pathwat involves W n t binding to both Frizzled and Ror. These two pathways combine to act on Dishevelled and initiate a sequence that also involves D A A M, R s c 1 / C d c 42, R h o A, ROCK, and J N K. The end result is cytoskeletal rearrangement and enhanced motility and invasiveness. A third pathway is W n t-Calcium plus 2. It and the W n t-Ror pathway combine to act on Dishevelled and initiate a sequence that also involves phospholipase C (P L C), phosphatidylinositol-(4,5) bisphosphate (P I P 2) attached to diacylglycerol (D A G), inositol (1,4,5)-triphosphate (I P 3) detached

from D A G, Calcium plus 2, calcineurin, C a M K, N F A T, protein kinase C (P K C), and J N K. The end result is transcription.

Figure 6.20 Non-canonical Wnt signaling A second set of Wnt signaling pathways operates entirely differently from the canonical Wnt pathway that is described in Figure 6.19 that is involved in regulating cell proliferation and stemness. Some Wnt ligands bind preferentially to the Frizzled (Fzd) receptors that activate these non-canonical Wnt pathways (*dark green*), while other Wnt ligands can bind both canonical and non-canonical Frizzled receptors; in addition, certain Wnts (*purple*) can bind a set of non-canonical receptors [including Ror (*light green*), Ryk, PTK7, and MuSK and represented here by Ror] that are structured like RTKs but have a nonfunctional "pseudokinase" domain. Various canonical and non-canonical Wnt ligands associate with either non-canonical Frizzled receptors, Ror-like receptors, or physical complexes involving both Ror-like receptors and Frizzled receptors and elicit a distinct set of cell-biological processes largely associated, at least in carcinoma cells, with motility, invasiveness, and, ultimately, metastatic dissemination. For example, the *p*lanar cell *p*olarity (Wnt-PCP) pathway is involved in reorganization of the actin cytoskeleton, motility, and associated invasiveness, while the Wnt-Ca^{2+} pathway also contributes to motility and invasiveness by up-regulating a constituency of nuclear genes. In addition, the Wnt-Ror pathways can also function to suppress canonical Wnt β-catenin signaling. (Not illustrated here are the Wnt ligand-driven heterodimerizations of Ror receptors with certain RTKs.)

These RTKs display a structurally diverse group of Wnt-binding ectodomains, some of which are structurally related to the Frizzled receptors cited above; like other "pseudokinase" receptors, these appear to act via dimerization with other actively signaling receptors (see Section 5.6 and **Supplementary Sidebar 6.5**). In some instances, these RTKs may form heterodimers with the structurally unrelated Frizzled receptors. The downstream signaling mechanisms of these RTKs are complex and still being resolved. However, their roles in cancer pathogenesis are clearly significant, since these receptors have been reported to contribute to a broad spectrum of cell-biological traits relevant to tumor formation and progression, namely, cell growth, proliferation, motility, invasiveness, and inhibition of apoptosis. Some have even suggested that a historically earlier discovery of these Wnt RTKs would have caused them, rather than the much-studied Frizzled proteins, to be portrayed as the "canonical" Wnt receptors.

Yet other non-canonical Wnt pathways have been reported, but their role in cancer pathogenesis is less clear. Some of these distinct subsets of signaling cascades, termed the Wnt-PCP and the Wnt-Ca^{2+} pathways, lie downstream of Frizzled receptors, while others may be activated by the pseudokinase RTKs mentioned above. While the

canonical Wnt pathway has been found to play a role in cancer cell proliferation and stemness—and thus the formation of tumor-initiating cancer stem cells—the non-canonical Wnt pathway largely contributes to critical aspects of the malignant cell phenotype, notably cytoskeletal rearrangement, motility, and invasiveness. Canonical Wnt ligands can occasionally activate non-canonical signaling and vice versa, and the non-canonical Wnt-PCP pathway has been found in some contexts to inhibit canonical Wnt signaling. For better or worse, as non-canonical Wnt signaling pathways are studied in ever-increasing detail, their complexity grows exponentially.

OceanofPDF.com

Glossary

adherens junction
: Lateral cell–cell junction between adjacent cells, notably epithelial cells, that is formed by cadherins displayed on the opposing surfaces of participating pairs of cells; these junctions include the cytoplasmic proteins that are physically associated with the cytoplasmic domains of both participating cadherins and serve to link these junctions, in turn, to the actin cytoskeletons of the two cells.

ubiquitylation
: Process by which one or more ubiquitin molecules are attached covalently to a protein substrate molecule, which often results in the degradation of the tagged protein in a proteasome, *alternatively termed* **ubiquitination**.

morphogen
: Low–molecular-weight substance that induces cells to assemble and participate in the construction of a tissue of a certain shape and form.

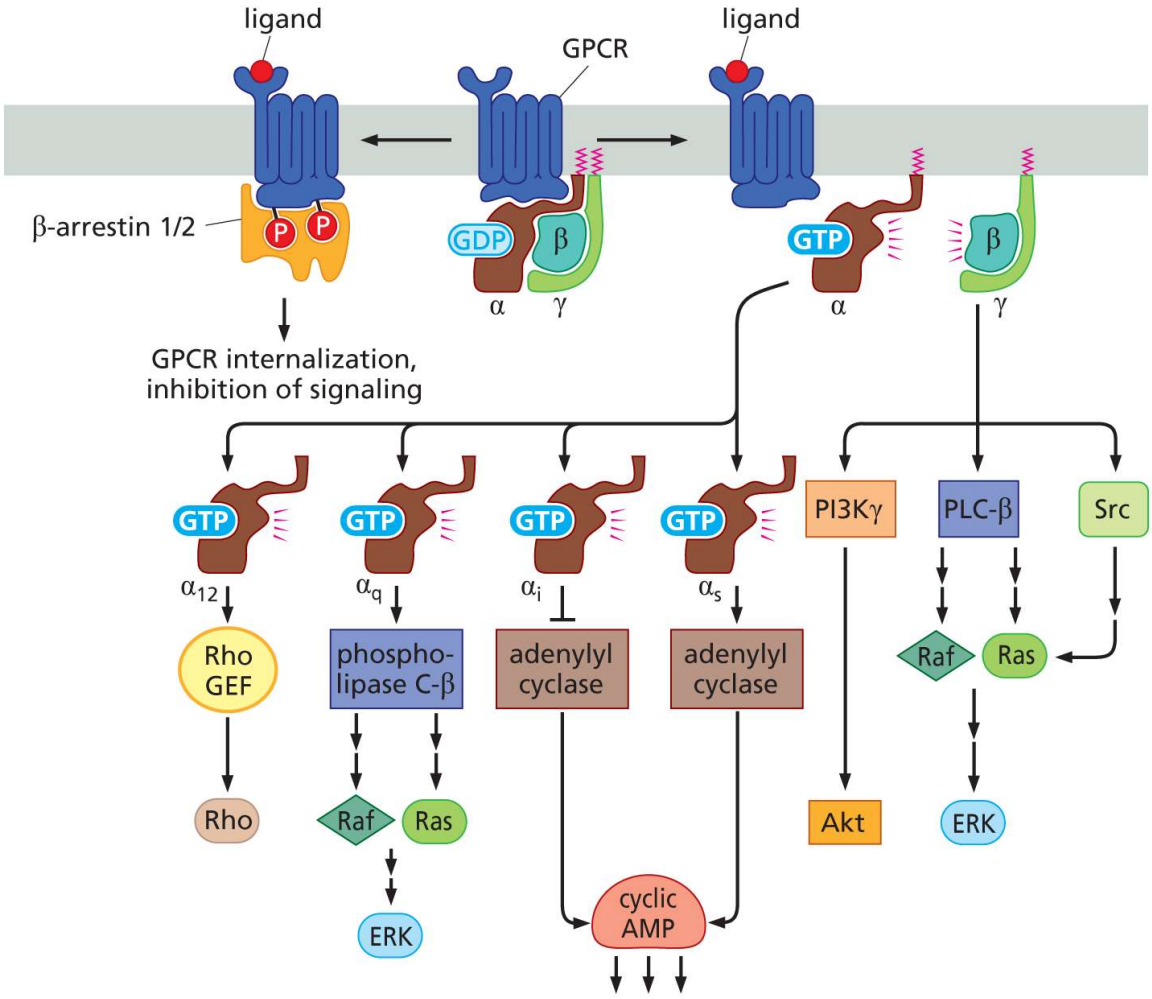
6.11 G-protein–coupled receptors can also drive normal and neoplastic proliferation

As we read in the last chapter (Section 5.7), G-protein–coupled receptors (GPCRs) are transmembrane proteins that weave their way back and forth through the plasma membrane seven times. Upon binding their extracellular ligands, each of these “serpentine” receptors activates one or more types of cytoplasmic heterotrimeric G protein, so named because of its three distinct subunits (Gα, Gβ, and Gγ), the first of which binds either GDP or GTP. As is the case with the Ras protein, the activated state of Gα is achieved when it binds GTP. Hence, a ligand-activated GPCR can act as a GEF (guanine nucleotide exchange factor) for Gα proteins, much like the GEFs for Ras-like proteins (see Figure 5.24). While the majority of known GPCR ligands are soluble molecules, a small number of these receptors use their ectodomains to sense adhesion to the extracellular matrix (ECM).

Of note, only a relatively small proportion of the ~830 GPCRs encoded in the human genome are involved in cancer pathogenesis. About half of the rest are olfactory receptors, while several dozen others are involved in other types of sensation, such as taste and light, and in signaling via neurotransmitters in the brain. These receptors are of more than passing interest to clinical medicine, since more than 35% of currently approved pharmaceutical agents target various GPCRs. As many as 100 of the GPCRs have no known ligands and, as such, are termed “orphan receptors.” The multiplicity of downstream heterotrimeric G proteins derives from the variability of the constituent subunits: there are at least 21 distinct Gα, 6 distinct Gβ, and 12 Gγ subunits, which can associate in various combinations.

Once stimulated by a G-protein–coupled receptor (GPCR), the Gα subunit of a heterotrimeric G protein dissociates from its two partners, Gβ and Gγ, and proceeds to activate a number of distinct cytoplasmic enzymes (**Figure 6.21**). Included among these are adenylyl cyclase (which converts ATP into cyclic AMP) and phospholipase C-β (PLC-β), which cleaves PIP3 to yield diacylglycerol (DAG) and inositol triphosphate (IP3) (see Figure 6.11B). The latter are potent second messengers that can function to stimulate cell proliferation. (The Frizzled

receptors enabling canonical Wnt signaling [see Section 6.10] are structurally classified as GPCRs and some have been found to associate with heterodimeric G proteins. However, the importance of Wnt signaling through heterotrimeric G proteins remains unclear.)



A diagram shows signaling originating with a G-protein–coupled receptor, or G P C R. Initially, the G P C R within a plasma membrane is connected on the cytoplasmic side to an alpha unit containing a G D P, a beta unit, and a gamma unit. When a ligand binds to the G P C R on the extracellular side, the alpha unit detaches, with the G D P replaced with a G T P. The beta and gamma units detach while remaining attached to each other. Both detached units remain attached to the cytoplasmic side of the plasma membrane. The beta-gamma complex activates A k t via P I 3 K gamma. It also activates E R K via two pathways that involve P L C-beta, Sarc, R a f, and R a s. The alpha-G T P activates one of several cytoplasmic effectors, depending on the identity of the alpha unit. Alpha 12 activates R h o via R h o G E F. Alpha q

activates E R K via phospholipase C-beta, R a f and R a s. Alpha i inhibits cyclic A M P by inhibiting the adenylyl cyclase that would normally activate it. Alpha s activates cyclic A M P by activating the adenylyl cyclase. Meanwhile, the ligand-bound G P C R, now doubly phosphorylated, binds to beta arrestin 1 slash 2. The result is G P C R internalization and inhibition of signaling.

Figure 6.21 G-protein–coupled receptors The seven-membrane-spanning ("serpentine") receptors (*dark purple*) are able to activate a variety of heterotrimeric G proteins that differ largely in the identity of their Gα subunits (*dark brown*). Once stimulated by a ligand-activated GPCR, a Gα subunit evicts its bound GDP, binding GTP instead, separates from the Gβ + Gγ complex, and proceeds to activate or inhibit a variety of cytoplasmic effectors, only four of which are shown here. In addition to activating enzymes, a guanine nucleotide exchange factor (GEF) for the Rho family of small GTPase proteins (Rho, Rac, and Cdc42) can be activated (*light yellow, lower left*). These enzymes, in turn, can have mitogenic or anti-mitogenic influences, depending upon the cell type. At the same time, the Gβ + Gγ dimer complexes (*right*) can activate their own set of effectors, including phosphatidylinositol 3-kinase γ (PI3Kγ), phospholipase C-β (PLC-β), and Src. Following GPCR activation, these receptors are rapidly phosphorylated and attract β-arrestins 1 and 2 (*light orange, left)*, which results in cessation of further GPCR firing and in GPCR internalization. Soon, each Gα subunit will hydrolyze its bound GTP, returning it to the inactive, nonsignaling state (*not shown*). Moreover, this cartoon provides only a hint of the diverse array of G proteins and their effectors that have been discovered. For example, there are nine subtypes of adenylyl cyclase.

There is also evidence that the Src kinase can be activated by certain GTP-bound Gα subunits. Moreover, complexes of the other two subunits of the heterotrimeric G protein—Gβ and Gγ—have been found to stimulate yet other important mitogenic signaling proteins, such as one form of phosphatidylinositol 3-kinase (PI3K). The ability of GPCRs to activate mitogenic pathways suggests that deregulation of signaling by these receptors and associated G proteins may well contribute to cell transformation and tumorigenesis—a speculation that has been borne out by analyses of a limited number of types of human cancer cells (**Table 6.5**).

Table 6.5 G-protein–coupled receptors and G proteins involved in human cancer pathogenesis

G protein or receptor	Type of tumor
Activating mutations affecting G proteins	
$G\alpha_s$	thyroid adenomas and carcinomas, pituitary adenomas
$G\alpha_{i2}$	ovarian tumors, adrenal cortical tumors
$G\alpha_q$	melanocyte-derived tumors, uveal melanomas
$G\alpha_{11}$	uveal melanomas
Activating mutations affecting G-protein–coupled receptors	
Thyroid-stimulating hormone receptor	thyroid adenomas and carcinomas
Follicle-stimulating hormone receptor	ovarian tumors
Luteinizing hormone receptor	Leydig cell hyperplasias
Cholecystokinin-2 receptor	colorectal carcinomas
Ca^{2+}-sensing receptor	various neoplasms

G protein or receptor	Type of tumor
Activating mutations affecting G proteins	
GPR98	melanomas
GRM3	melanomas
Autocrine and paracrine activation	
Neuromedin B receptor	small cell lung cancer (SCLC)
Neurotensin receptor	prostate carcinomas and SCLC
Gastrin receptor	gastric carcinomas and SCLC
Cholecystokinin receptor	pancreatic hyperplasias and carcinomas, gastrointestinal carcinomas, and SCLC
Virus-encoded G-protein–coupled receptors	
Kaposi’s sarcoma herpesvirus (HHV-8)	Kaposi’s sarcoma
Herpesvirus saimiri	primate leukemias and lymphomas
Jaagsiekte sheep retrovirus	sheep pulmonary carcinomas

G protein or receptor	Type of tumor
Activating mutations affecting G proteins	

Adapted in part from M.J. Marinissen and J.S. Gutkind, *Trends Pharmacol. Sci.* 22:368–376, 2001. With permission from Elsevier.

The role of GPCRs in human cancer pathogenesis is highlighted by the behavior of small-cell lung carcinomas (SCLCs), a common tumor of cigarette smokers. SCLC cells release a number of distinct peptide factors, some with neuropeptide-like properties. In some SCLCs, the tumor cells may simultaneously secrete bombesin (also known as gastrin-releasing peptide, or GRP), bradykinin, cholecystokinin (CCK), gastrin, neurotensin, and vasopressin. At the same time, these cells display the GPCRs that recognize and bind all of these released factors, resulting in the establishment of multiple autocrine signaling loops.

The experimental proof that these autocrine loops are actually responsible for driving the proliferation and/or survival of the SCLC cells is straightforward: SCLC cells can be incubated *in vitro* in the presence of an antibody that binds and neutralizes a secreted autocrine growth factor, such as GRP. In a number of SCLC cell lines, this treatment results in the rapid cessation of growth and even leads to apoptosis. Such a response indicates that these cancer cells depend on a GRP-based autocrine signaling loop for their survival, and it suggested a novel therapy for SCLC patients: in twelve SCLC patients who were treated with a GRP-neutralizing antibody, one patient showed a complete remission, while four patients exhibited a partial shrinkage of their tumors. (This therapeutic strategy has not, however, been further pursued in recent years.)

In another class of neoplasias—thyroid adenomas and some thyroid carcinomas—the gene encoding the thyroid-stimulating hormone receptor (TSHR), another GPCR, is often found to carry a point mutation. This leads to constitutive, ligand-independent firing of the TSH receptor, which in turn results in the release of strong mitogenic signals into the thyroid epithelial cells (see Table 6.5). In yet other tumors of the thyroid gland, a Gα subunit has suffered a point mutation that functions much like the mutations activating Ras signaling (see Figure 5.24), by depriving this Gα subunit of the ability to shut itself off through its own intrinsic GTPase activity. Altogether, at least 10 of the 17 human genes encoding Gα

subunits have been found to function as oncogenes in certain cell types and in various human malignancies.

The most bizarre subversion of these G-protein–coupled receptors occurs during infections by certain herpesviruses, such as human herpesvirus type 8 (HHV-8), also known as the Kaposi's sarcoma herpesvirus (KSHV; refer to **Supplementary Sidebar 3.5**). This virus is responsible for the vascular tumors that frequently afflict AIDS patients. At one point in its evolutionary past, this virus acquired a cellular gene specifying a G-protein–coupled receptor. The viral form of this gene has been remodeled, so that the encoded receptor releases signals in a ligand-independent manner. Among other consequences, this signaling causes HHV-8–infected endothelial cells (lining the walls of blood vessels) to secrete vascular endothelial growth factor (VEGF); the released VEGF then creates an autocrine signaling loop by binding to its cognate receptors on the surface of these infected endothelial cells and driving their proliferation. Later we will read (Chapter 15) about the role of chemokines, which serve as ligands of a special class of GPCRs (altogether 20 in humans), for recruiting various types of immune cells to specific sites within tissues.

Glossary

neuropeptide

A small protein or oligopeptide that is produced by cleavage of a higher–molecular-weight precursor and is released by certain cells of the central nervous system and neuroendocrinal cells and that impinges upon and thereby signals to other cells inside and outside of the central nervous system.

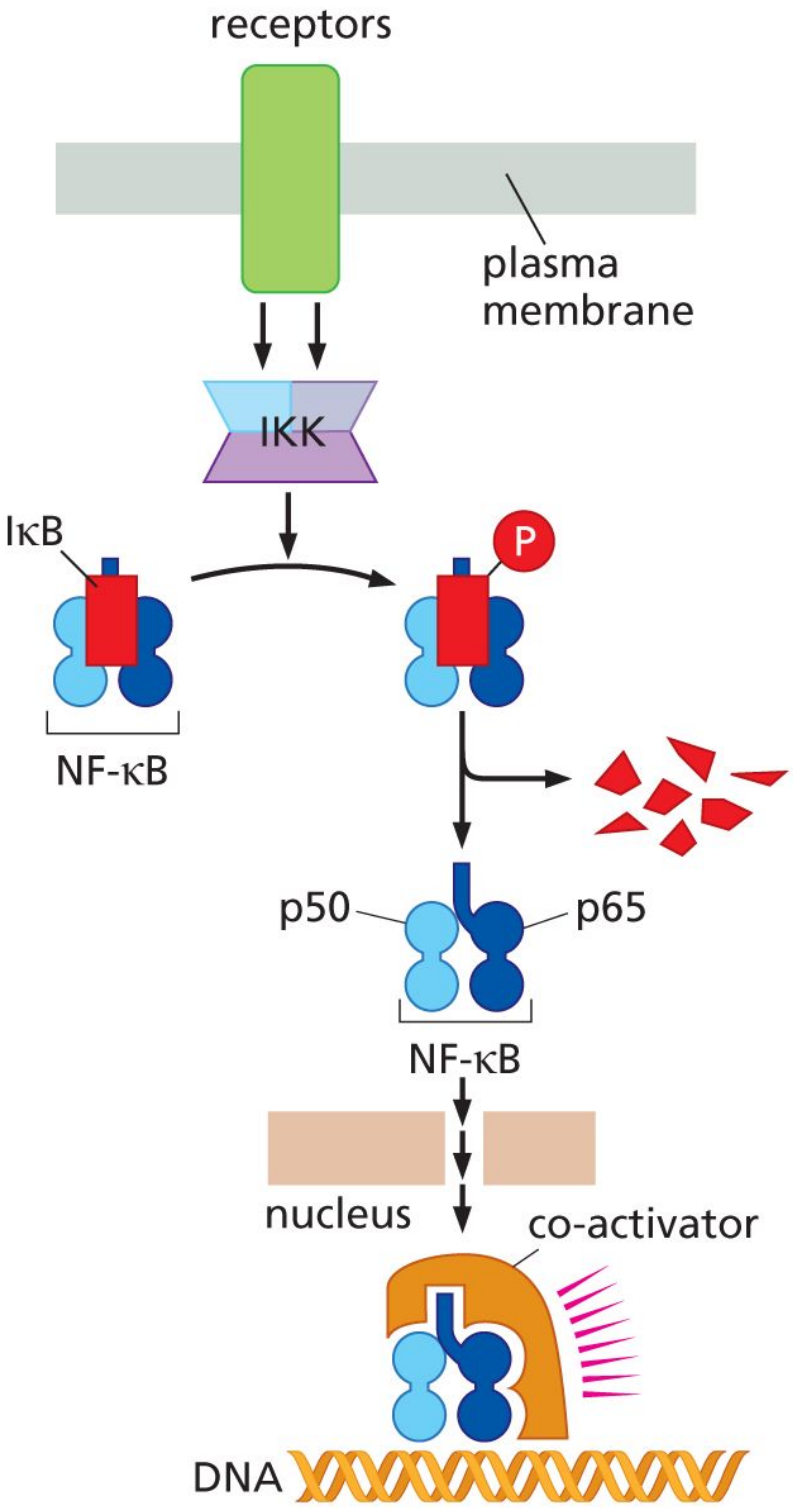
chemokine

(1) A polypeptide that serves as an attractant for motile cells, notably leukocytes, via chemotaxis. (2) More narrowly, a member of a family of low–molecular-weight (8–10 kD) secreted proteins, most of which contain four cysteine residues in evolutionarily conserved sites. *See also* **chemotaxis**.

OceanofPDF.com

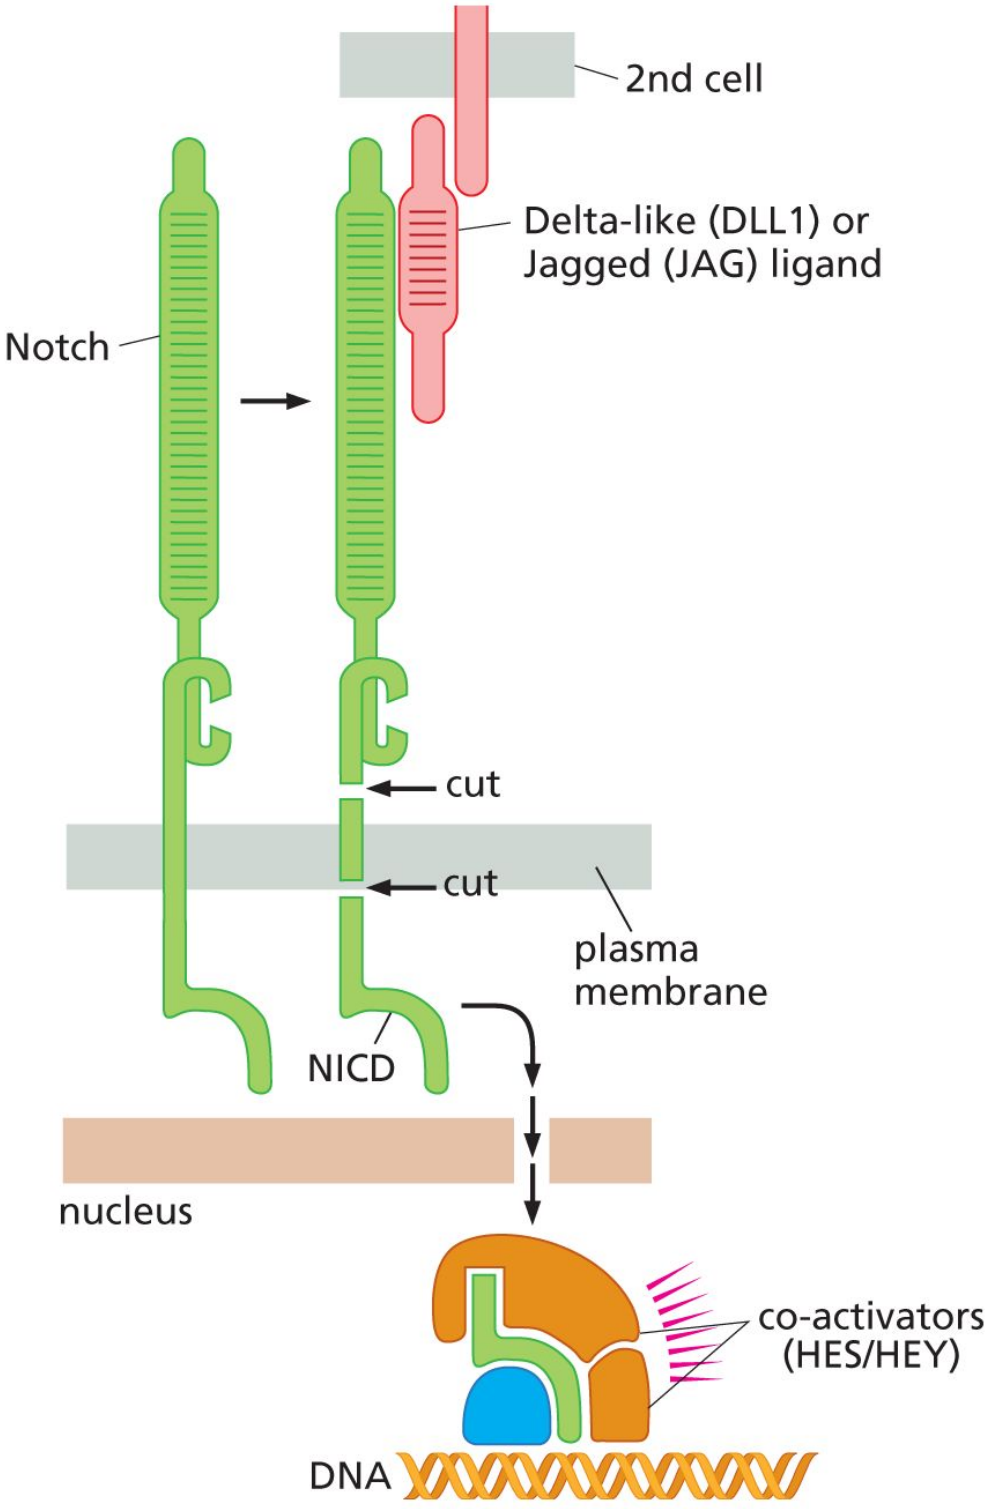
6.12 Four additional “dual-address” signaling pathways contribute in various ways to normal and neoplastic proliferation

Both JAK–STAT and Wnt–β-catenin signaling represent “dual-address” pathways, which operate by modifying and dispatching to the nucleus certain signaling proteins that normally reside in the cytoplasm; once in the nucleus, the key proteins in these two pathways (that is, STATs and β-catenin) function as components of specific transcription factor complexes to drive gene expression. In fact, four other dual-address signaling channels play important roles in the pathogenesis of human cancers. Here, we will briefly summarize the downstream actions of these four pathways (**Figure 6.22**) and cite examples of how each is deregulated in one or another type of human tumor (**Figure 6.23**).



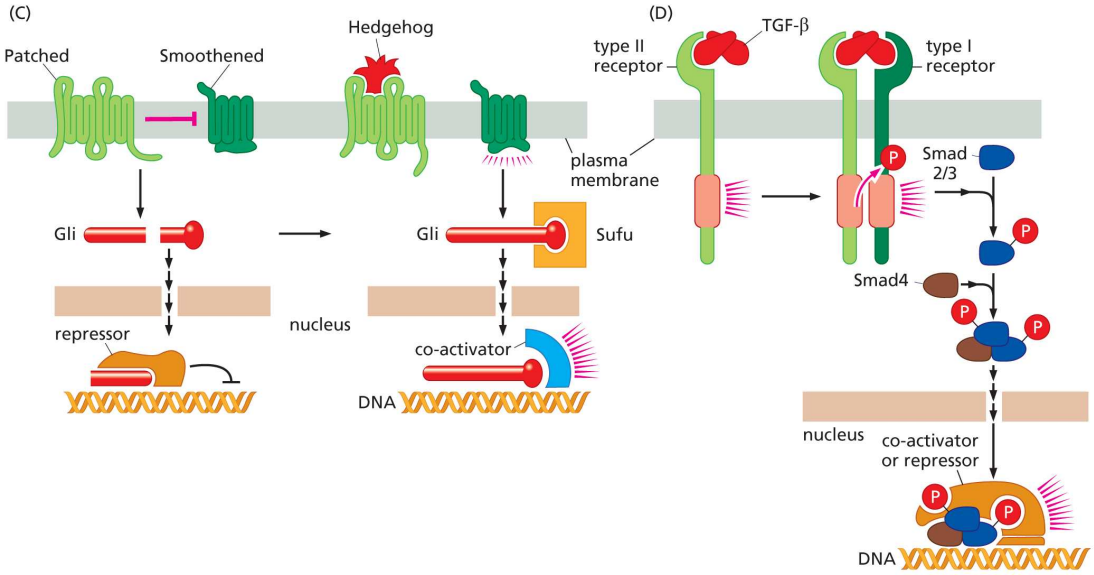
A receptor in the plasma membrane activates I K K, which phosphorylates an I kappa B within an N F-kappa B. This leads to the degradation of the I kappa B, leaving behind N F-kappa B with just a p 50 subunit and a p 65 subunit.

This passes into the nucleus, where the N F-kappa B joins a co-activator in attaching to a D N A helix.
(A)



A notch receptor in one cell's plasma membrane binds to a Delta-like (D L L1) or Jagged (J A G) ligand already bound to a receptor on another cell. This causes the notch receptor to break in two places, namely the inner and outer surfaces of the plasma membrane. The cytoplasmic domain, labeled N I C D, migrates into the nucleus, where it joins co-activators co-activators (H E S / H E Y) in attaching to a D N A helix.

(B)

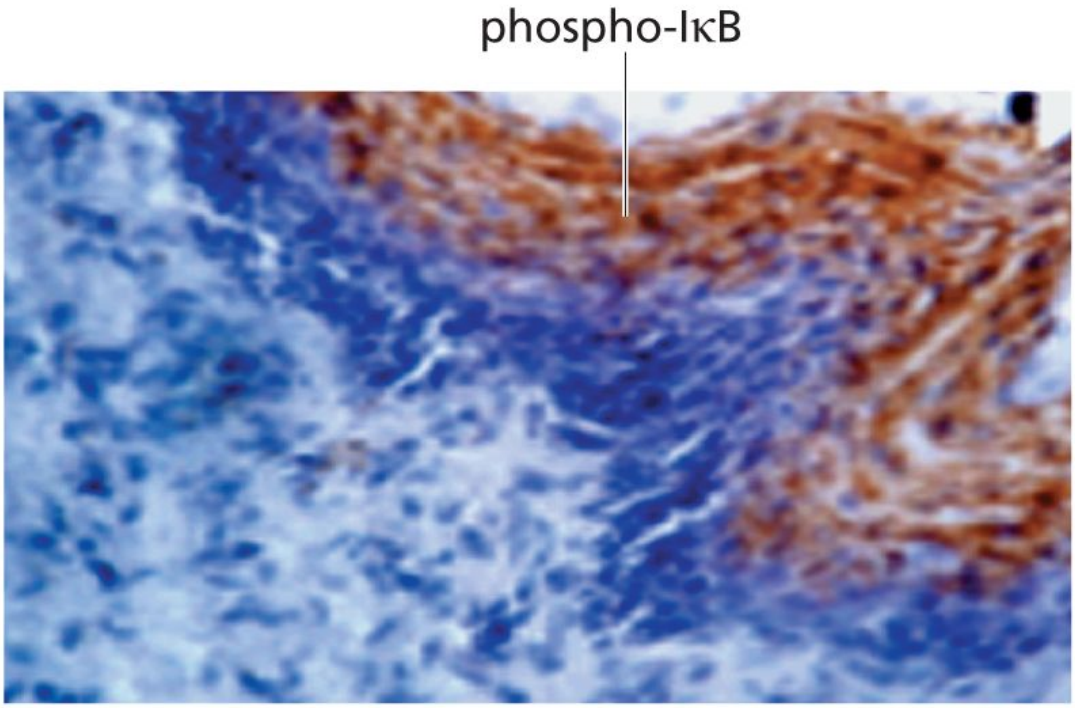


Patched initially inhibits Smoothened. This promotes the degradation of G l i, part of which moves into the nucleus and participates in transcription repression. When Patched is bound by a Hedgehog ligand, it stops inhibiting Smoothened. Then G l i is no longer degraded, it temporarily binds to Sufu and then translocates to the nucleus, where it joins with a co-activator to promote D N A transcription.

Binding of a Type 1 receptor by a T G F-ligand joins it with a Type 2 receptor. A series of phosphorylation steps involving S m a d 2 slash 3 and S m a d 4 results in a complex that in the nucleus joins with a co-activator or co-repressor to either activate or repress gene expression.

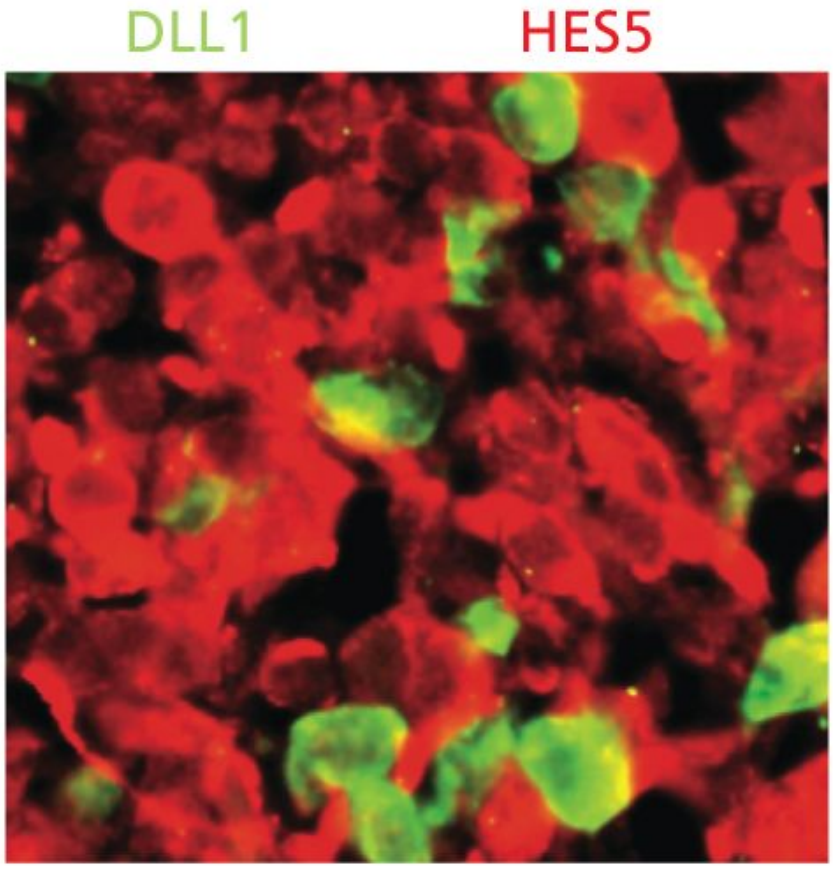
Figure 6.22 Four different "dual-address" signaling pathways (A) The NF-κB family of five transcription factor proteins, which function as homo- and heterodimers represented here by the commonly found p50 and p65 (*light and dark blue*), are sequestered in the cytoplasm by IκB (*red*). A variety of receptors and afferent signals (such as inflammatory cytokines) activate the IKK heterotetramer, which contains two distinct kinase subunits and phosphorylates

IκB, tagging it for proteolytic degradation. Once liberated from IκB, the NF-κB dimer can translocate to the nucleus, where it activates a broad constituency of genes, including anti-apoptotic and mitogenic genes. A prominent gene target of NF-κB transcriptional regulation is the gene encoding IκBα, which ( ) generates this inhibitory protein that proceeds to move into the nucleus to shut down further transcription by NF-κB, thereby functioning as a negative-feedback inhibitor (*not shown*). Also not shown are the alternative, non-canonical, and atypical NF-κB pathways. (B) The Notch receptor can bind ligands belonging to the Delta-like and Jagged families that are presented by a closely apposed second cell. Ligand binding causes two proteolytic cuts in Notch (*below*), liberating a cytoplasmic fragment (termed Notch intracellular domain, NICD) that can translocate to the nucleus, where it functions as part of a transcription factor complex. At the same time, the Notch ligand and the ectodomain of the Notch receptor are internalized and then degraded by the ligand-presenting cell (*not shown*; see Figure 5.16). (C) In this simplified depiction of Patched (Ptc)–Smoothened signaling, the binding of a Hedgehog (Hh) ligand releases Smo from Ptc control (see Figure 5.17 for more details). Smo then allows Gli to escape ongoing degradation (where its cleaved form acts as a transcriptional repressor in the nucleus). The resulting full-length Gli protein appears to be sequestered by Sufu in the cytoplasm and in the primary cilium. In response to Hh ligand binding, Sufu releases its grip on the Gli protein, allowing the latter to accumulate in full-length form and translocate to the nucleus, where it functions as a transcriptional inducer or repressor. (In fact, two of the three Gli proteins function as repressors; a third one can act to stimulate transcription under certain conditions.) (D) Binding of the TGF-β ligand to the type II TGF-β receptor brings the type II and type I receptors together and results in the phosphorylation by the type II receptor of the type I receptor. The latter, now activated, phosphorylates cytosolic Smad2 and/or Smad3 proteins; these phospho-Smads then bind to Smad4. The resulting heterotrimeric Smad complexes (composed of Smad 2/2/4, 2/3/4, or 3/3/4 subunits) translocate to the nucleus, where they bind specifically to a tetranucleotide DNA segment and associate with other adjacently bound transcription factors (*light brown*) to induce or repress gene expression.



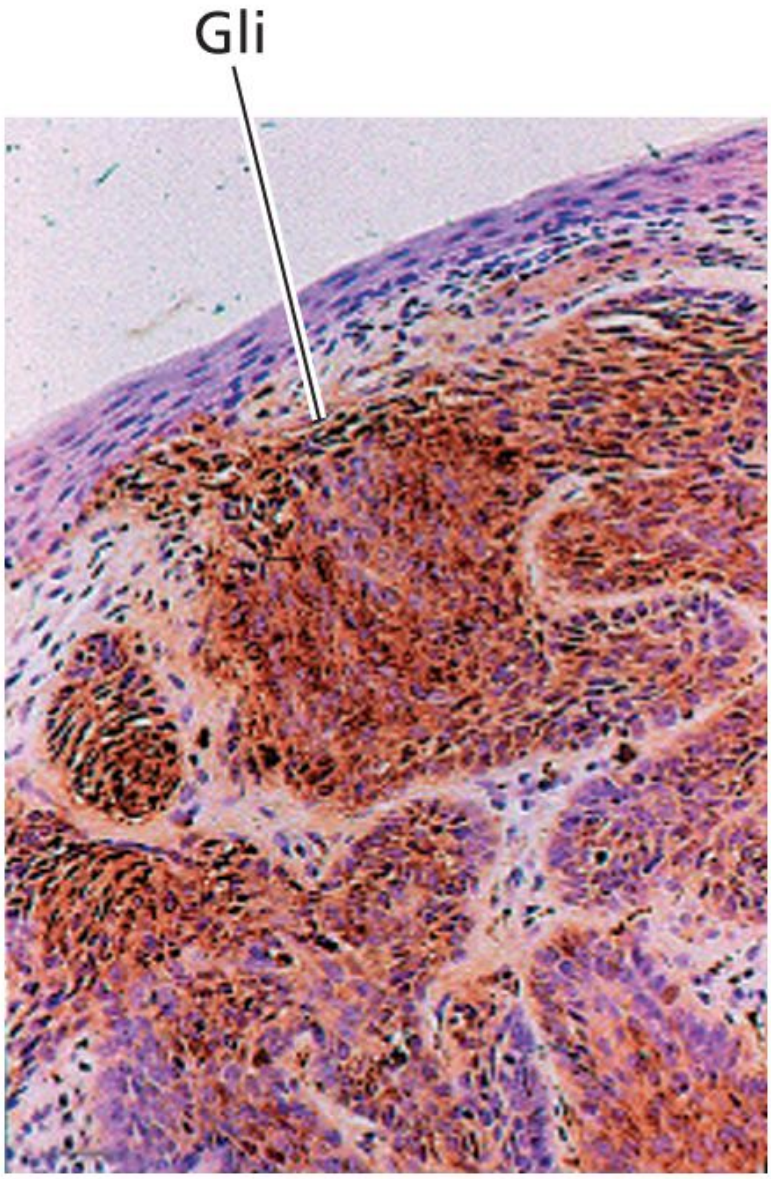
A histology image showing a undulating band of epithelial cells stained brown, surrounded by cells stained blue.

(A)



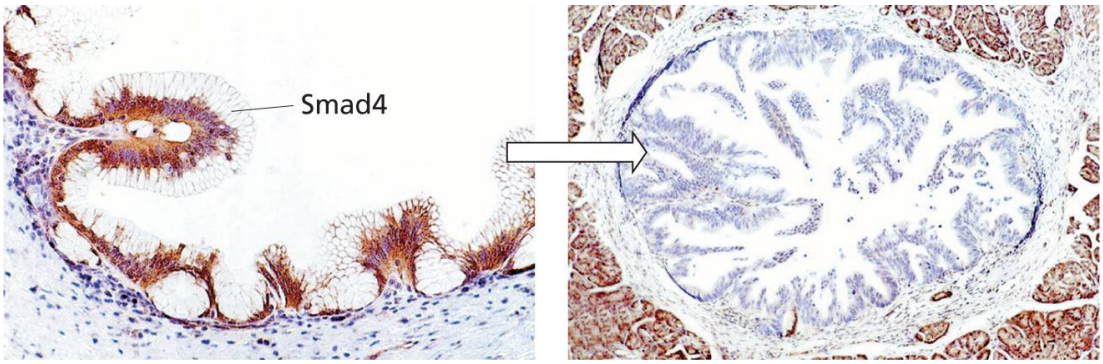
A false-color micrograph showing a few bright green blobs in a field of red-orange blobs. Above the image is the green label D L L1 and the red label HES5.

(B)



A histology image of cells stained rust brown surrounded by cells stained purplish pink. The brown cells are labeled G l i 1.

(C)



Two histology images. In the first, a tissue sample shows healthy cells in pale blue, with brown tree-like projections growing from the edge of the sample at irregular intervals. One of these is labeled S m a d 4. In the second image, a pale blue lesion is surrounded by brown tissue. Fissures run through tissues of both colors.

(D)

Figure 6.23 Deregulation of dual-address pathways in human cancers (A) NF-κB pathway. Immunostaining for the phosphorylated form of IκB reveals the localized activation of the NF-κB pathway (*brown area*) early in the multi-step development of a human cervical carcinoma, in this case in a low-grade squamous intraepithelial lesion. (B) Notch pathway. This pathway is often deregulated through localized expression of Notch ligands. Characteristic downstream targets of Notch-stimulated transcription are a pair of bHLH transcription factors (see Figure 8.21) termed HES and HEY. In human glioblastomas, the DLL1 Notch ligand is expressed by endothelial cells forming the microvasculature of the tumor (*green*). Close to these endothelial cells are neoplastic glioblastoma cells that have responded to this DLL1-mediated activation of their Notch1 and Notch2 receptors by expressing HES5, a clear marker of activated Notch signaling (*red orange*). This *juxtacrine* signaling also causes the glioblastoma cells to express Nestin (*not shown*), a marker of both normal and neoplastic stem cells in the brain. (C) Hedgehog pathway. This pathway is deregulated in the majority of basal cell carcinomas of the skin (BCCs). Its deregulation is indicated by the elevated concentration of Gli1 protein in BCCs, detected here by immunostaining (*brown*), while being barely evident in normal cells (*light pink*). Northern (RNA) blot analyses (*not shown*) indicate as much as a 40-fold elevation in Gli1 mRNA in BCCs compared with normal skin. (D) TGF-β pathway. This pathway is inactivated in a wide variety of carcinomas through several mechanisms. During pancreatic carcinoma progression, low-grade pancreatic intraepithelial neoplasias (PanIN-1) usually express Smad4 (*brown, left panel*), a critical transcription factor in TGF-β signaling (see Figure 6.22D). These can progress (*arrow*) to high-grade PanIN-3 lesions, which often lose Smad4 expression, typically because of

mutation of the encoding gene (*center of right panel*). (A, from A. Nair et al., *Oncogene* 22:50–58, 2003. With permission from Nature. B, from T.S. Zhu et al., *Cancer Res*. 71:6061–6062, 2011. Wilentz et al., *Cancer Res*. 60:2002–2006, 2000. With permission from American Association for Cancer Research.)

Nuclear factor-κB The first indication of the importance of this pathway to cancer pathogenesis came from the discovery of the *rel* oncogene in a rapidly transforming turkey retrovirus responsible for reticuloendotheliosis, a hematopoietic tumor of the monocyte/macrophage lineage. Later investigations into the transcription factors responsible for regulating immunoglobulin gene expression revealed Rel to be a member of a family of transcription factors that came to be called collectively NF-κBs. These proteins form homo- and heterodimers in the cytoplasm.

The most common form of NF-κB is a heterodimer composed of a p65 and a p50 subunit. Usually, NF-κB is sequestered in the cytoplasm by a third polypeptide named IκB (inhibitor of NF-κB; see Figure 6.22A); while in this state, this signaling system is kept silent. However, in response to signals originating from a diverse array of sources, IκB becomes phosphorylated and thereby tagged for rapid destruction. (Recall that β-catenin suffers the same fate following its phosphorylation in the cytoplasm.) As a result, NF-κB is liberated from the clutches of IκB, migrates into the nucleus, and proceeds to activate the expression of a cohort of as many as 500 target genes.

The kinase that tags IκB for destruction (named IκB kinase or simply IKK) and thereby activates NF-κB signaling is itself stimulated by signals as diverse as tumor necrosis factor-α and interleukin-1β (extracellular factors involved in the inflammatory response of the immune system), lipopolysaccharide (a component of the outer membrane of certain bacteria and thus an indicator of bacterial infection), reactive oxygen species (ROS), anti-cancer drugs, and gamma irradiation. In the context of cancer, NF-κBs affect cell survival and proliferation. Once they have arrived in the nucleus, the NF-κBs can induce expression of genes specifying a number of key anti-apoptotic proteins, such as Bcl-2 and IAP-1 and -2; we will learn more about these proteins in Chapter 9. At the same time, NF-κBs function in a mitogenic fashion by inducing expression of the *myc* and cyclin D1 genes, components of the cell cycle machinery that we will encounter in Chapter 8. Hence, NF-κBs can protect cancer cells from apoptosis (programmed cell death) and, at the same time, drive their proliferation. An alternative, non-canonical form of NF-κB participates, albeit less frequently, in the development of certain tumors.

While components of the NF-κB signaling cascade are rarely found in mutant form in human cancers, this pathway is frequently found to be constitutively activated. In

breast cancers, for example, the pathway is often highly active, ostensibly through the actions of IKKε, which is overexpressed in ~30% of these tumors. NF-κB seems to play its most important role in malignancies of various lymphocyte lineages. The *REL* gene, which encodes one of the subunits of NF-κB, is amplified in about one-fourth of diffuse large B-cell lymphomas, resulting in a 4- to 35-fold increase in expression of its gene product. Translocations affecting the *NFKB2* locus have been found frequently in B- and T-cell lymphomas and in myelomas (tumors of antibody-producing cells). And deregulation of this pathway can often be observed early in the development of low-grade malignant growths (see Figure 6.23A). More generally, overexpression of NF-κB is associated with poor prognosis in a variety of common cancers.

Notch Study of another unusual signaling pathway, this one controlled by the Notch protein, traces its roots to the discovery in 1913 of an allele of a *Drosophila* gene that causes notches to form in the edges of this fly's wings. Only many decades later was it realized that Notch is a transmembrane protein; four different varieties of Notch (products of four different genes) are expressed by mammalian cells. As described in the last chapter (see Figure 5.16), after Notch, acting as a cell surface receptor, binds a ligand (a Jagged- or Notch-like protein), it undergoes two proteolytic cleavages, one in its ectodomain, the other within its transmembrane domain. The latter cleavage liberates a largely cytoplasmic protein fragment from its tethering to the plasma membrane. This fragment of Notch then migrates to the nucleus of targeted cells, where it functions, together with partner proteins, as a transcription factor (see Figure 6.22B).

Notch signaling is especially important in governing cell fate decisions during development and tumorigenesis, that is, the decision by a less differentiated cell to enter into one or another alternative differentiation pathway. Indeed, the repertoire of genes activated in different cell types by Notch is strongly affected by the differentiation pathways that these cells have entered. In addition, Notch has proliferation-inducing functions independent of its tissue-specific effects; these are most apparent from its ability to activate expression of Myc, which we will see in Chapter 8 is a potent driver of cell proliferation.

This signaling system operates using biochemical mechanisms that are clearly very different from those governing signaling by tyrosine kinase receptors. Each time a Notch receptor binds its ligand, the receptor undergoes irreversible covalent alterations, specifically, the proteolytic cleavages cited above. Hence, receptor firing occurs in direct proportion to the number of ligands encountered in the extracellular space, and each Notch receptor molecule can presumably fire only once after it has bound its ligand and therefore relies on its ability to drive multiple cycles of transcription in the nucleus in order to amplify the signal initiated by Notch ligand binding. Tyrosine kinase receptors, in dramatic contrast, release signals repetitively over an extended period of time following ligand binding, and therefore already

amplify the signals initiated by their growth factor ligands in the cytoplasm; this amplification is multiplied further by the ability of their downstream partners, many of which are enumerated in Figure 6.5. In addition, as mentioned in the last chapter, Notch signaling operates in a *juxtacrine* fashion, that is, between two cells that are in direct physical contact with one another. This contrasts with many other signaling interactions that depend on soluble ligands diffusing through the interstitial space between cells located near one another within a tissue but not necessarily in direct physical contact, creating the contrasting *paracrine* signaling interactions.

Truncated forms of *Notch* that specify only the cytoplasmic domain of the Notch protein are potent oncogenes for transforming cells, suggesting that altered forms of Notch contribute to human cancer pathogenesis. Indeed, overexpression of one or another of the Notch proteins is seen in the great majority of cervical carcinomas, in a subset of colon and prostate carcinomas, and in squamous cell carcinomas of the lung. This overexpression is often accompanied by nuclear localization of the cytoplasmic cleavage fragment of Notch, indicating that active signaling through this pathway is occurring in tumor cells. Increased expression of two classes of Notch ligands, termed Jagged and Delta, has also been found in some cervical and prostate carcinomas (Figure 6.23B). More dramatically, in about 60% of T-cell acute lymphocytic leukemias (T-ALLs), constitutively active forms of Notch are found; these result from genetic deletions of the portion of the *NOTCH-1* gene encoding the extracellular domain of the protein. Some experiments also suggest that Notch signaling contributes to transformation by *ras* oncogenes. In general, however, variant forms of *Notch* act as oncogenes in hematopoietic malignancies and in an array of other tumors but may function in an opposite fashion as tumor suppressors in certain carcinomas; hence, the contributions of Notch signaling to cancer development seem to be highly dependent on cellular context.

Hedgehog As was discussed previously, binding of the Patched receptor by its ligand, Hedgehog (Hh), somehow alters the interactions between Patched (Ptc) and Smoothened (Smo). As a consequence, Smoothened and Gli then accumulate in the primary cilium, often at its tip (see Figure 5.17). Normally, in the absence of intervention by Smoothened, the Gli precursor protein is cleaved into two fragments, one of which moves into the nucleus, where it functions as a transcriptional repressor. However, following Hedgehog stimulation, Smoothened and Gli interact in the primary cilium, where the Gli precursor is protected from cleavage. The resulting intact Gli protein migrates to the nucleus, where it serves as an activator of transcription (see Figure 6.22C). During the course of embryogenesis, Hh signaling has been associated with development of patterned development in certain tissues as well as commitments to specific cell states (although acting over greater distances than Notch). It can also emit signals promoting cell proliferation.

Gli was first discovered as a highly expressed protein in glioblastomas (whence its name). When overexpressed, Gli and several closely related cousins can function as oncoproteins. Subsequent research into this pathway has revealed other instances where its malfunctioning contributes to tumor development. For example, germ-line inactivating mutations of the human patched (*PTCH*) gene cause Gorlin syndrome, an inherited cancer susceptibility syndrome, which involves increased risk of multiple basal cell carcinomas of the skin as well as other tumors, notably medulloblastomas—tumors of cells arising from primitive stem cells in the cerebellum. Such inactivating mutations prevent Patched from inhibiting Smoothened, giving the latter a free hand to dispatch an uninterrupted stream of active Gli protein to the cell nucleus.

As many as 50% of sporadic basal cell carcinomas of the skin (which, by definition occur because of somatic rather than germ-line mutations) carry mutant *PTCH1* or *SMO* alleles—the latter encoding Smoothened. These basal cell carcinomas are the most common form of cancer in Western populations and fortunately are usually benign (see Figure 6.23C). Somatically mutated alleles of *PTCH1* have also been found in a variety of other tumors, including medulloblastomas (as noted above) and meningiomas, as well as breast and esophageal carcinomas. These somatic mutations, like those present in mutant germ-line alleles of *PTCH1*, seem to compromise Patched 1 function, once again permitting Smoothened to constitutively activate Gli transcription factors. Recently, germ-line and somatically mutated inactivating alleles of *SUFU*—which otherwise sequesters some full-length Gli proteins (see Figure 6.22C)—have been described in association with human medulloblastoma development.

These various cancers, all involving mutations that affect the structure of various components of the Hedgehog pathway, represent only a small portion of the human tumors in which this signaling cascade is hyperactivated. Thus, a survey of esophageal, gastric, biliary tract, and pancreatic carcinoma cell lines and tumors has revealed that virtually all of these expressed significant levels of the Patched receptor as well as its ligands (either Sonic Hedgehog or Indian Hedgehog). Often the ligands are produced by the epithelial cells within carcinomas while the Patched receptor is expressed in nearby stromal cells, suggesting the operations of a paracrine signaling channel. This notion was confirmed by demonstrating elevated nuclear levels of the Gli factor, the downstream product of the activated pathway, in stromal cells rather than the epithelial carcinoma cells themselves. Moreover, treatment of tumors with anti-Hedgehog antibody caused cessation of proliferation and/or death of tumor cells, suggesting that stromal cells stimulated by Hedgehog ligands reciprocate by sending mitogenic and survival signals back to nearby carcinoma cells. Similar findings have been reported for small-cell lung carcinomas (SCLCs). Equally plausible is an alternative mechanism, in which both the Hh ligands and the Patched receptor are expressed in the carcinoma cells, causing cell proliferation to be driven by autocrine signaling loops. Quite often, Hedgehog-responsive tumor cells have been identified as

neoplastic cells with stem cell-like properties. Together, these reports point to an important role of this signaling pathway in the tumors including those that arise in the multiple tissues deriving developmentally from the embryonic gut.

TGF-β A fourth signaling pathway that involves the dispatch of cytoplasmic proteins to the nucleus is represented by the pathway leading from TGF-β receptors (Section 5.7). TGF-β and the signaling pathway that it controls appear to play major roles in the pathogenesis of many if not all carcinomas, both in their early stages, when TGF-β acts to arrest the growth of many cell types, and later in cancer progression, when it contributes, paradoxically, to the phenotype of tumor invasiveness. We will defer detailed discussions of the cell-biological functions of this important pathway until Section 8.10 and Chapter 14. For the moment, suffice it to say that activation of this pathway leads to dispatch of Smad transcription factors to the nucleus, where they can bind a specific tetranucleotide sequence in the DNA and associate with adjacently bound transcription factors to induce the expression of a large constituency of genes and repress many others (see Figure 6.22D). In the absence of critical Smads, epithelial cancer cells can escape the growth-inhibitory actions of TGF-β and thrive—a state that is often observed in the precursors of invasive human pancreatic carcinomas (see Figure 6.23D).

The Smad transcription factors (TFs) are most unusual, because they recognize and bind only a tetranucleotide sequence in chromosomal DNA, as mentioned above. This DNA binding, on its own, is too weak to maintain the stable association of Smads with the DNA. Instead, the Smads often and perhaps invariably bind DNA segments immediately adjacent to the binding sites of other more stably bound TFs with which they establish non-covalent associations. The resulting lateral protein–protein interactions between the Smad and its diverse TF partners ensure that binding by Smads and its partners to DNA is cooperative and quite strong. To date, Smads have been found to form such partnerships with more than 130 distinct TFs; the functions of most of these have not been explored. As one example among many, the complex of Smad2 and Smad4 can associate with the YAP/TAZ + TEAD complex described in the next section. This versatility explains why TGF-β and its Smad effectors can elicit diverse responses from cells, depending on the signaling context. TGF-β can induce apoptosis in certain cells but in the presence of active PI3K signaling may simply be cytostatic (see Chapter 8). When signaling in the presence of a Ras oncoprotein, TGF-β may induce an epithelial–mesenchymal transition (Chapters 13 and 14).

OceanofPDF.com

Glossary

reticuloendotheliosis
: Tumor of monocyte/macrophage lineage common in chickens and turkeys.

myeloma
: A malignancy of the antibody-producing cells of the bone marrow, often called multiple myeloma to indicate the large number of osteolytic lesions that are encountered in patients with advanced disease.

interstitial
: (n. pl., **interstices**) (1) Referring to the space between an array of objects. (2) The space within a tissue that lies between cells.

cell fate
: The entrance of a less-differentiated cell into a specific differentiation lineage and eventual differentiated state, often determined by a cell long before such a cell manifests specific markers of such a state.

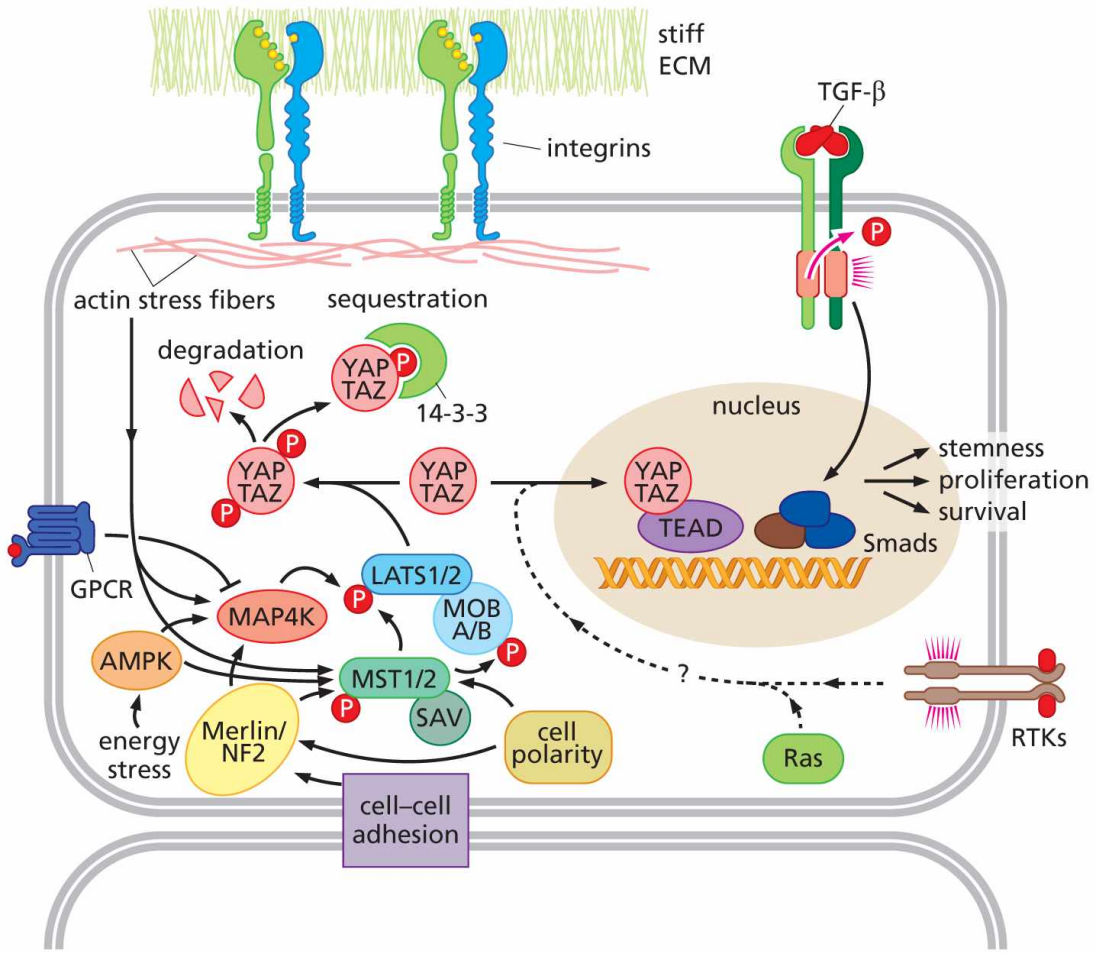
6.13 The Hippo signaling circuit integrates diverse inputs to govern diverse cell phenotypes

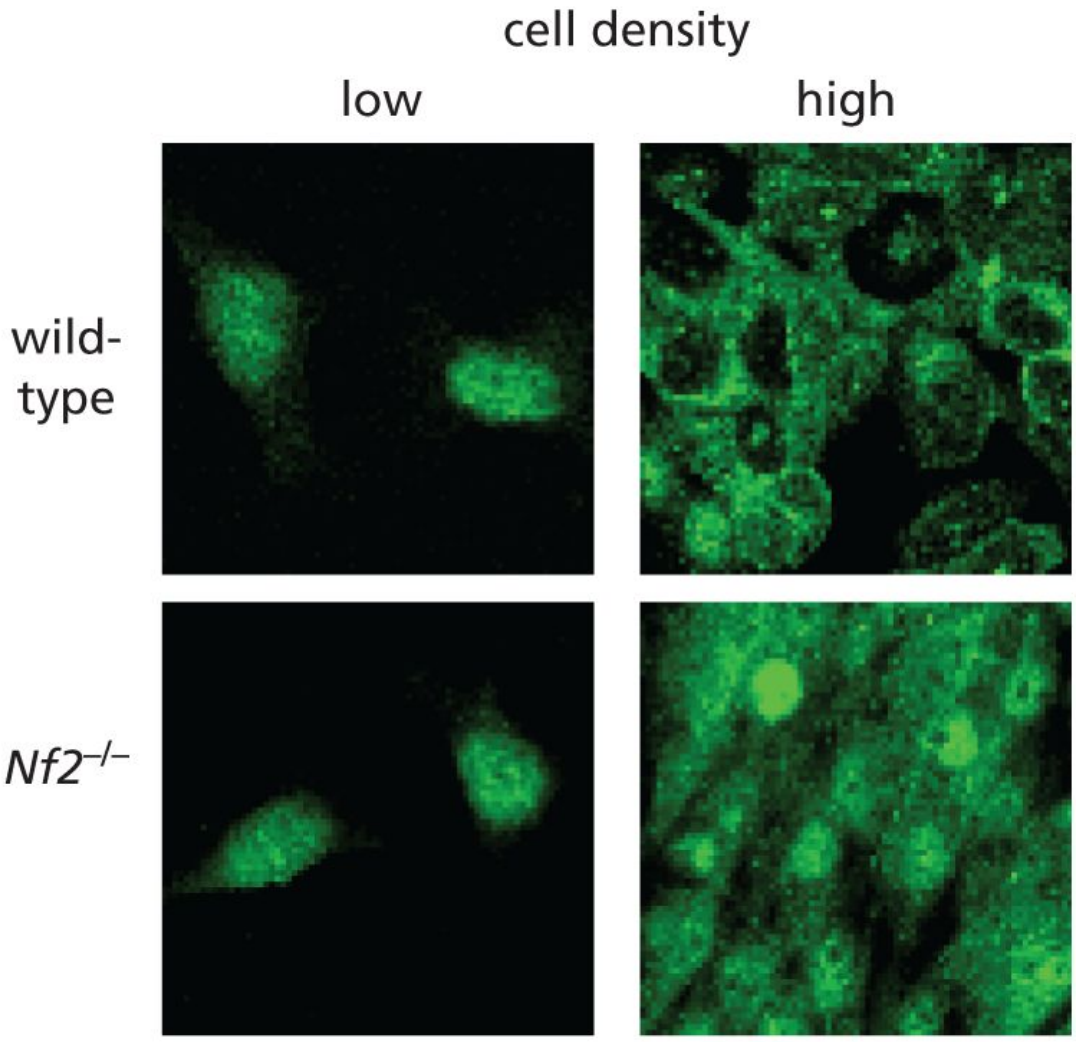
Virtually all of the discussions of signaling in this chapter have been motivated by a simple paradigm: an extracellular signal, conveyed by a soluble or insoluble protein, activates a cell surface receptor, which then proceeds through a dedicated signaling cascade to evoke multiple downstream cell-biological responses in a cell. While fruitful and accessible, such discussions ignore other types of signal-processing circuits that are not dedicated to serving specific cell surface receptors. Instead, these other types of circuits receive incoming (afferent) signals from diverse extracellular sources, integrate these signals with others of intracellular origin (for example, monitors of ATP levels), and only then proceed to effect key decisions in the life of a cell. One prominent example of such an intracellular control circuit is the cell-cycle clock, which is explored in detail in Chapter 8. Others involve the circuits that monitor genomic integrity, energy metabolism, and nutrient availability; some of these will be visited in future chapters.

The Hippo signaling circuit, involving prominently the YAP and TAZ transcription factors, represents one of the key intracellular circuit that responds to diverse afferent signals and merits our attention because of the roles that it plays in cancer pathogenesis. It was originally studied for its control of organ size, that is, the mechanisms governing how large individual organs become within a metazoan body, be they of a fly or a human. More recently, its role in governing the proliferation of normal and neoplastic mammalian cells has become apparent. Thus, the Hippo signaling circuit is a central element in the circuitry that processes a diverse set of inputs including the cell's localization within a tissue, its attachment to other cells, and the state of the surrounding extracellular matrix. Hence, unlike other extracellular signals described above, the YAP and TAZ paralogs monitor the overall tissue context of a cell, only some of which is defined by the presence in the surrounding space of discrete, soluble signaling molecules (**Figure 6.24A**). In response to the proper combinations of signals, YAP/TAZ will move into the nucleus (Figure 6.24B) and there encourage gene expression that favors cell proliferation, survival, and stemness. Of additional interest, YAP/TAZ is also a "dual-address" circuit like the six others described earlier, but one in which the modifying signal (protein phosphorylation) results in functional inactivation via sequestration or degradation in the cytoplasm and thus blockage of signals being dispatched to the transcriptional apparatus in the nucleus.



A diagram shows integrins with their ectodomains in a stiff extracellular matrix and their cytodomains connected to cytoplasmic actin stress fibers. These fibers are at the head of a signaling sequence that proceeds through many complex intermediate steps to the handling of Y A P and T A Z: either degradation, or sequestration, or translocation into the nucleus. The last of these three involves joining with T E A D to foster stemness, proliferation, and survival.

(A)



A two by two block of green-on-black images. The top two images show wild-type cells at low and high density. The bottom two images show N f 2 double minus cells at low and high density. In the high density images, the N f 2 cells have grown more densely packed than the wild-type cells.

(B)

Figure 6.24 YAP-TAZ signaling The YAP/TAZ signaling circuit is designed to integrate diverse inputs and, under the proper conditions, respond by fostering cell proliferation, acquisition of stemness properties, and suppression of apoptosis. (A) The key components are the closely related YAP and TAZ transcriptional co-activators which, when permitted to enter the nucleus, associate with a TEAD transcription factor (there are four in all) to evoke these various downstream responses. A key input is the Hippo pathway, which drives YAP/TAZ phosphorylation, ensuring that these two transcription factors are sequestered in

the cytoplasm and even destroyed in proteasomes (*not shown*); this inhibitory phosphorylation is driven by the actions of the LATS1/2 kinases. Upstream of LATS1/2 kinases are yet other regulators. MST1/2 kinases (termed Hippo in *Drosophila* genetics) phosphorylate and thereby activate the LATS1/2 kinases, a step that requires the tumor suppressor NF2, the formation of cell–cell contacts at adherens junctions (depicted in Figure 6.19A), and apico-basal polarity in epithelia (see Figure 2.4C). An overarching input controlling YAP/TAZ activity is cellular *mechanotransduction*, i.e., the ability of cells to sense the rigidity of the ECM around them as well as their own shape. These cues are regulated by the cell's attachment via focal adhesions to the ECM, the resulting tension transferred to the actin cytoskeleton, and the surrounding tissue architecture in which it is embedded. Both canonical and non-canonical Wnt signaling (see Figures 6.19 and 6.20) as well as the TGF-β pathway (see Figure 6.22D) also govern the outputs of this pathway. Finally, cellular metabolism influences this pathway through AMPK (AMP kinase), which monitors the level of AMP vs. ATP in cells. (B) Wild-type and *Nf2* mutant mouse Schwann cells were immunostained with anti-YAP antibody (*green*). In wild-type cells grown in monolayer culture, YAP, which acts as a transcription factor to promote cell proliferation, is enriched in the nucleus at low cell density but is preferentially localized in the cytosol at high cell density and thus effectively excluded from the nucleus; this may explain much of the phenomenon of contact inhibition described in Figure 3.4. However, in cells lacking the Merlin/NF2 tumor suppressor protein, which normally transduces signals from the cell surface to YAP/TAZ, the nuclear localization of YAP is unaffected by the density of cells in monolayer culture, ostensibly allowing cells to continue proliferating long after they have sensed contact with their neighbors. (A, adapted from S. Piccolo, S. Dupont and M. Cordenonsi, *Physiol. Rev*. 94:1287–1312. B, Courtesy of Duojia (DJ) Pan.)

The fact that nuclear YAP/TAZ favors cell proliferation already suggests that its actions are, with great likelihood, deregulated within various human tumors, and indeed this is the case. High-level expression of YAP or TAZ, especially when present in the nuclei of the carcinoma cells in a variety of human tumors, is, on its own, correlated with aggressive clinical behavior, including a tendency to spawn metastases and, in the case of certain breast cancers, a reduced tendency of involved tumors to respond to otherwise-effective therapies. Among carcinomas, ranging from liver and pancreatic tumors to those of lung and colon, these correlations have been documented repeatedly. Conversely, shutting down YAP/TAZ nuclear localization by overexpressing some of their negative regulators results in loss of proliferation and, in certain instances, tumor shrinkage. Unlike most of the signaling circuits discussed in this chapter, this one is still poorly understood because of the daunting complexity of

its inputs and the myriad cross-connections between this circuit and other regulatory circuits operating within cancer cells.

6.14 Well-designed signaling circuits require both negative and positive feedback controls

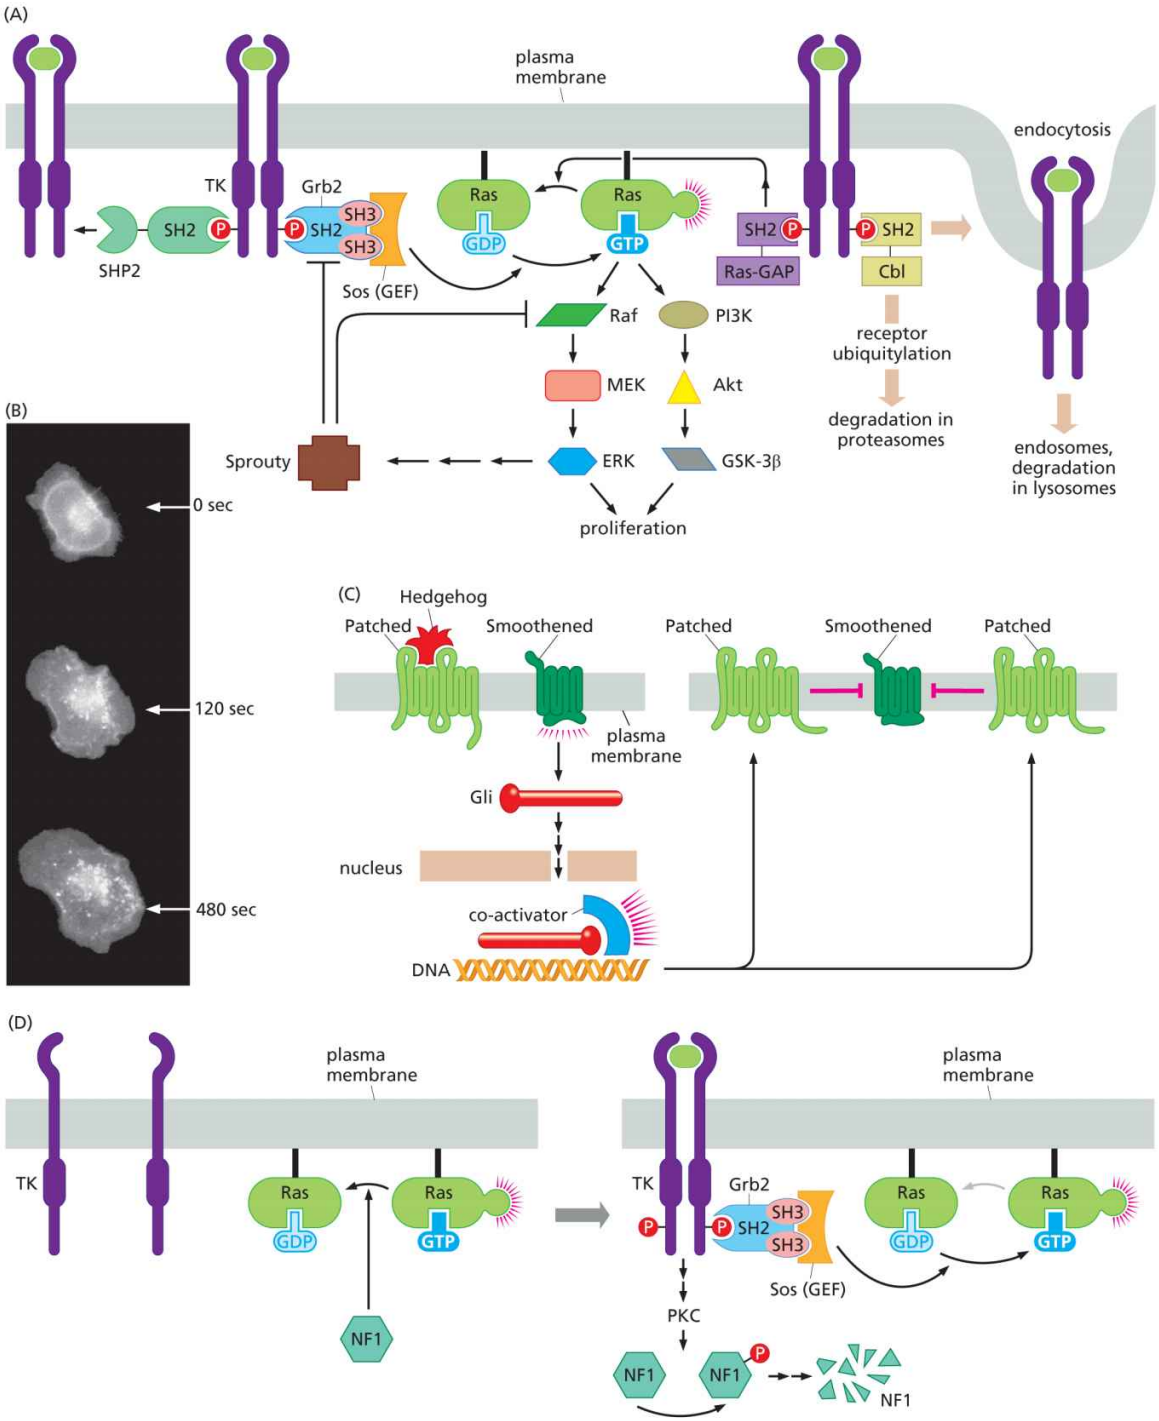
All well-designed regulatory circuits are fine-tuned by feedback controls that ensure that the flux of signaling through one or another pathway is at appropriate levels for optimal performance. Such well-regulated signal-processing circuits contain inhibitory components that counterbalance and modulate the behavior of other components that emit positive signals. Without these negative controls, positive signals, such as those that promote cell proliferation, may run rampant; in the case of mitogenic signals, this can lead to the runaway proliferation that we associate with neoplastic cells.

In principle, one effective strategy for constraining the signals flowing through the mitogenic signaling pathways that we have encountered could rely on limiting the amounts of growth factor molecules to which a cell is exposed. That way, even if this cell displayed abundant growth factor receptors on its surface, the limited number of available GF ligand molecules in the extracellular space would ensure only minimal firing by these receptors and therefore limited activation of downstream signaling pathways.

However, a more precisely targeted and effective strategy for regulating the flow of such mitogenic signals depends on modulating signal processing *within* the responding cell. Often, the inhibitory components operating in an intracellular signaling circuit are functionally inactive until the circuit becomes active; however, once signaling begins flowing through the circuit, the inhibitory proteins become activated sooner or later and proceed to block further signaling. This type of inducible inhibition is often termed negative feedback and is an important feature of many, possibly all, signal-processing circuits within cells.

Actually, without noting this feature explicitly in the last two chapters, we have encountered a number of proteins that are involved in negative-feedback loops. For example, when a GF receptor becomes activated by ligand binding and autophosphorylation, the SH2 domains of Ras-GAP (see Figure 5.24) allow this protein to bind to phosphotyrosines of the receptor. This places Ras-GAP in a position where it can trigger the GTPase function and resulting inactivation of

Ras (**Figure 6.25A**); the latter, which had recently been activated into its active, GTP-bound state, is now forced to shut down its signaling. This negative-feedback loop ensures the release of only a small burst of mitogenic signals by Ras. Yet other mechanisms involved in shutting down receptor signaling are depicted in Figure 6.25A, B, and C; in fact, dozens of such negative-feedback loops have been uncovered in various regulatory circuits operating within the cell, and far more are likely to be found in the future. As predicted from this scenario, the loss of various proteins that function as Ras-GAPs can contribute to runaway Ras signaling. For example, mutant *Ras* oncogenes are rarely found in human breast cancers; however, some especially aggressive breast tumors nonetheless acquire strong Ras signaling by inactivating key Ras-GAP proteins.



A four-part figure depicting negative and positive feedback controls on signaling. Part A shows negative feedback. A cascade begins when R a s-G D P is activated into R a s-G T P. This cascade leads to E R K but also signals Sprouty to block further R a s activation. At the same time, the binding of R a s-G A P via one or both of its S H 2 groups to a ligand-activated receptor drives G T P hydrolysis by R a s. Moreover, the binding of C b l to a receptor

via its S H 2 group results in ubiquitylation of the receptor and its destruction within proteasomes. Two more negative-feedback loops operate via the ligand induced endocytosis of an R T K, such as the E G F-R, and lead to its introduction either into endosomes or lysosomes, in which it is degraded. Finally, the binding of the S H P-2 phosphatase to the receptor removes the phosphates previously attached to tyrosine residues. Part B shows a sequence of three images of a single gray cell. In the first image, at 0 seconds, the cell has an oblong halo on its body. In the second image, at 120 seconds, the halo has begun to enlarge, break up, and become more granular. In the third image, at 480 seconds, the halo has disintegrated into bright granules distributed throughout the cell. In Part C, Patched is initially bound by a Hedgehog ligand, and so it does not inhibit Smoothened. Then G l i is not degraded, and it translocates to the nucleus, where it joins with a co-activator to promote D N A transcription. This creates new Patched copies that are not bound by Hedgehog. They inhibit Smoothened. Part D is an example of positive feedback. N F 1 initially deactivates R a s by converting it from R a s G T P to R a s G D P. However, when a G F-activated receptor begins to release signals, it activates a form of P K C (protein kinase C) that phosphorylates N F 1, causing its ubiquitylation and degradation, thereby enabling a rapid increase in firing by active, G T P-bound R a s molecules.

Figure 6.25 Negative and positive feedback controls on signaling An elaborate array of negative-feedback loops ensures that excessive signaling in normal cells is reduced to levels that are compatible with maintenance of normal cell behavior. (A) When RTKs bind their cognate ligands, the resulting activation of the Ras → Raf → MEK → ERK signaling cascade causes Sprouty (*brown, lower left*) to block binding of Grb2 to Sos (*light orange*), thereby shutting down further Ras activation. Sprouty also binds and inhibits the Raf kinase as well as other targets (*not shown*). Functioning concomitantly with this negative-feedback loop, the binding of Ras-GAP (*purple*; see also Figure 5.24) via one or both of its SH2 groups to a ligand-activated receptor drives GTP hydrolysis by Ras. Moreover, the binding of Cbl (*light beige*) to a receptor via its SH2 group results in ubiquitylation of the receptor and its destruction within proteasomes. Two more negative-feedback loops operate via the ligand-induced endocytosis of an RTK, such as the EGF-R, and lead to its introduction either into endosomes at low ligand-binding levels (from which it may continue to fire for a period) or into lysosomes (at high ligand-binding levels), in which it is degraded (*right*). Finally, the binding of the SHP-2 phosphatase to the receptor removes the phosphates previously attached to tyrosine residues (*left*). (Not shown is a second SH2 group carried by SHP-2.) See also Sidebar 5.2. (B) As illustrated

in part A, an important mechanism of shutting down RTK signaling involves the physical internalization of receptor molecules via endocytosis. When a cell is exposed to epidermal growth factor (EGF), introduced into the medium at the location shown (*white arrows*), the EGF initially causes the cell surface EGF receptor molecules, which were previously localized to the plasma membrane and in this case have been linked to a fluorescent dye, to release mitogenic signals into the cell (*not shown*). However, within 120 seconds, the fluorescing EGF-R molecules have been internalized into the cytosol on the side of the cell facing the EGF source; and by 480 seconds, they are found in internalized clusters throughout the cell, which are either endosomes or lysosomes. (C) Binding of Hedgehog to Patched (*top left*) permits signaling by Smoothened, one of the consequences of which is the activation, via Gli, of transcription of the Patched-encoding gene. The resulting increased numbers of Patched molecules then function to inhibit further signaling by Smoothened. (D) A positive-feedback mechanism is illustrated by the actions of NF1 (neurofibromin), which in resting cells ensures the hydrolysis of Ras-bound GTP and associated inactivation of signaling by Ras. However, when a GF-activated receptor begins to release signals, it activates a form of PKC (protein kinase C) that phosphorylates NF1, causing its ubiquitylation and degradation (see Supplementary Sidebar 7.5), thereby enabling a rapid increase in firing by active, GTP-bound Ras molecules (*right*). (B, from M. Bailly et al., *Mol. Biol. Cell* 11:3873–3883, 2000. With permission from American Society for Cell Biology.)

An alternative mechanism of signal regulation is embodied in positive-feedback loops, which function to further *amplify* initial signaling. For example, the neurofibromin (NF1) protein normally functions like Ras-GAP to induce GTP hydrolysis by Ras proteins (Figure 6.25D). Thus, in cells that are not experiencing mitogenic signaling, NF1 ensures that the level of GTP-loaded Ras is held very low. However, soon after mitogenic signaling is initiated by a ligand-bound GF receptor, a cell's pool of NF1 protein is quickly degraded, clearing the way for Ras to rapidly become activated. Here, this feedforward loop is exploited to accelerate the initial activation of the signaling event, allowing it to reach its maximum more quickly. (Later on, NF1 levels are restored by yet other regulators, ensuring eventual shutdown of Ras signaling.)

Alternatively, feedforward mechanisms can be used to *stabilize* a decision, such as a decision to *maintain* a certain state of differentiation. Thus, a cell in a certain differentiated state may produce a growth factor or cytokine that functions in an

autocrine manner to induce and thereby ensure continued maintenance of this state of differentiation. In Chapter 8, we will encounter yet other examples of positive-feedback loops exploited by cells that have executed a decision and use these loops to guarantee the *irreversibility* of this decision; for example, once a cell decides to advance into the next phase of the cell cycle, positive-feedback signaling loops reinforce and amplify this decision, preventing the cell from inadvertently slipping backward into an earlier phase of the cell cycle. Still, we need to remember that feedforward loops also represent a liability, at least in the case where mitogenic signaling is being regulated: since they allow signaling to become self-perpetuating, feedforward loops may lead to loss of the finely tuned control of cell proliferation that is central to the normal cell phenotype.

It turns out that some of the negative-feedback controls can have major effects on the successes or failures of targeted pharmacologic therapies, such as the one that is directed toward shutting down the B-Raf kinase, which is mutated in a majority of human melanomas and in a subset of colorectal carcinoma (CRC) cells. The inhibitory drug termed vemurafinib (discussed in greater detail in Chapter 17) is effective in shutting down the proliferation of the *B-Raf*–mutant melanoma cells but is unable to elicit the same response in the CRC cells. As it happens, a powerful negative-feedback loop operates in CRC cells: B-Raf signaling activates ERK, which in turn acts via a negative-feedback loop to suppress signaling by the EGF-R, which lies upstream in the signaling pathway (Figure 6.25A). However, when MEK is shut down (through B-Raf inhibition), the negative-feedback loop no longer operates and EGF-R quickly begins highly effective firing, now signaling via an alternative downstream pathway—the Ras–PI3K–Akt–GSK-3β cascade—to drive CRC proliferation; this circumvents the anti-mitogenic actions of the B-Raf inhibitor. Melanoma cells do not express significant levels of the EGF-R and therefore cannot compensate for B-Raf inhibition, explaining their sensitivity to B-Raf inhibition. This represents only one of myriad feedback pathways that can thwart the most carefully designed anti-cancer therapies.

6.15 Synopsis and prospects

The signaling pathways that we have described in this chapter represent only the bare bones of the complexity of signal processing that actually operates within mammalian cells. In describing these, we have overlooked many of the endless complexities, some of which are enumerated below. Stated simply, the signaling networks created by the interactions between hundreds of proteins acting in various combinations create a complexity that is vastly beyond our current abilities to assimilate, dooming our attempts at present to understand the behavior of an individual cell as a whole. Moreover, this complexity grows progressively—driven by increasingly powerful analytical tools, so that the overall cellular signaling circuitry can no longer be grasped by a single human mind. Instead, as the years go on, each of the pathways described here has attracted its own coterie of highly specialized researchers.

Why has evolution cobbled together so many different solutions to processing signals within cells and tissues? The answer can only come from appreciating the extraordinary complexity of the metazoan body and the mechanisms that make its normal development possible. Long after the fact, we are trying to tease apart the biochemical solutions that were developed, step-by-step, during the ~1.4 billion years between the emergence of eukaryotes (~2.1×10^9 years ago) and the development of complex metazoan bodies (~0.7×10^9 years ago).

The resulting complexity greatly complicates most current attempts at understanding this circuitry for the purpose of treating human tumors in the oncology clinic. Those researchers who have chosen to develop new anti-cancer therapies are forced to flee into corners of this now-vast field of research and embrace extreme reductionism, focusing as they do on a small number of signal-processing components while purposively ignoring the surrounding complexity; their reductionism is the only rational and pragmatic approach to making solid progress.

Importantly, this complexity has caused cancer researchers to develop new ways to navigate through these thickets. The advent of genome-wide screens (to be discussed in Chapter 17) has allowed the discovery of the vulnerabilities of cancer cells—the choke points in specific circuits that can be revealed even if the detailed operations of the surrounding signaling cascades remain poorly

understood. These powerful and incisive approaches to developing clinical treatments of cancer have begun to yield impressive fruit.

Signal transduction in cancer cells As described in this chapter, one of the hallmarks of cancer cells is their ability to generate their own mitogenic signals endogenously. These signals liberate cancer cells from dependence on external mitogenic signals, specifically those conveyed by growth factors. It is now clear that the mitogenic pathway of greatest importance to human cancer pathogenesis is the one that was initially discovered and has been discussed here in detail, that is:

GFs → RTKs → Grb2 → Sos → Ras → Raf → MEK → ERK

As described in Chapter 5 and in this one, a variety of molecular mechanisms cause the upstream portion of this signaling pathway to become continuously activated in cancer cells. Neoplastic cells may acquire the ability to make and release growth factors (GFs) that initiate autocrine signaling loops. Alternatively, the growth factor receptors (RTKs) may suffer significant structural alterations. Even more common are the human tumors whose cells display elevated levels of wild-type versions of receptors such as the EGF receptor or its close relative, ErbB2/HER2/Neu. It is clear that excessively high levels of these receptor molecules, often expressed by breast, brain, and stomach cancer cells, favor increased cell proliferation. Such receptor overexpression is often achieved through either deregulated transcription or amplification of the gene encoding the receptor. Reductions in the elimination via endocytosis from the cell surface of ligand-activated RTKs also seem to contribute frequently.

As we learn more about the regulation of cell signaling, it is becoming apparent that negative-feedback controls like those modulating the signaling in this particular pathway (see Figure 6.25A) operate in essentially all the intracellular signaling pathways, ensuring that signals stimulating cellular growth and division are released in carefully titered amounts to ensure proper homeostasis—the proper physiologic balance of cell birth and death that is so critical to tissue and thus organismic viability. We will revisit some of these negative-feedback controls in Chapter 17, since they play an important role in thwarting recently developed therapeutic agents that have been designed to shut down certain key signaling molecules.

Moving down the mitogenic pathway from the receptors, we note that few, if any, alterations in signal-transducing proteins have been documented in human tumors until we reach the Ras proteins. Recall that point mutations in the 12th, 13th, or

61st codon of the reading frames of encoding *ras* genes result in constitutively activated Ras oncoproteins. The power of these Ras oncoproteins comes directly from their ability to activate two major and critical mitogenic pathways—those involving Raf and PI3K. Moving further downstream in the RTK → Sos → Ras signaling cascade, we once again find a relative dearth of mutant proteins in human cancer cells. The B-Raf protein, a close cousin of the Raf kinase, is one exception. It is found in mutant form in about 8% of a large panel of human tumor lines. Most importantly, almost half of all human melanomas possess point-mutated versions of the *BRAF* gene, whose normal product, like Raf, requires Ras stimulation before it can fire. The resulting mutant B-Raf proteins have a greatly reduced dependence on interaction with Ras.

Another exception is provided by phosphatidylinositol 3-kinase (PI3K), which also operates immediately downstream of Ras. Recall that the PI3K enzyme is activated by Ras, by growth factor receptors, or by the two acting in concert (see Figures 6.12 to 6.14). Its product is phosphatidylinositol triphosphate (PIP3). By 2020, activating mutations in the PI3K gene (termed *PIK3CA*) had been documented in the genomes of about 10% of all human cancers, with almost one-third of certain cancer types, notably those of the breast and endometrium, harboring mutant, oncogenic *PIK3CA* alleles. Far more commonly, however, *inhibition* of this pathway is defective in cancer cells: levels of PIP3, the product of PI3K, are normally held down by the actions of the PTEN phosphatase, which is lost in a wide variety of cancers. Almost 30% of all human tumors suffer loss of *PTEN* gene function, caused by either mutational inactivation or transcriptional repression. The resulting loss of PTEN function may be as effective for increasing PIP3 levels as the hyperactivity of the PI3K that is induced by Ras oncoproteins. In both cases, the increased PIP3 levels drive activation of Akt/PKB, which in turn has widespread effects on cell survival, growth, and proliferation.

In theory, future research may reveal that other pathways, some mentioned in this chapter (involving GPCRs, Patched, Notch, NF-κB, and Hippo), rival the importance of the RTK → Ras pathway in providing the mitogenic signals that drive cell proliferation in certain types of human cancer cells. In reality, however, every year’s worth of newly published genomic studies seems to reinforce the primacy of the canonical RTK pathway in human cancer pathogenesis.

Organization of mitogenic signaling pathways Evolution might have constructed complex metazoa like ourselves by using a small number of cellular signaling pathways (or even a single one) to regulate the proliferation of individual cells in various tissues. As it happened, a quite different design plan

was cobbled together: each of our cells uses a number of distinct signaling pathways to control its proliferation (with one of these, involving tyrosine kinase receptors, playing an especially prominent role). In each type of cell, the signaling pathways work in a *combinatorial fashion* to ensure that proliferation occurs in the right place and at the right time during development and, in the adult, during tissue maintenance and repair. Moreover, different cell types use different combinations of pathways to regulate their growth and division. This helps to explain why the biochemistry of cancer, as described in this chapter, is so complex.

The signaling circuitry that was described in this chapter operates largely in the cytoplasm and receives inputs from cell surface receptors—those that bind either soluble extracellular ligands, notably growth factors, or insoluble matrix components (the integrins). Having received a complex mixture of afferent (incoming) signals from these receptors, this cytoplasmic circuitry emits signals to molecular targets in both the cytoplasm and the nucleus.

Included among the cytoplasmic targets are the regulators of cell shape and motility, energy metabolism, protein synthesis, and the apoptotic machinery, which decides on the life or death of the cell. The remaining signals are transmitted to the nucleus, where they modulate the transcription of thousands of genes involved in the programming of cell growth and differentiation as well as cell cycle progression. We will return to some of these themes later. Thus, the regulation of the cell cycle and differentiation is described in Chapter 8, while the regulation of programmed cell death—apoptosis—will be presented in Chapter 9. The regulators of cell motility, which is critical to high-grade malignancy, will be described in outline in Chapter 14.

Certain major themes have recurred throughout this chapter. Most apparent are the three ways in which signals are transduced through the signaling pathways of normal and neoplastic cells. First, the *intrinsic activity* of signaling molecules may be modulated. This can be achieved by noncovalent modifications (for example, the binding of GTP by Ras) or receptor dimerization. Alternatively, a signaling molecule may be covalently modified; the phosphorylation of MEK by Raf, the phosphorylation of PIP2 by PI3K, and the proteolytic cleavage of Notch are three examples of this.

Second, the *concentration* of a signaling molecule may be modulated, often by orders of magnitude. Thus, the concentration of β-catenin is strongly reduced by

GSK-3β phosphorylation, and the concentration of PIP3 is regulated by PI3K (positively) as well as PTEN (negatively).

Third, the intracellular *localization* of signaling molecules can be regulated, which results in moving them from a site where they are inactive to a new site where they can do their work. The most dramatic examples of these derive from the phosphorylation of the C-terminal tails of receptor tyrosine kinases (RTKs) and the subsequent recruitment of multiple, distinct SH2-containing molecules to the resulting phosphotyrosines (see Figure 6.5). Once anchored to the receptors, many of these signal-transducing molecules are brought in close proximity with other molecules that are associated with the plasma membrane; examples of the latter are the Ras molecule (the target of Sos action) and PIP3 (the target of PI3K action).

The translocation of cytoplasmic molecules to the nucleus is another manifestation of this third class of regulatory mechanisms. For example, the "dual-address" transcription factors dwell in inactive form in the cytoplasm and may be dispatched as active transcription factors (or components thereof) to the nucleus. Examples of these include β-catenin, NF-κB, the Smads, Notch, Gli, YAP/TAZ, and the STATs.

The kinetics with which signals are transduced from one site to another within a cell may also vary enormously. One very rapid mechanism involves the actions of kinase cascades. Thus, the cytoplasmic MAP kinases (MAPKs), including ERKs lying at the bottom of these cascades, are activated almost immediately (in much less than a minute) following mitogen treatment of cells, and, following activation, the ERKs move into the nucleus essentially instantaneously. Once there, they proceed to phosphorylate and functionally activate a number of key transcription factors.

A slightly slower but nonetheless highly effective signaling route derives from the strategy, cited above, of activating dormant transcription factors in the cytoplasm and dispatching them in activated form to the nucleus. By far the slowest signaling mechanisms depend on modulating the *concentrations* of signaling proteins. This mode of regulation depends on changes in the rates of transcription of genes, the translation of their mRNAs, and the post-translational stabilization of their protein products.

The intracellular signaling circuitry encountered in this chapter appears to be organized similarly in various cell types throughout the body. This fact holds important implications for our understanding of cancer and its development.

More specifically, it suggests that the biochemical lessons learned from studying the neoplastic transformation of one cell type often prove to be applicable to a number of other cell types throughout the body. The ever-increasing body of information on the genetic aberrations of human cancer cells provides strong support for this notion.

The similar design of the intracellular growth-regulating circuitry in diverse cell types forces us to ask why different kinds of cells behave so differently in response to various external signals. Many of the answers will eventually come from understanding the spectrum of receptors that each cell type displays on its surface. In principle, knowledge of the cell type–specific display of cell surface receptors and of the largely invariant organization of the intracellular circuitry should enable us to predict the behaviors of various cell types following exposure to various mitogens and to growth-inhibitory factors like TGF-β. Similarly, by understanding the array of mutant alleles coexisting within the genome of a cancer cell, we should be able to predict how these alleles perturb behavior and how they conspire to program the neoplastic cell phenotype. In practice, we are still far from being able to do so for at least nine reasons:

1. We possess only a rudimentary knowledge of the layout of the circuit diagram—the map of intermolecular interactions that describe how different proteins and signaling molecules intercommunicate within a cell. One approach to describing this map involves determining all the binary protein–protein physical interactions operating within a single human cell—the sum of which represents the human interactome. Given the coding capacity of the human genome, approximately 200 million such binary interactions are theoretically possible. Of these, only about 64,000 binary physical interactions were validated experimentally by 2016. Nonetheless, even the most rigorous attempts at mapping the binary interactome are unlikely to reveal all of the signaling interactions between pairs of proteins, which often involve only transient, weak physical associations between interacting partner proteins, such as those between an enzyme and its substrate. In addition, physical interactions resulting in the formation of multiprotein complexes with more than two participating subunits are commonly overlooked in existing protein–protein interaction analyses. Such complexes are found everywhere throughout the signaling circuits operating in our cells.
2. In this chapter, we have described only the bare outlines of how these circuits operate and have consciously avoided many details. But such details are critical. For example, individual steps in these pathways are often

controlled by multiple, similarly acting paralogs, each of which transduces signals slightly differently from the others. Examples of this are the four structurally distinct Ras proteins; the three forms of Akt/PKB; Raf and its close cousins, A-Raf and B-Raf; and the nine similarly structured Src-family kinases (SFKs), which have partially overlapping functions. In most cases, we remain ignorant of the functional differences between the superficially similar proteins operating within a pathway, and therefore have only an incomplete understanding of how the pathway as a whole operates.

3. Complex negative-feedback and positive-feedback loops serve to dampen or amplify the signals fluxing through each of these pathways. While this chapter touched on these only briefly, negative-feedback loops are an indispensable feature of all signaling pathways, (Section 6.14). The feedback loops discovered to date surely represent only the tip of a vastly larger iceberg. For example, more than 100 phosphotyrosine phosphatase (PTP)–encoding genes have been found in the human genome. PTPs remove the phosphate groups attached by the 90 tyrosine kinases (TKs) present in our cells. We know almost nothing about the substrates of the phosphatase enzymes and how they are regulated in response to tyrosine phosphorylation events.
4. Each component in a signaling circuit acts as a complex signal-processing device that can amplify, attenuate, and/or integrate the upstream signals that it receives before passing them on to downstream targets. We have not begun to understand the quantitative parameters governing the efficiency of signal processing by individual signal-transducing proteins. As one example, the GTP-bound normal Ras protein exhibits different binding affinities to its three major downstream effectors, and these affinities change when amino acid substitutions block Ras-GTPase function and create Ras oncoproteins.
5. Calculations of diffusion times in cells indicate that efficient, rapid signal transduction is likely to occur only when interacting proteins are co-localized within microspaces within a cell. Only very fragmentary information is available about the intracellular localizations of most signaling proteins and, in some cases, the scaffolding proteins that bring them together with their interacting partners (see, for example, Figure 6.9B). The ability of proteins to transduce signals to one another is also affected by their localized intracellular concentrations; here, we have only begun to plumb the depths of this complexity. As one example, the four Ras proteins localize to various cytoplasmic membranes following their activation, where they have more or less access to their downstream effectors.
6. The phosphorylation of proteins has been discussed repeatedly in this chapter. These phosphorylation events, on their own, represent extraordinary

complexity: More than 50,000 distinct phosphopeptides have been cataloged in human cells; each of these is associated with one or another cellular protein and the effects of these modifications on protein function are generally not known. In fact, post-translational covalent modifications (PTMs) of proteins are vastly more varied and complex than these phosphorylation events. Proteins may become methylated, acetylated, lipidated, or ubiquitylated (see **Supplementary Sidebar 7.5**). There are also a variety of ubiquitin-like PTMs that are bound covalently to the amino acids constituting the primary structures of proteins. In almost all cases, the effects on protein function of these bulky PTMs are poorly understood; included among these modifying groups are NEDD8, ISG15, FAT10, MNSFβ, Ufm1, six Atg8 paralogs, Atg12, Urm1, Ubl5, and four SUMO paralogs. Beyond these at least 40 other types of distinct covalent modifications of proteins have been cataloged. In virtually all cases, the consequences on protein function of these PTMs are entirely obscure. In most cases, the PTMs are presumed to alter the functions of a modified protein, such as its catalytic activity or its interactions with other proteins or its levels within a cell. As one specific example, the highly modified histone H4 has been found to carry prominent acetylation, methylation, and phosphorylation PTMs on its various amino acid residues, yielding combinatorially a calculated 98,304 theoretical distinct proteoforms of this single cellular protein.

7. None of these intracellular pathways operates in isolation. Instead, each is influenced by cross-connections with other pathways. Understandably, the search for these cross-connections has been largely postponed until the operations of each primary pathway are elucidated. Once these cross-connections are added to the maps of these primary pathways, the drawings of signal transduction circuitry will likely resemble a weblike structure (see **Supplementary Sidebar 6.8**) rather than a series of parallel pathways that begin at the plasma membrane and extend linearly from there into the nucleus.
8. Distinct from these extensive cross-connections (such as those operating in the cytoplasm) there exists another dimension of combinatorial complexity: the most apparent endpoints of signaling—specific changes in cell phenotype achieved by transcriptional regulation of certain genes—are the results of interactions between multiple signaling pathways that converge in various combinations on specific gene promoters and their associated enhancers. Once again, this dimension of complexity continues to baffle us.
9. Our depiction of how signals are transmitted through a cell is likely to be fundamentally flawed. We have spoken here, time and again, about potent signaling pulses speeding along signal-transducing pathways and evoking, at

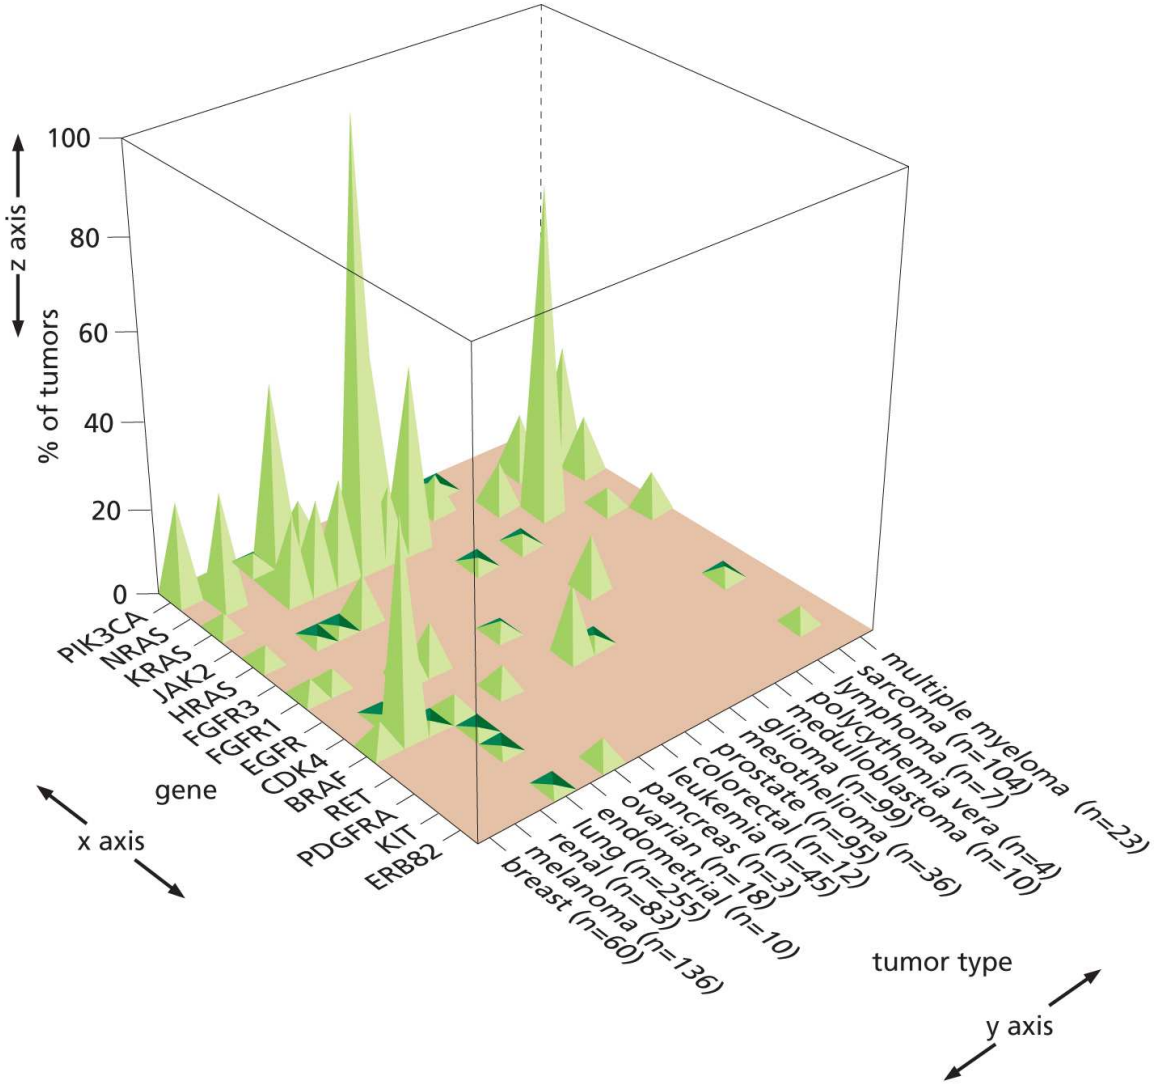
endpoints, strong and clearly defined responses within a cell. In reality, each signaling cascade is likely to operate in a finely tuned, dynamic equilibrium, where positive and negative regulators continuously counterbalance one another. Accordingly, a signaling input (for example, a mitogenic stimulus) may operate like the plucking of a fiber in one part of a spider web, which results in small reverberations at distant sites throughout the web. Here, neither our language nor our existing mathematical representations of signaling suffice to clarify our understanding.

Undaunted by these obstructions to understanding, some cancer researchers would like to be able to draw a complete and accurate wiring diagram of the cell —the scheme that depicts how these pathways are interconnected. This project will only be accomplished many years from now. One measure of the difficulties associated with this task comes from censuses of the various classes of genes in the human genome. According to one enumeration, there are 518 distinct genes specifying various types of protein kinases; 40% of these genes make alternatively spliced mRNAs encoding slightly different protein structures, leading to a collection of more than 1000 distinct kinase proteins that may be present in human cells. Of the 518 kinase genes, 90 encode tyrosine kinases, the remainder being serine/threonine kinases. Among the 90 tyrosine kinases, 58 function as the signaling domains of growth factor receptors. These numbers provide some measure of the complexity of the signaling circuitry that underlies one component of cancer pathogenesis, since many of these kinases are involved in regulating the proliferation and survival of cells.

Another dimension of complexity has come from more detailed burrowing into the details of individual signaling circuits. While we have portrayed Ras signaling as focused on three downstream effectors (see Figure 6.9A), directed biochemical analyses have indicated that the Ras proteins command additional effectors to do their work (**Supplementary Sidebar 6.9**). It remains unclear whether these additional pathways contribute in critical ways to the transforming powers of the corresponding oncoproteins.

The difficulties of explaining cell behavior in terms of the design of signal transduction circuitry underlie our current inability to understand another set of problems, these being related specifically to the genetics of cancer cell genomes: Why do various types of human tumors display highly specific types of genetic alterations (**Figure 6.26**)? Why do 90% of pancreatic carcinomas carry a mutant K-*ras* oncogene, while this mutation is seen in only a small proportion (~10%) of breast cancers? Why are amplifications of the EGF receptor and its cousin,

HER2/erbB2, encountered in more than a third of human breast cancers but seen uncommonly in certain other epithelial cancers, even though these receptors are widely displayed in many kinds of normal epithelia?



A three-dimensional histogram of frequencies of oncogene activation. The genes covered are P I K 3 C A, N RAS, K RAS, JAK2, H RAS, F G F R 3, F G F R 1, E G F R, C D K 4, B RAF, RET, P D G F R A, KIT, and E R B 82. The tumors covered are multiple myeloma (n=23), sarcoma (n=104), lymphoma (n=7), polycythemia vera (n=4), medulloblastoma (n=10), glioma (n=99), mesothelioma (n=36), prostate (n=95), colorectal (n=12), leukemia (n=45), pancreas (n=3), ovarian (n=18), endometrial (n=10), lung (n=255), renal (n=83), melanoma (n=136), and breast (n=60). Some genes are activated only rarely, in a single tumor type. F G F R 3 is only activated in a

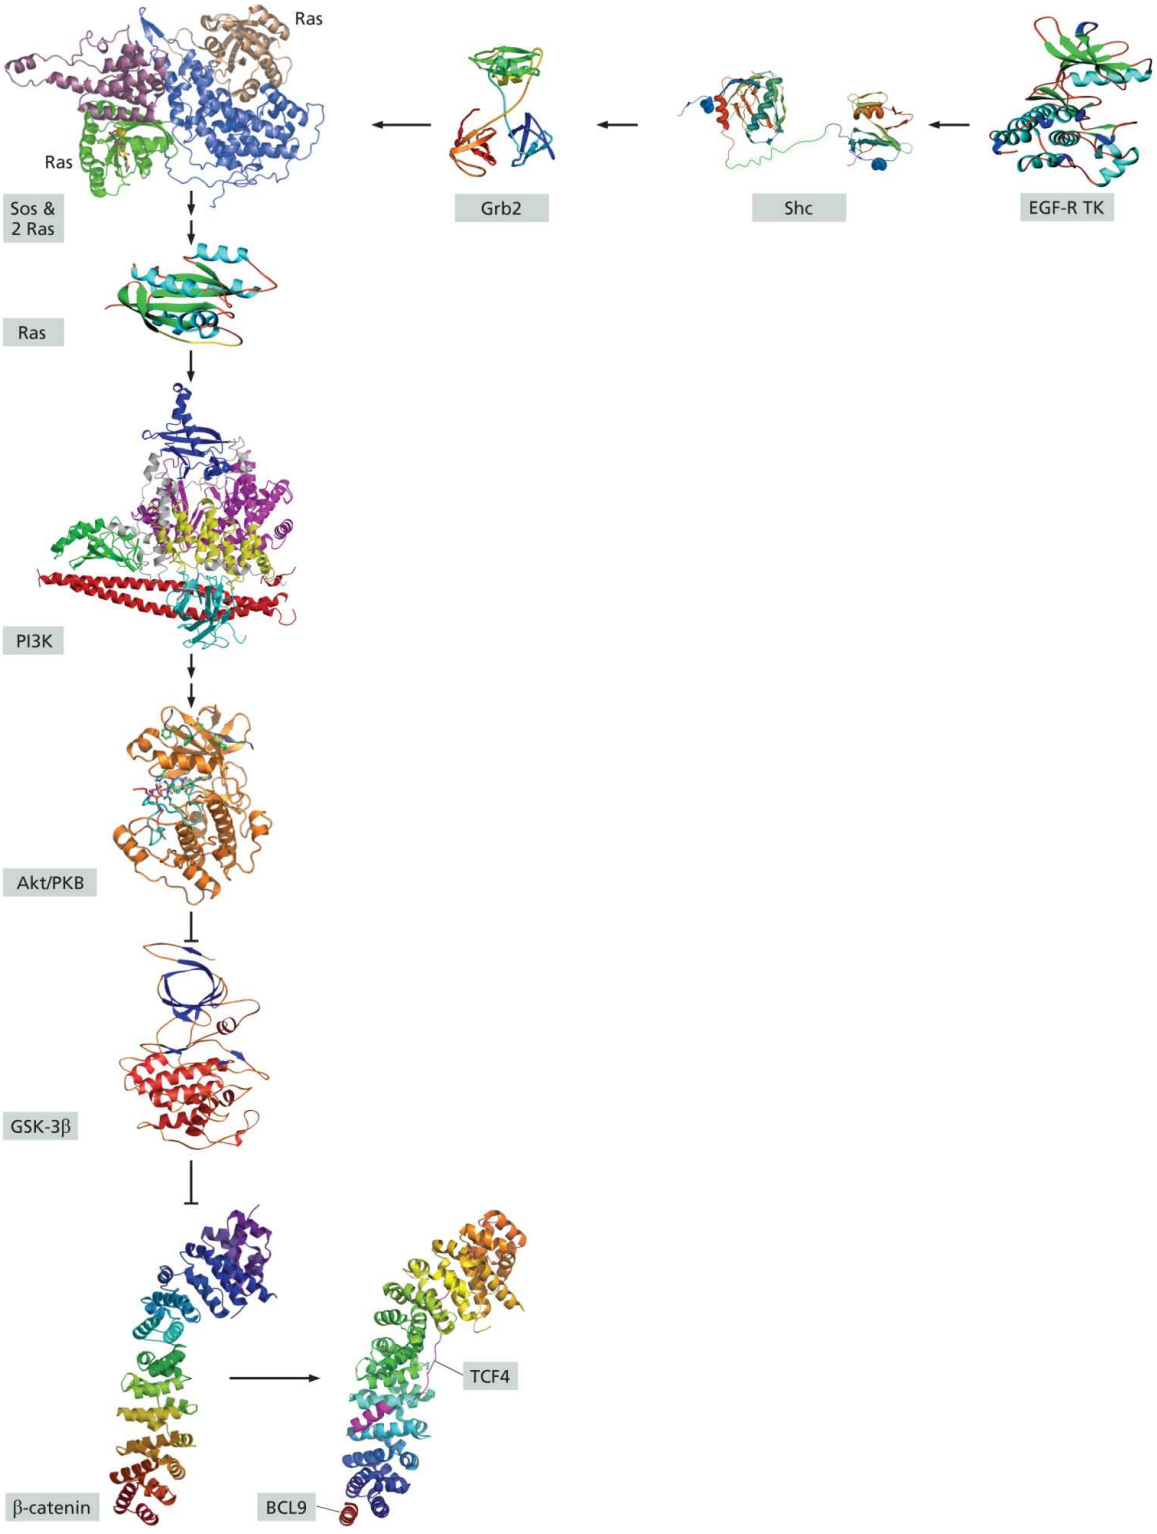
small percentage of multiple myeloma tumors, for instance, KIT is only activated in a small percentage of sarcomas, and R E T and P D G F R A are each activated only in a very small percentage of lung tumors. Other genes are activated often, in multiple cancer types. K RAS, notably, is activated at least some of the time in nine different tumor types. Rarely, however, is a particular gene activated in a majority of cases for any given tumor type. Most percentages in the histogram are in the 0 to 20 range.

Figure 6.26 Frequencies of oncogene activation in various human tumors This three-dimensional histogram illustrates the great variability with which various commonly studied human oncogenes are found in mutant, activated forms in the genomes of human tumors. The percentage (*z axis*) of tumors of a given type (*arrayed along y axis*) that harbor mutant forms of a given oncogene (*arrayed along x axis*) reveals great differences in the involvement of each of these oncogenes in human tumor pathogenesis; the underlying mechanisms that explain these strong variations between tumor types are largely obscure. (From R.S. Thomas et al., *Nat. Genet.* 39:347–351, 2007. With permission from Nature.)

Why do approximately 50% of colon carcinomas carry a mutant K-*ras* gene, and how do the remaining 50% of these tumors acquire a comparable mitogenic signal? Some of these other tumors have mutant B-Raf or PI3K proteins. Still, this leaves many cancers with no apparent alterations affecting either the Ras → Raf → MAPK signaling cascade or the parallel PI3K → Akt/PKB pathway (a question that we revisit in Chapter 11). Do these tumors harbor still-undiscovered genetic lesions that activate one or the other pathway? Or, alternatively, are the cells in these tumors able to proliferate uncontrollably because of mechanisms that have nothing to do with the operations of these particular pathways?

Finally, there remains a major problem in clinical oncology that remains far from being solved: Why do certain combinations of mutant alleles and protein expression patterns in cancer cells portend good or bad prognoses for patients? Many of the responses to this question will surely derive from our detailed precise understanding of the elusive signal-processing circuitry operating in the cytoplasm. At present, we are largely limited to noting correlations between these patterns and clinical outcomes. But correlations hardly reveal the chains of causality connecting the genomes of cancer cells with the behavior of the tumors that these cells create. Many years will likely pass before these and related mysteries are solved definitively.

Our ability to address some of these problems is being enhanced by rapid progress in the field of structural biology: use of artificial intelligence has made it routine to determine the detailed structures of protein molecules, including the signal-transducing proteins that play key roles in cancer pathogenesis. Since structure determines function, the elucidation of these structures will greatly enrich our understanding of how signal-transducing pathways actually operate inside cancer cells. In the future, the detailed structural information present in images such as **Figure 6.27** will provide critical clues for resolving major puzzles in cancer biology.



A signaling pathway, shown as a sequence of ribbon diagrams. E G F-R T K activates S h c, which activates G r b 2, which activates S O S and two R a s, which dissociate. An R a s activates P I 3 K, which activates A k t / P K B,

which inhibits G S K-3 beta, which inhibits beta catenin, which activates a complex containing a T C F 4 segment in the middle and a small B C L 9 segment at one end.

Figure 6.27 Structure of a signaling pathway The signaling pathway leading from EGF to the activation of signaling by β-catenin can now be depicted in terms of the detailed structures of the participating proteins, almost all of which have been determined by X-ray crystallography. The details of these structures will help our understanding of how signals flow through pathways like this one. Note that the structure of the central portion of Shc has not been determined and that the PI3K structure shown is of PI3Kγ, which is closely related to, but distinct from, the PI3Ks that are activated by receptor tyrosine kinases. This chapter has focused largely on the cytoplasmic signaling molecules that convey signals from cell surface receptors to the nucleus. This focus overlooks a critical path of oncogenic signaling that plays a key role in the development of common human cancers, specifically carcinomas of the breast, ovary, and prostate: steroid hormones leapfrog over this cytoplasmic circuitry by passing directly from the cell surface to the nucleus, where they bind nuclear receptors, notably the estrogen and androgen receptors (see Section 5.8 and **Sidebar 6.5**). Their central importance in the progression in the pathogenesis of certain common human carcinomas of the breast, prostate, and uterus is not reflected appropriately in the time that we have spent on them in this text.

Sidebar 6.5 The mysteries of breast and prostate cancer mitogenesis

Breast and prostate cancers are commonly occurring diseases in the West that have been the subjects of extensive research, yet we still have only a vague understanding at the molecular level of how the growth of the majority of these

tumors is controlled. A majority of breast cancers express the estrogen receptor (ER), while almost all prostate cancers express the androgen receptor (AR); both of these nuclear receptors act through mechanisms that are very different from those of the cell surface receptors we have studied (see Section 5.8). Like other "nuclear receptors," the ER binds its ligand, estrogen (more precisely, estradiol), and then proceeds to bind to specific DNA sequences in the promoters of certain target genes; this binding, followed by association with transcriptional co-regulators, leads to the transcription of these genes.

Estrogen acts as a critically important mitogen for ER-positive breast cancer cells. This is indicated by the fact that a number of "anti-estrogens" such as tamoxifen, which bind to the ER and block some of its transcription-activating powers, prevent the growth of ER-positive cells and tumors and can actually cause tumor regression. However, none of this seems to explain precisely how, at the biochemical level, estrogen and the ER drive the proliferation of ER-positive breast cancer cells. Some reports indicate that within minutes after estrogen is added to these cells, the Ras → MAPK signaling cascade is activated. This rapid response cannot be explained by the fact that ER acts as a nuclear transcription factor, since changes in nuclear gene transcription are not felt in the cytoplasm (in the form of proteins synthesized on newly formed mRNA templates) for at least half an hour.

One critical clue may come from the observation that some of the ligand-activated ER molecules are found to be tethered to cytoplasmic membranes rather than being localized to their usual sites of action in the nucleus; this association depends on the covalent modification of the ER via palmitoylation, much like the lipid tails attached to the C′-termini of Ras proteins. Following ligand binding, some of this cytoplasmic ER has been reported to be bound to Shc, the important SH2- and SH3-containing bridging protein that participates in Sos activation and Ras signaling (see Figure 6.7B); alternatively, some research reports physical association between the ER and either Src or RTKs in the cytoplasm depending on the epithelial versus mesenchymal phenotype of mammary cells. Moreover, in some cell types, nuclear ER via transcriptional regulation is key to estrogen-induced mitogenesis, whereas in others, the cytoplasmic palmitoylated form of ER appears to play a dominant role. This fragmentary description of a major mitogenic pathway is most unexpected, in light of the fact that breast cancer has, by now, been studied far more intensively than any other type of human malignancy.

OceanofPDF.com

Glossary

homeostasis
: (adj. **homeostatic**) The product of physiological control mechanisms that operate to maintain an optimal, often unchanging level of a certain signaling process, metabolic product, physiological function, or cell type.

interactome
: (1) The collection of all protein–protein interactions that operate within a cell. (2) The subset of these that can be determined experimentally.

proteoform
: A specific biochemical form of a protein that is defined by its primary amino acid residues together with a specific set of post-translational modifications. A single initially synthesized protein may be associated with multiple alternative proteoforms, each defined by its own combination of post-translational modifications.

OceanofPDF.com

Key concepts

- Discovery of Src's three homology domains (SH1, 2, and 3) led to the following model of tyrosine kinase receptor (RTK) signaling cascades: ligand-induced transphosphorylation results in an RTK displaying on its cytoplasmic tail an array of phosphotyrosines, each of which attracts and binds a specific SH2-containing cytoplasmic protein. Such relocalization permits the SH2-containing proteins to interact with plasma membrane–associated proteins that can activate their own downstream targets or with other signal-transducing molecules that pass on activating signals to yet other targets.
- One such signal-transducing protein tethered to the plasma membrane is Ras. Linker proteins form a physical bridge between ligand-activated RTKs and Sos, the latter acting as a guanine nucleotide exchange factor (GEF) that induces Ras to replace its bound GDP with GTP, thereby activating Ras signaling.
- Three major downstream signaling cascades emanate from activated Ras via binding of its effector loop with its main downstream signaling partners—Raf kinase, phosphatidylinositol 3-kinase (PI3K), and Ral-GEF. Yet other downstream effectors that bind to activated Ras appear to play secondary roles in Ras signaling.
- Raf phosphorylates residues on MEK, activating the latter. MEK then phosphorylates and activates the extracellular signal–regulated kinases 1 and 2 (ERK 1 and 2), which are classified as MAPKs (mitogen-activated protein kinases). The Raf signaling cascade, often called a MAPK pathway, is the foremost mitogenic pathway in mammalian cells, both normal and neoplastic.
- The phosphatidylinositol 3-kinase (PI3K) pathway depends on kinases phosphorylating a membrane-embedded phosphatidylinositol, converting it to PIP3. Once formed, the latter attracts molecules (such as Akt) that carry a pleckstrin homology (PH) domain. The resulting activation of Akt activates a series of downstream proteins. PIP3 levels are normally kept low in cells by phosphatases, notably PTEN.
- In the third Ras-regulated pathway, Ras binds Ral-GEFs, causing localization of Ral-GEF near the inner surface of the plasma

membrane. Ral-GEF then induces nearby Ral to exchange its GDP for GTP, enabling Ral to activate downstream targets. This has multiple effects on the cell, including changes in the cytoskeleton and cellular motility.

- Cytokine receptors use noncovalently bonded TKs of the JAK class to phosphorylate STATs. The STATs form dimers that migrate to the nucleus, where they serve as transcription factors.
- Integrins bind components of the ECM, leading to the formation of focal adhesions and activation of focal adhesion kinase (FAK), which is associated with the integrin cytoplasmic tail. Transphosphorylation of FAK and its recruitment of SH2-containing molecules activates many of the same signaling pathways as RTKs.
- The pathway controlled by Wnt factors enables cells to remain in a relatively undifferentiated state—an important attribute of certain cancer cells. Wnt, acting via Frizzled receptors, prevents glycogen synthase kinase-3β (GSK-3β) from tagging its substrates, including β-catenin, for destruction. The spared β-catenin moves into the nucleus, where it activates transcription of key mitogenic genes and contributes to stemness.
- Ligand-bound G-protein–coupled receptors (GPCRs) activate cytoplasmic heterotrimeric G proteins whose α subunit responds by exchanging its GDP for GTP. The Gα subunit then dissociates from its partners (Gβ + Gγ) and affects a number of cytoplasmic enzymes, while the Gβ + Gγ dimer activates its own effectors, including PI3Kγ, Src, and Rho-GEFs.
- Among the pathways relying on dual-address proteins is the nuclear factor-κB (NF-κB) signaling system. It depends on liberation of cytoplasmic NF-κB homo- and heterodimers from sequestration by IκBs. Following migration of NF-κB subunits into the nucleus, these proteins function as transcription factors that activate expression of at least 150 genes, including cell proliferation and anti-apoptotic genes.
- The cleavage of Notch at two sites following ligand binding liberates a cytoplasmic fragment that migrates to the nucleus and functions as part of a transcription factor complex. Notch aberrations are seen in the majority of cervical carcinomas.
- When Hedgehog binds a Patched receptor, Smoothened is released from inhibition and emits signals that protect cytoplasmic Gli protein

from cleavage. The resulting intact Gli migrates to the nucleus, where it activates transcription, whereas cleaved Gli acts as a transcriptional repressor.

- The binding of TGF-β to its receptors causes phosphorylation of cytoplasmic Smad proteins and their dispatch to the nucleus, where they collaborate with other transcription factors to activate a large contingent of genes. This pathway plays a major role in the pathogenesis of many carcinomas, both in the early stages when TGF-β fails to arrest cell proliferation and later, when it contributes to tumor cell invasiveness.
- YAP/TAZ signaling represents a major intracellular hub for integrating a diverse array of signals, many of them affected by the physical surroundings of a cell. These transcription factors are normally phosphorylated and sequestered in the cytoplasm and when dephosphorylated migrate to the nucleus, where they drive, among other things, cell proliferation.

Thought questions

1. What molecular mechanisms have evolved to ensure that the signals coursing down a signaling cascade reach the proper endpoint targets rather than being broadcast nonspecifically to “unintended” targets in the cytoplasm?
2. How many distinct molecular mechanisms can you cite that lead to the conversion of a proto-oncogene into an active oncogene?
3. Why are point mutations in *ras* oncogenes confined so narrowly to a small number of nucleotides, while point mutations in genes encoding other cancer-related proteins are generally distributed far more broadly throughout the reading frames?
4. What factors determine the lifetime of the activated state of a Ras oncoprotein?
5. Treatment of cells with proteases that cleave the ectodomain of E-cadherin often result in rapid changes in gene expression. How might you rationalize this response, given what we know about this cell surface protein?
6. What mechanisms have we encountered that ensure that a signal initiated by a growth factor receptor can be greatly amplified as the signal is transduced down a signaling cascade in the cytoplasm? Conversely, what signaling cascade(s) strongly limit the possible amplification of a signal initiated at the cell surface?
7. What quantitative parameters describing individual signal-transducing proteins will need to be determined before the behavior of the signaling cascade formed by these proteins can be predicted through mathematical modeling?

Supplementary Sidebars

Supplementary Sidebar 6.1 Effects of serum stimulation on the cytoskeleton

In addition to inducing the expression of a number of mRNAs encoding proliferation-related proteins, the addition of serum to serum-starved cells evokes rapid changes in the cytoskeleton of a cell that are ostensibly preparatory to its eventual growth and division

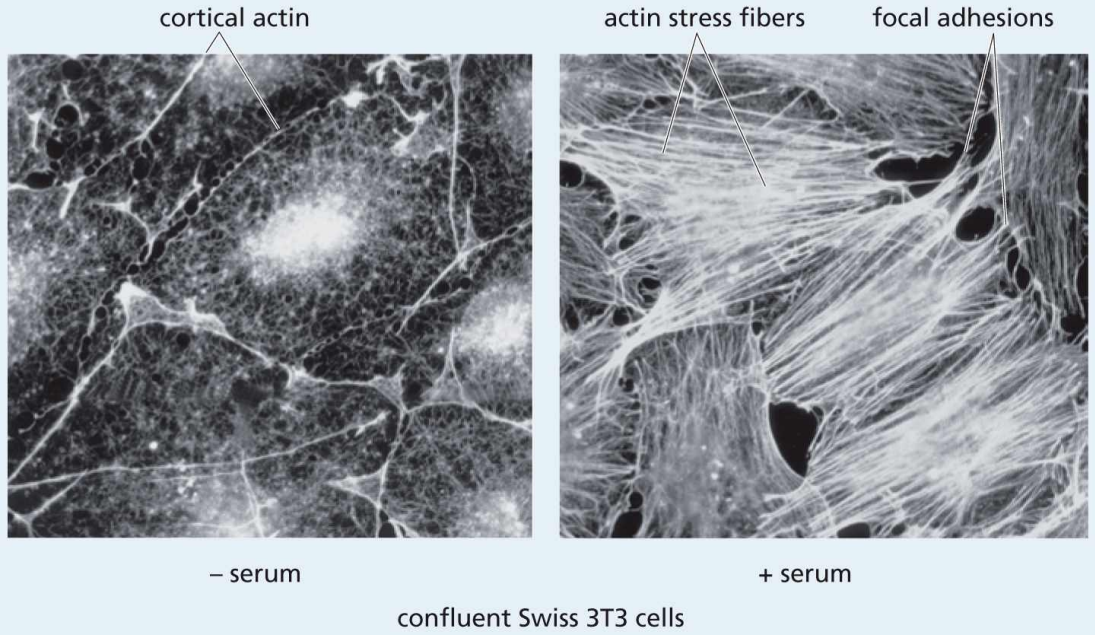

Figure S6.1 Serum-induced alterations of cell shape Like many other cell types, serum-starved mouse Swiss 3T3 cells undergo profound changes in their actin cytoskeleton following serum stimulation. Under serum-starved conditions, most of the polymerized actin is found in a layer beneath the plasma membrane termed cortical actin, whereas within ten minutes of serum addition, focal adhesions are formed by integrins (see Figure 5.22) that are linked to actin *stress fibers* that stretch across the cell. In addition, the serum stimulation, much of it mediated by platelet-derived growth factor (PDGF), induces greatly increased cell motility (*not shown*). (Courtesy of C. Nobes.)

Supplementary Sidebar 6.2 The complexities of understanding RTK signaling

One goal of research into the biochemistry of signal transduction is to generate mathematical models that explain why and how cells respond to signals from specific ligand-activated growth factor receptors (RTKs), such as the EGF and PDGF receptors. Such models must, by necessity, take into account the behavior of individual signal-transducing proteins that lie downstream of these receptors and are responsible for processing receptor-initiated signals and mediating eventual cell-biological responses. This goal is far from being realized because of the large number of biochemical parameters that affect responses to ligand-activated receptors. Included among these are

1. The diverse array of receptor tyrosine kinases (58 in all) that are displayed in various combinations on the surfaces of various cell types
2. The concentrations of each of these receptors on the surface of a given cell type
3. The functional interactions of these diverse RTKs in fostering signaling by one another and in competing for limiting amounts of downstream signal-transducing proteins
4. The actual physiologic concentrations of various growth factor ligands in the extracellular spaces
5. The influences on receptor function of other cell-surface proteins (for example, integrins) that potentiate or limit receptor activation
6. The intensity of tyrosine phosphorylation on various phosphotyrosine residues following ligand binding by receptors
7. The expression in differentiated cell types of various combinations of the 103 signal-transducing cytoplasmic partner proteins possessing one or more SH2 domains and 42 with one or more PTB-containing domains, these proteins binding to the phosphotyrosines (pYs) created in the cytoplasmic tails of ligand-activated receptors
8. The functional interactions between these partner proteins in enhancing or blocking each other’s binding to ligand-activated receptors
9. The binding affinities of the various SH2- and PTB-containing partner proteins to the various receptor-associated phosphotyrosines (see Figure S6.2)
10. The lifetimes of these phosphotyrosines (that is, the period between the initial formation of each pY and its destruction by a phosphotyrosine phosphatase)
11. Various other negative-feedback controls on individual receptors, such as ligand-induced endocytosis, that are designed to delimit their signaling lifetimes (for example, see Figure 6.25B)
12. Parameters governing the signal-transducing efficiencies of downstream signal-transducing partner proteins that govern their cross-communicating interactions with one another

Together, these parameters interact in myriad ways to create a complexity that is vastly beyond our current abilities to analyze and to exploit in order to generate truly predictive models of cell-biological responses to growth factor stimulation.

Supplementary Sidebar 6.3 Protein:protein interaction motifs

The SH2 and SH3 domains described in Figures 6.4 and 6.5 represent only a small subset of the domains that have evolved during prokaryotic and eukaryotic cell evolution and are employed in order to enable interactions between functionally interacting proteins to occur specifically and with high efficiency; in addition, the "ligands" of some of these domains—the latter acting as intracellular "receptors"—also include a number of low–molecular-weight molecules such as phospholipids. As seen in Figure S6.2, a large number of these have been cataloged over the past few decades, and there are plausibly yet other such domains that will be added to this roster.

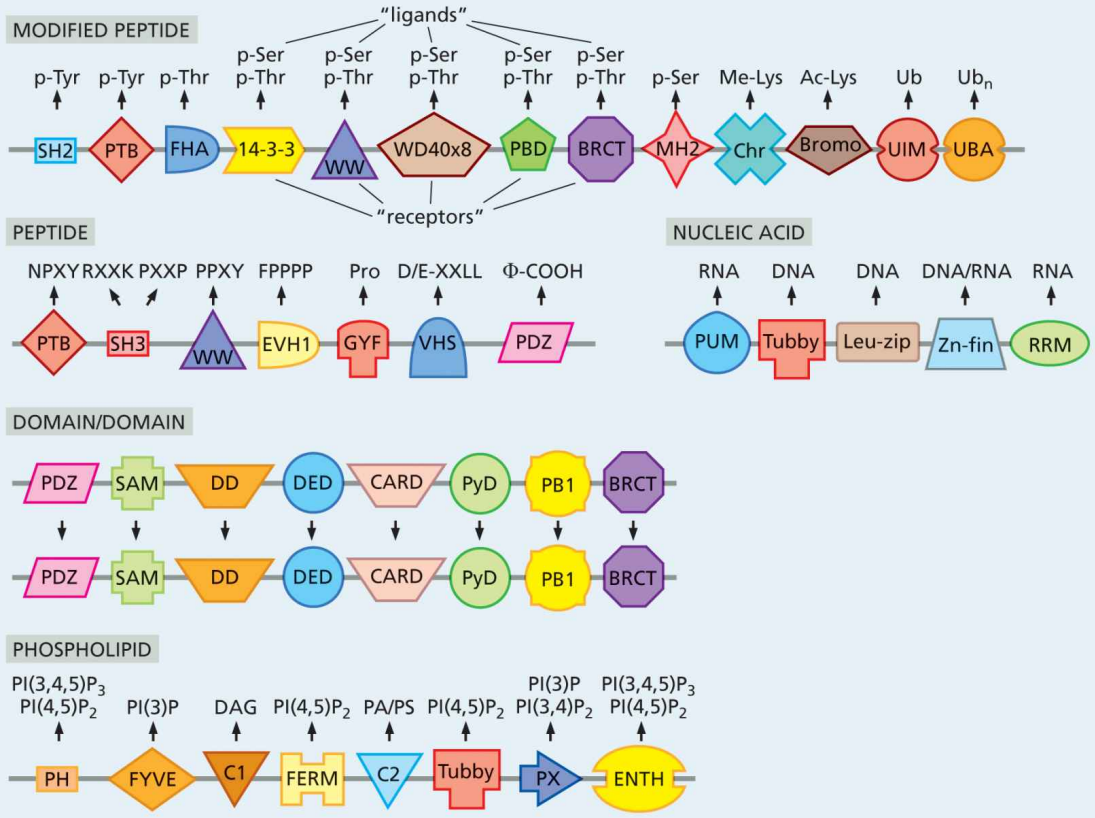

Figure S6.2 Diverse protein domains enable specific intermolecular interactions The spectrum of molecular "ligands" that can be bound by complementary "receptor" domains in order to form intermolecular complexes is far larger than indicated in Figure 6.5C. As shown, a variety of modified amino acid residues, peptide sequences, nucleic acids, and phospholipids can serve as ligands of the indicated domains. In addition, certain domains ("domain/domain") favor the homodimerization of two protein molecules. (From T. Pawson and P. Nash, *Science* 300:445–452, 2003. With permission from AAAS.)

Supplementary Sidebar 6.4 Subtleties of Ras signaling

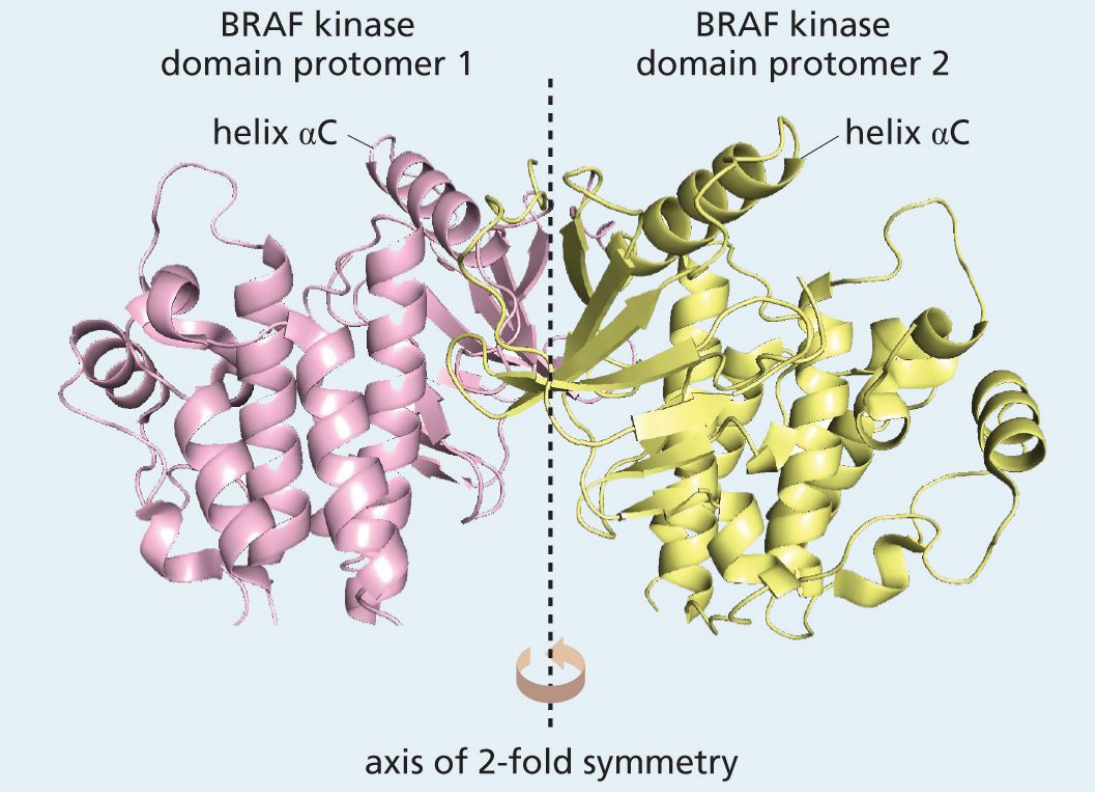
At one level, the three Ras oncoproteins (H-, N-, and K-) would seem to function identically to one another. They all carry mutations that compromise GTPase activity, they elicit similar if not identical cell-biological responses when expressed in cells, and it is highly unusual for two of these to be present concomitantly in a single spontaneously arising human tumor—the last observation testifying to their functional redundancy. Moreover, replacement of the chromosomal K-*ras* protein-coding sequence by that of H-*ras* yields cells and tissues that respond identically to subsequent carcinogen exposure. Still, there are hints that they do indeed exhibit subtle differences in function. For example, the K-Ras oncoprotein, but not its H-ras counterpart, suppresses non-canonical Wnt signaling, doing so by binding a key intermediate in calcium signaling termed calmodulin, which functions via a succession of signals to enhance K-Ras–mediated cell transformation. Moreover, K-Ras seems more capable of generating tumor-initiating cancer stem cells (discussed in Chapters 11 and 16).

In addition, the C-terminal tails that tether the various Ras proteins to intracellular membranes hint at the existence of multiple alternative membrane associations of Ras proteins, which in turn may influence the interactions of Ras proteins with their downstream effectors, which themselves are found in distinct intracytoplasmic sites. For example, in its GDP-bound state, the H-Ras protein preferentially associates with cholesterol-rich patches of the plasma membrane, while the binding of GTP causes it to associate alternatively with cholesterol-poor patches. The N-Ras protein, with its distinct set of C-terminal lipid anchoring tails, behaves in an opposite way, migrating from cholesterol-poor to cholesterol-rich plasma membrane patches following GTP binding. The association of 6 to 8 individual Ras molecules within a patch of membrane results in a “nanocluster” of these molecules, which is especially effective in activating the downstream effectors of GTP-bound Ras, in contrast to individual unclustered Ras proteins, which fail to do so effectively. Moreover, several of the Ras isoforms have been found to release downstream signals far more effectively when they form homodimers, as discussed in **Supplementary Sidebar 6.5**. Behavior like this complicates our ability to elucidate the interactions of Ras with its downstream effectors, since such subtle differences in localization are difficult to recapitulate outside of living cells.

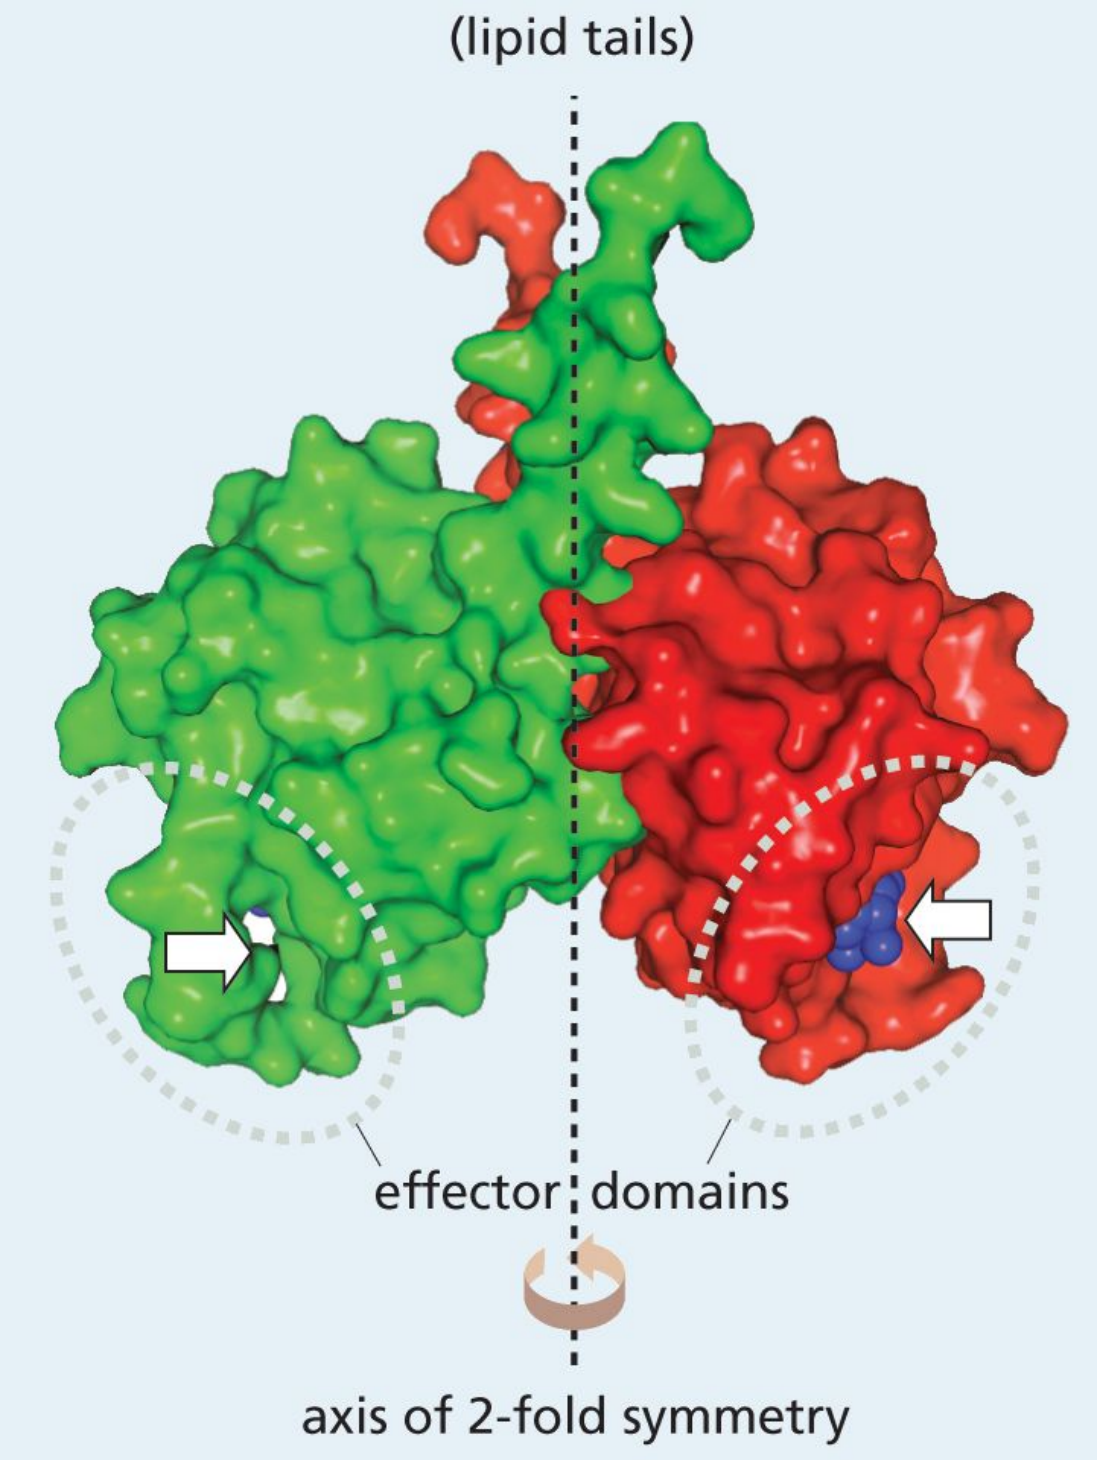
Supplementary Sidebar 6.5 Dimerization of protein kinases and Ras

Extensive evidence has been accumulated that a number of kinases undergo dimerization in association with their signaling. This process has been best

characterized in the context of signaling by the Raf and B-Raf proteins and is also strongly suggested in the context of the kinase domains of a number of growth factor receptors. Indeed, it is plausible that the shared, common stereochemistry of the tyrosine and serine/threonine kinases—those involved in oligopeptide phosphorylation—has included a dimerization function, which may facilitate the activation of their associated catalytic clefts (**Figure S6.3A**). Such kinase:kinase dimerization may explain the mysterious phenomenon that pseudokinase domains of certain growth factor receptors have been highly conserved evolutionarily (suggesting critically important function), in spite of the fact that these domains lack detectable enzymatic activity and carry amino acid replacements in the presumed catalytic cleft that are incompatible with the transfer of phosphate groups from ATP to protein substrates. Accordingly, these pseudokinase domains may serve to heterodimerize with and thereby help activate the catalytic functions of related catalytically competent kinase domains, doing so by inducing stereochemical shifts in these partners; such effects are sometimes termed allosteric, to indicate a shift in the stereochemistry of a protein that is induced in one region of the protein but affects another region (such as a catalytic domain).



(A)



(B)

Figure S6.3 Dimerization of Ras and Raf Both Ras and Raf have been found to undergo dimerization under certain conditions, and there is strong evidence that such dimerization is critical to the ability of the normal Raf kinase protein to emit

signals. (A) The crystal structure of B-Raf, the paralog of Raf, shows a head-to-head dimerization function. In the region of association between the two kinases, there are presumably interactions that enable each kinase subunit to activate via induced allosteric shifts the catalytic activity of its partner subunit. (B) Similar head-to-head dimerization has been documented for Ras proteins, with the C-terminal tails of the subunits within the K-Ras4B dimer shown here (*above*) both presumably being anchored within an adjacent lipid bilayer membrane via lipid tails (*not shown*) whereas the GTPase and the domains important for its interaction with its three major effectors are indicated (*below*; see also Figure 6.8A). Some work indicates that Ras dimerization is dependent on GTP loading. The two *white arrows* indicate the sites of guanine nucleotide (*blue*) binding. (A, courtesy of M. Therrien; see also T. Rajakulendran et al., *Nature* 461:542–545, 2009. B, Courtesy of K.D. Westover; see also S. Muratcioglu et al., *Structure* 23:1325–1335, 2015.)

As an example, both the EGF-R (= HER1) and HER2 receptors can form potent signaling heterodimers with HER3. HER1 and HER2 can each phosphorylate the C-terminal domain of HER3, allowing the latter to attract a number of SH2-containing effectors (see, as examples, Figure 6.5A and B). This does not explain, however, why the sequences of the HER3 kinase domain, which is enzymatically silent, have been highly conserved during evolution. X-ray crystallography has made it clear that HER3, when forming complexes with the tyrosine kinase domains of HER1 and of HER2, is able to help activate the catalytic functions of their kinase domains, in each case acting by causing allosteric shifts in these domains. Hence, the evolutionary conservation of the HER3 pseudokinase domain appears to be due to the role that it plays in such allosteric activation of partner kinase domains. The JAK3 kinase (see Figure 5.14) contains one catalytically active kinase domain and one pseudokinase, that is, a domain that has the overall structure of a catalytically active protein kinase but is clearly enzymatically inactive; in this instance the pseudokinase domain is thought to interact with the active domain to regulate, via allosteric shifts, the activity of the latter. Yet another example of such kinase:pseudokinase heterodimerization comes from study of the KSR scaffolding protein (see Figure 6.9B), which employs a kinase-like domain to heterodimerize with one of its partners, B-Raf. These observations of dimerization of kinase molecules (or of kinase domains) may also affect our interpretation of the term “autophosphorylation,” since observations of this process, with the implication of a single kinase molecule phosphorylating itself, may in fact have reflected the phosphorylation by dimerized kinase subunits of one another.

Even more unexpected have been the discoveries that the Ras proteins undergo dimerization for reasons that are not entirely clear in terms of signaling function (Figure S6.3B). One rationale might derive from the possibility that a dimerized Ras protein is required to properly regulate the dimerized Raf protein, and indeed

experiments have been reported indicating that dimerized Ras is needed to activate the Raf → MEK → ERK signaling cascade, apparently because dimerized Ras increases the intrinsic tendency of Raf (or B-Raf) molecules to dimerize and thus form an actively signaling kinase complex. Moreover, overexpression of Ras proteins leads to the formation of higher-order clusters of Ras proteins ("nanoclusters") tethered to the plasma membrane; these nanoclusters appear to be critical to high-level signaling by Ras proteins. Of additional interest, Rag proteins are small G proteins (like Ras and Ral) that regulate the functions of mTORC1; these also have been found to dimerize in head-to-head dimers. Indeed, the far larger mTORC1 also forms dimers.

Supplementary Sidebar 6.6 Akt and the control of cell growth

Cell growth is often assumed to imply cell proliferation, but in fact the two processes are quite distinct, with cell growth indicating an increase in the mass and thus overall size of a cell. This growth is a product of increased biosynthesis, largely of a cell's macromolecules, which is controlled in turn by a number of master regulators, such a mTORC1, which is regulated in turn by a variety of governors including, importantly, Akt (**Figure S6.4**).

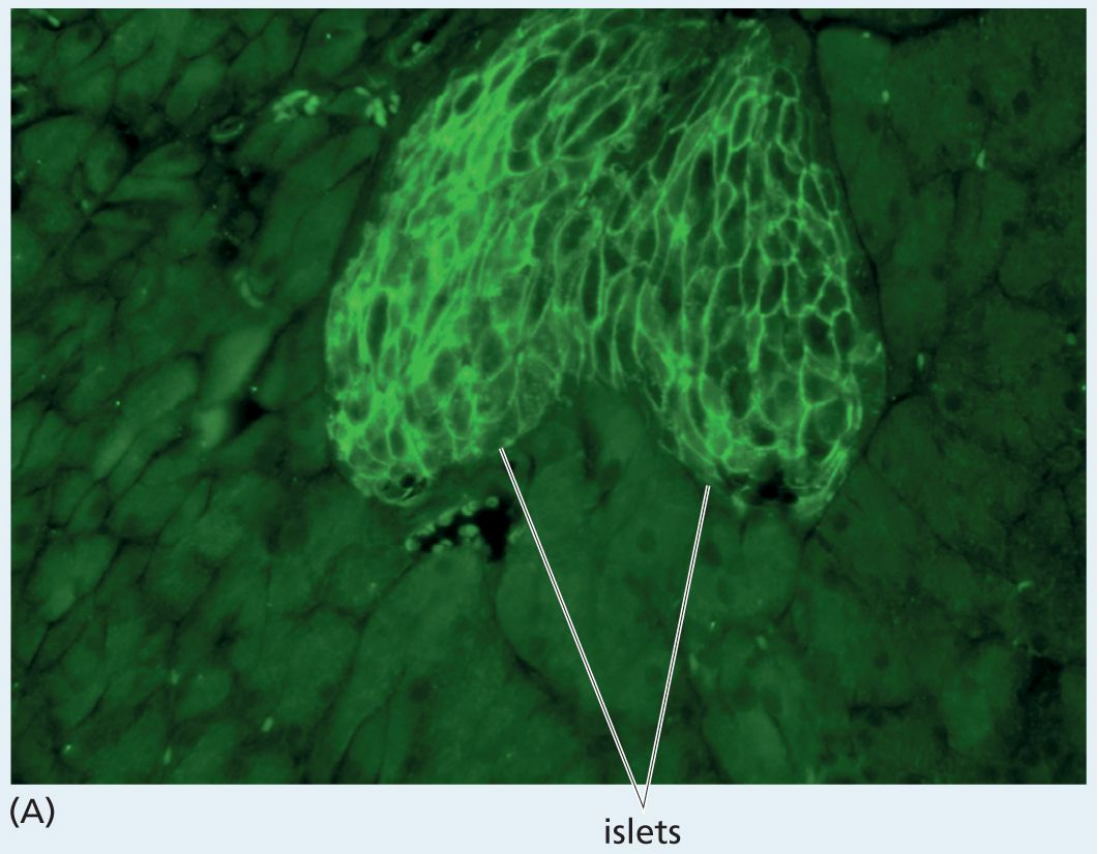


Figure S6.4 Akt and the control of cell growth As mentioned earlier, there is a distinction between cell "growth" and cell "proliferation," where the former yields increases in cell size whereas the latter yields increases in cell number. The endocrine β cells located in the pancreatic islets are normally responsible for secreting insulin in response to elevated concentrations of blood glucose. (A) A micrograph of a normal pancreatic islet. (B) If a constitutively active Akt/PKB kinase is expressed selectively in β cells, they grow to volumes that are as much as fourfold larger than normal. (From R.L. Tuttle et al., *Nat. Med*. 7:1133–1137, 2001. With permission from Nature.)

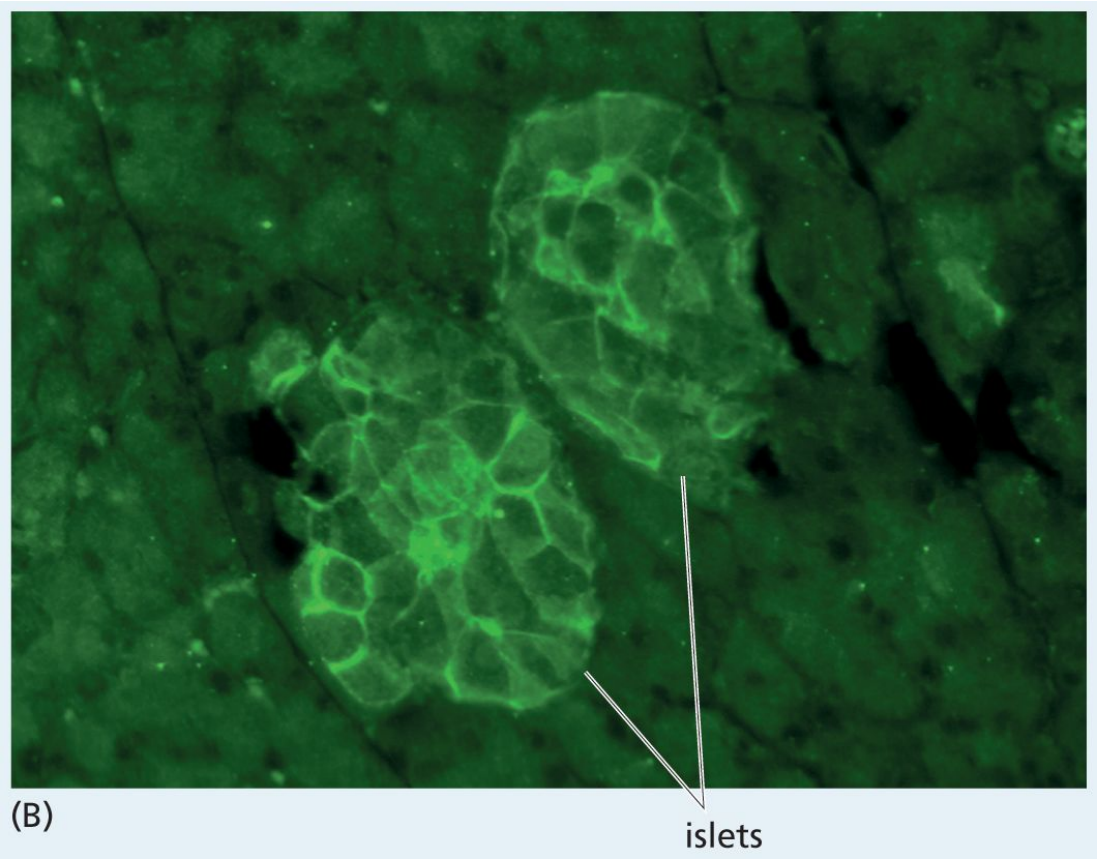
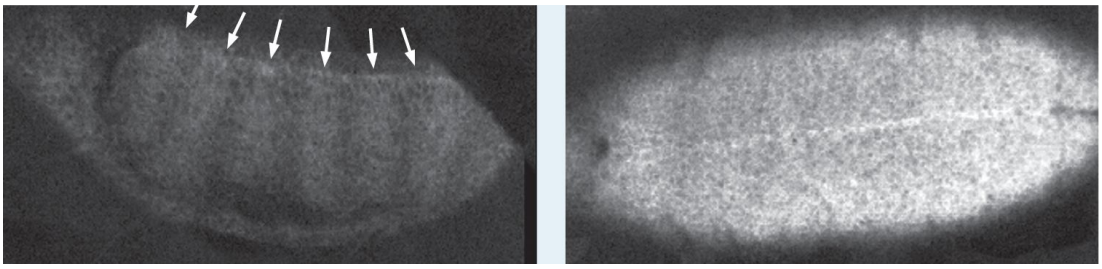
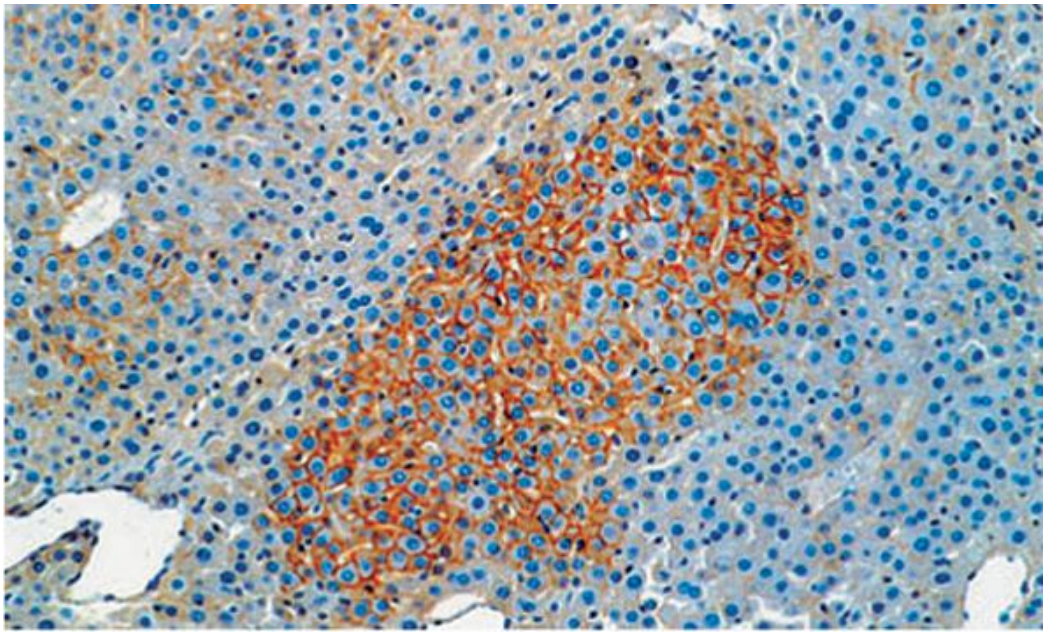


Supplementary Sidebar 6.7 Diverse mechanisms regulating β-catenin function

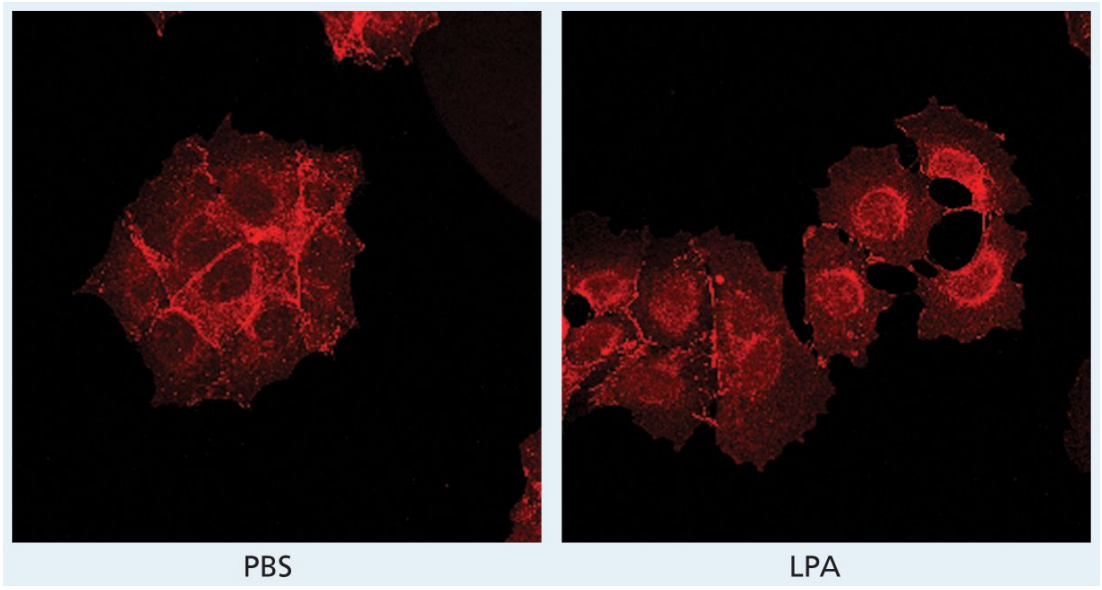
The diagrams of the regulation of β-catenin function in Figure 6.19 provide only the outlines of its operations in cells. Its key role in modulating the connection between the cell surface (via E-cadherin association) and its function in the nucleus as a key transcription factor involved in mitogenesis and stem-cell function (see Figure 6.19C) have dictated multiple layers of additional control on its activity. Some of the controls and biological functions in normal and neoplastic cells are illustrated in **Figure S6.5**.



(A)



(B)



(C)

Figure S6.5 Regulation of β-catenin signaling Increases in β-catenin levels and signaling are achieved through diverse mechanisms. (A) *Drosophila* embryos usually express β-catenin in a striped pattern (*arrows*, *left*). However, when the gene encoding GSK-3β is inactivated, high levels of β-catenin accumulate uniformly throughout the embryo (*right*). (B) Mice exposed to certain liver carcinogens develop hepatocellular carcinomas (hepatomas) in which β-catenin levels rise dramatically because the protein is mutant, enabling it to resist phosphorylation by GSK-3β and resulting degradation. The resulting cytoplasmic accumulation of β-catenin (*brown*) in this focus of premalignant hepatocytes is a prelude to increased levels of nuclear β-catenin that drive cell proliferation through association with Tcf/Lef transcription factors. (C) The dynamic interaction between the β-catenin sequestered in the adherens junctions and the form of this protein that conveys Wnt-dependent signals to the nucleus is illustrated here. When A431 human epidermoid carcinoma cells are propagated in monolayer culture and placed briefly in phosphate-buffered saline (PBS), β-catenin (*red*) is largely localized to the adherens junctions between adjacent cells (*left*). However, when these junctions are dissolved following brief exposure of the cells to lysophosphatidic acid (LPA), both E-cadherin and β-catenin are internalized and β-catenin is relocalized to perinuclear sites (*right*), where it now becomes available for activation and nuclear translocation by signals emanating from Frizzled receptors that have bound Wnt ligands (*not shown*; see Figure 6.19B). (A, courtesy of E.F. Wieschaus. B, from T.R. Devereux et al., *Oncogene* 18:4726–4733, 1999. With permission from Nature. C, from Y. Kam and V. Quaranta, *PloS One* 4:e4580, 2009. © 2009 Kam et al. Supplementary Sidebar 6.8 Cross connections between canonical pathways

The signaling cascades that historically are studied first are often termed “canonical” and therefore, implicitly, are the most important ones operating within cells. However, as the biochemical complexities of cells are uncovered in ever-greater detail, it becomes clear that all of these canonical pathways are connected to one another via numerous cross connections, a small portion of which are shown, for the sake of illustration, in **Figure S6.6**. As these networks are plotted out as seen in the figure, the usually depicted one-dimensional canonical signaling cascades begin to merge into complex two-dimensional webs, which ultimately can be properly depicted only in three dimensions, given the actual organization of these networks and the difficulty of depicting three-dimensional networks in two-dimensional space.

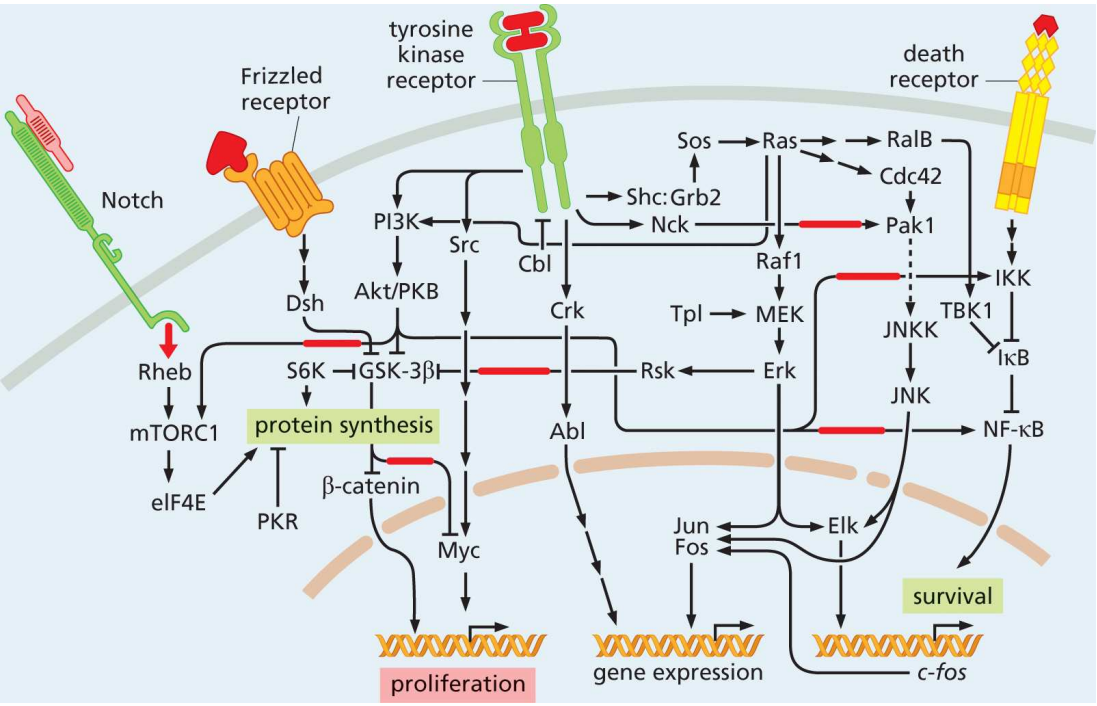

Figure S6.6 Two-dimensional signaling maps While we have depicted signaling pathways as linear cascades reaching from the plasma membrane to the nucleus with occasional lateral branch points, a rapidly growing body of research reveals that these pathways interact via numerous lateral cross connections and points of convergence. A small subset of these are highlighted by a *red thickening* of the depicted cross connection. Note, for example, that GSK-3β, which plays a central role in the Wnt–β-catenin pathway, is also regulated by signaling proteins lying downstream of tyrosine kinase receptors. (We will encounter the death receptors in Chapter 9.) Importantly, as more and more of these cross connections are uncovered, two-dimensional maps will need to be replaced by three-dimensional depictions to accommodate them. (Adapted from T. Hunter, *Cell* 88:333–346, 1997. With permission from Elsevier.)

Supplementary Sidebar 6.9 The actual Ras effector circuit

The effector pathways of Ras, as laid out in Figure 6.9A and subsequent figures in Chapter 6, appear to represent only the most important and apparent of the Ras downstream signaling channels. More detailed analyses indicate that Ras proteins, including Ras oncoproteins, appear to employ additional downstream effectors to induce changes in cell phenotype (**Figure S6.7**). As this figure implies, a number of cell-biological phenotypes associated with the transformed cell state may be influenced in part by some of these other effectors. Importantly, however, while these additional Ras effectors have been found to form physical complexes with GTP-bound

Ras, their precise contributions to the transformed cell phenotype have not been documented.

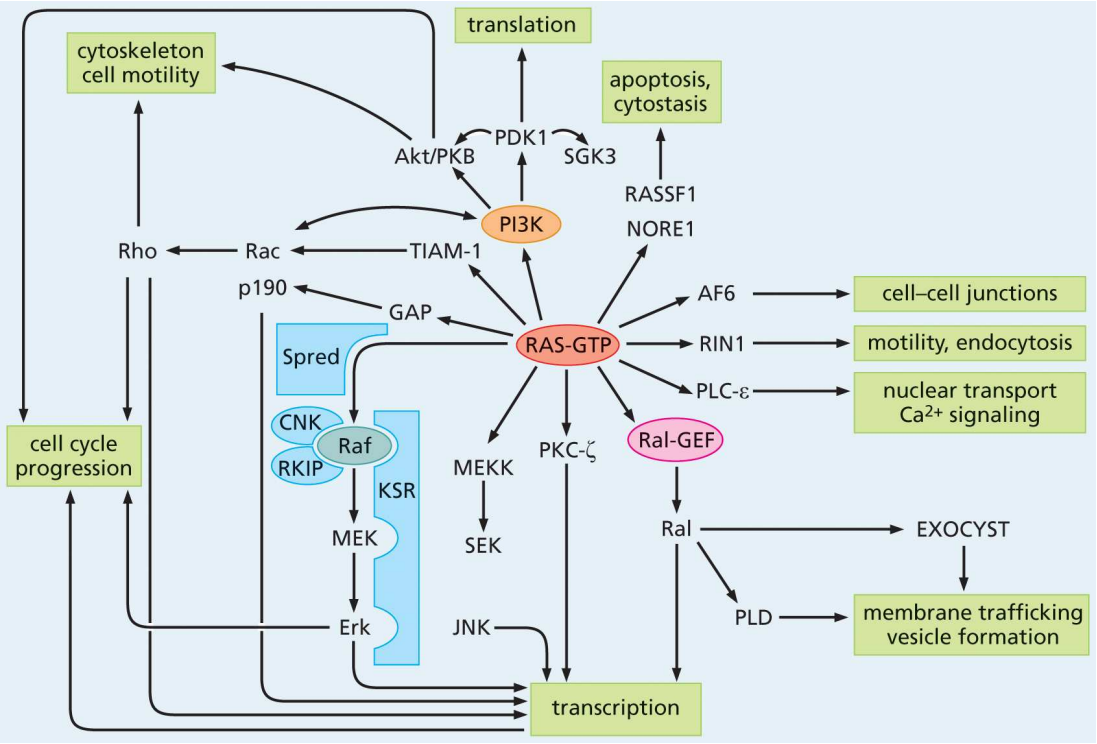

Figure S6.7 Ras effector pathways Detailed biochemical analyses of the GTP-bound, activated form of the Ras proteins indicate that these proteins bind to far more than the three major effectors of Ras signaling—Raf, PI3 kinase (PI3K), and Ral-GEF, as illustrated in Figures 6.9A, 6.10, and 6.15, respectively. As shown here, at least eight additional Ras-interacting proteins have been uncovered, most of which are known or suspected to play key roles in relaying Ras signals to specialized downstream signaling circuits involved in functions as diverse as transcription, membrane trafficking, endocytosis, and translation. (Adapted from M. Malumbres and M. Barbacid, *Nat. Rev. Cancer* 3:459–465, 2003. With permission from Nature.)

Even this diagram does not begin to indicate some important biochemical subtleties. The four different Ras proteins (including the two alternative K-Ras isoforms) interact in slightly different ways with their various canonical effectors (see Figure 6.9A), influenced in part by (1) the distinct homodimerization abilities of the various Ras proteins; (2) their distinct types of lipidation; (3) the binding affinities of the different effectors, each via its Ras-binding domain (RBD); and (4) whether normal or oncogenic forms of Ras proteins are involved. A further dimension of complexity derives from the fact that some of the Ras-binding domains of these candidate and

validated Ras effectors can also bind to other small G proteins that are distantly related to Ras proteins and execute very different functions.

OceanofPDF.com

Glossary

allosteric
: Referring to a mechanism for regulating the activity of a protein, notably an enzyme, in which its activity or function is modulated by changes in its three-dimensional structure; the change results from binding of a regulatory molecule at a site within the protein that is distant from the functionally important site, such as, in the case of enzymes, from its catalytic cleft.

pseudokinase
: A protein domain that exhibits many of the structural features of a bona fide kinase and is a paralog of bona fide kinases but that lacks the catalytic activity of the latter because of amino acid replacements in the catalytic cleft.

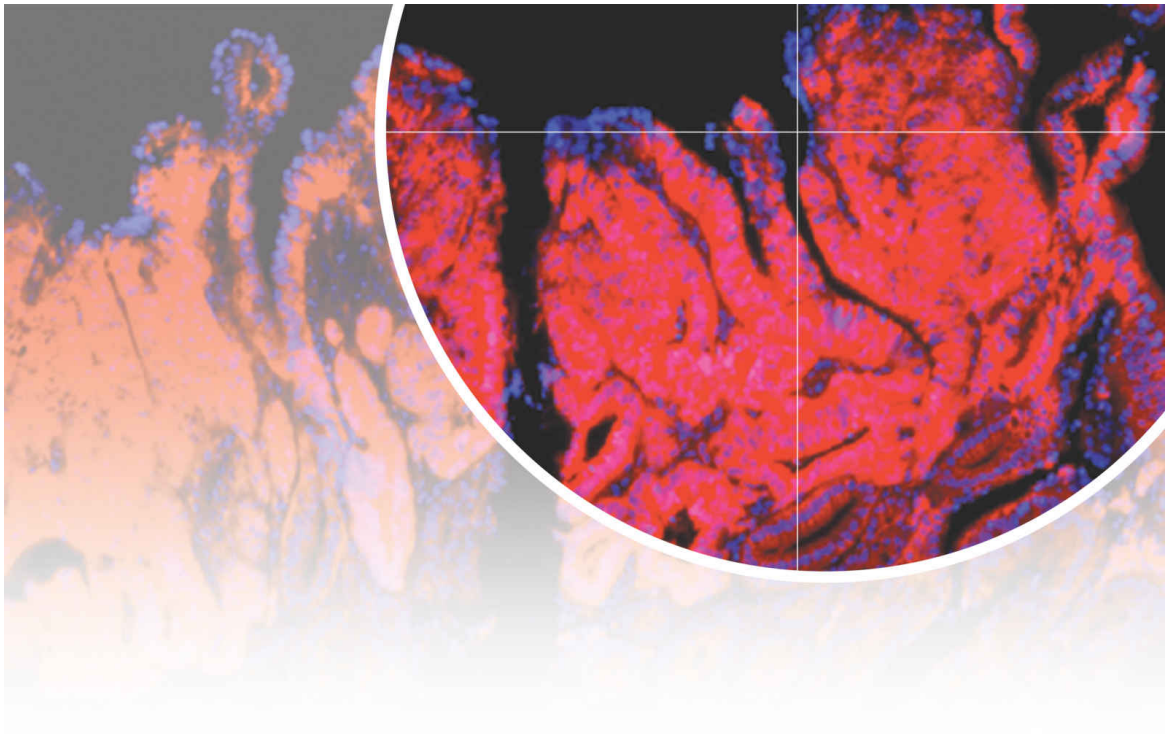
Chapter 7
Tumor Suppressor Genes



A fluorescence microscopy image of adenoma cells, stained bright pink, overlying normal cells in which blue nuclei are visible.

> Let me add . . . a consideration of the inheritance of tumors. . . . In order that a tumor may arise in such cases, the homologous elements in both series of chromosomes must be weakened in the same way.
>
> Theodor Boveri, pathologist, 1914

The discovery of proto-oncogenes and oncogenes, as described in Chapter 6, provided a simple and powerful explanation of how the proliferation of cells is driven. The proteins encoded by proto-oncogenes participate in various ways in receiving and processing growth-stimulating signals that originate in the extracellular environment. When these genes suffer mutation, the flow of these growth-promoting signals becomes deregulated. Instead of emitting them in

carefully controlled bursts, oncoproteins release a steady stream of growth-stimulating signals, resulting in the unrelenting proliferation associated with cancer cells.

The logic underlying well-designed control systems dictates, however, that the components promoting a process must be counterbalanced by others that oppose this process. Biological systems seem to follow this logic as well, which leads us to conclude that the growth-promoting genes we have discussed until now provide only part of the story of cellular growth control.

In the 1970s and early 1980s, certain pieces of experimental evidence about cancer cell genetics began to accumulate that were hard to reconcile with the known properties of oncogenes. This evidence hinted at the existence of a second, fundamentally different type of growth-controlling gene—one that operates to constrain or suppress cell proliferation. These antigrowth genes came to be called tumor suppressor genes (TSGs). Their involvement in tumor formation seemed to happen when the genes were inactivated or lost, thereby liberating affected cells from their growth-suppressing effects.

Now, more than four decades later, we have come to realize that the inactivation of TSGs plays a role in cancer pathogenesis that is as important to cancer as the activation of oncogenes. Indeed, the inactivation of these growth-suppressing genes may be even more important than oncogene activation for the formation of many kinds of human cancer.

OceanofPDF.com

Glossary

tumor suppressor gene

(1) A gene whose partial or complete inactivation, occurring in either the germ line or the genome of a somatic cell, leads to an increased likelihood of cancer development. (2) Such a gene that is responsible for constraining cell proliferation. *See also* **gatekeeper**.

OceanofPDF.com

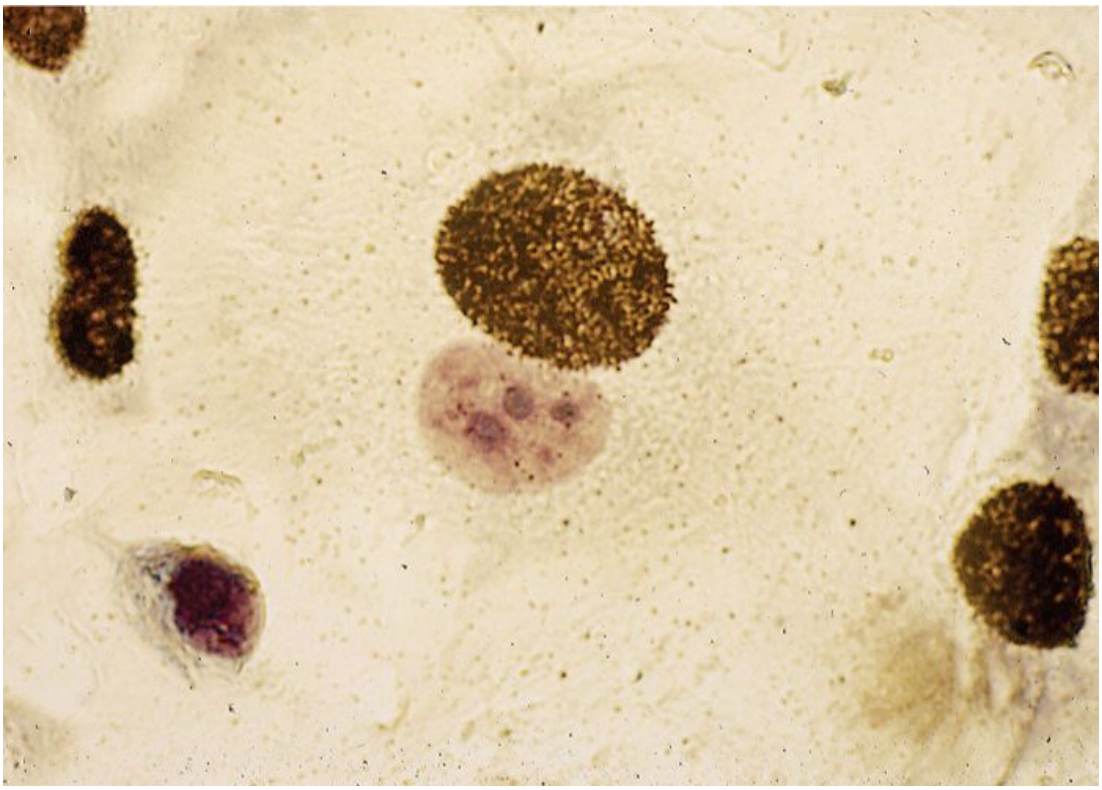
7.1 Cell fusion experiments indicate that the cancer phenotype is recessive

The study of tumor viruses in the 1970s revealed that these infectious agents carried a number of cancer-inducing genes, specifically viral oncogenes, which acted in a dominant fashion when viral genomes were introduced into previously normal cells (see Chapter 3). In particular, the introduction of a tumor virus genome into a normal cell would result in transformation of that cell. This response meant that viral oncogenes could dictate cell behavior in spite of the continued presence and expression of opposing cellular genes within the virus-infected cell that usually functioned to ensure controlled, appropriate cell proliferation. Because the viral oncogenes could overrule these cellular genes, by definition the viral genes displayed a *dominant* phenotype—they were bringing about cellular transformation. This observation suggested, by extension, that cancerous cell growth was a dominant phenotype when compared to normal (wild-type) cell growth, which was therefore considered to be *recessive* (see Section 1.1).

However, as was suspected at the time, and reinforced by research in the 1980s, most human cancers do not seem to arise as consequences of tumor virus infections. Thus, the lessons learned from studying such viruses might well be irrelevant to understanding how human tumors arise. Hence, this issue needed to be revisited, making it possible that human cancer cells might even exhibit a recessive phenotype.

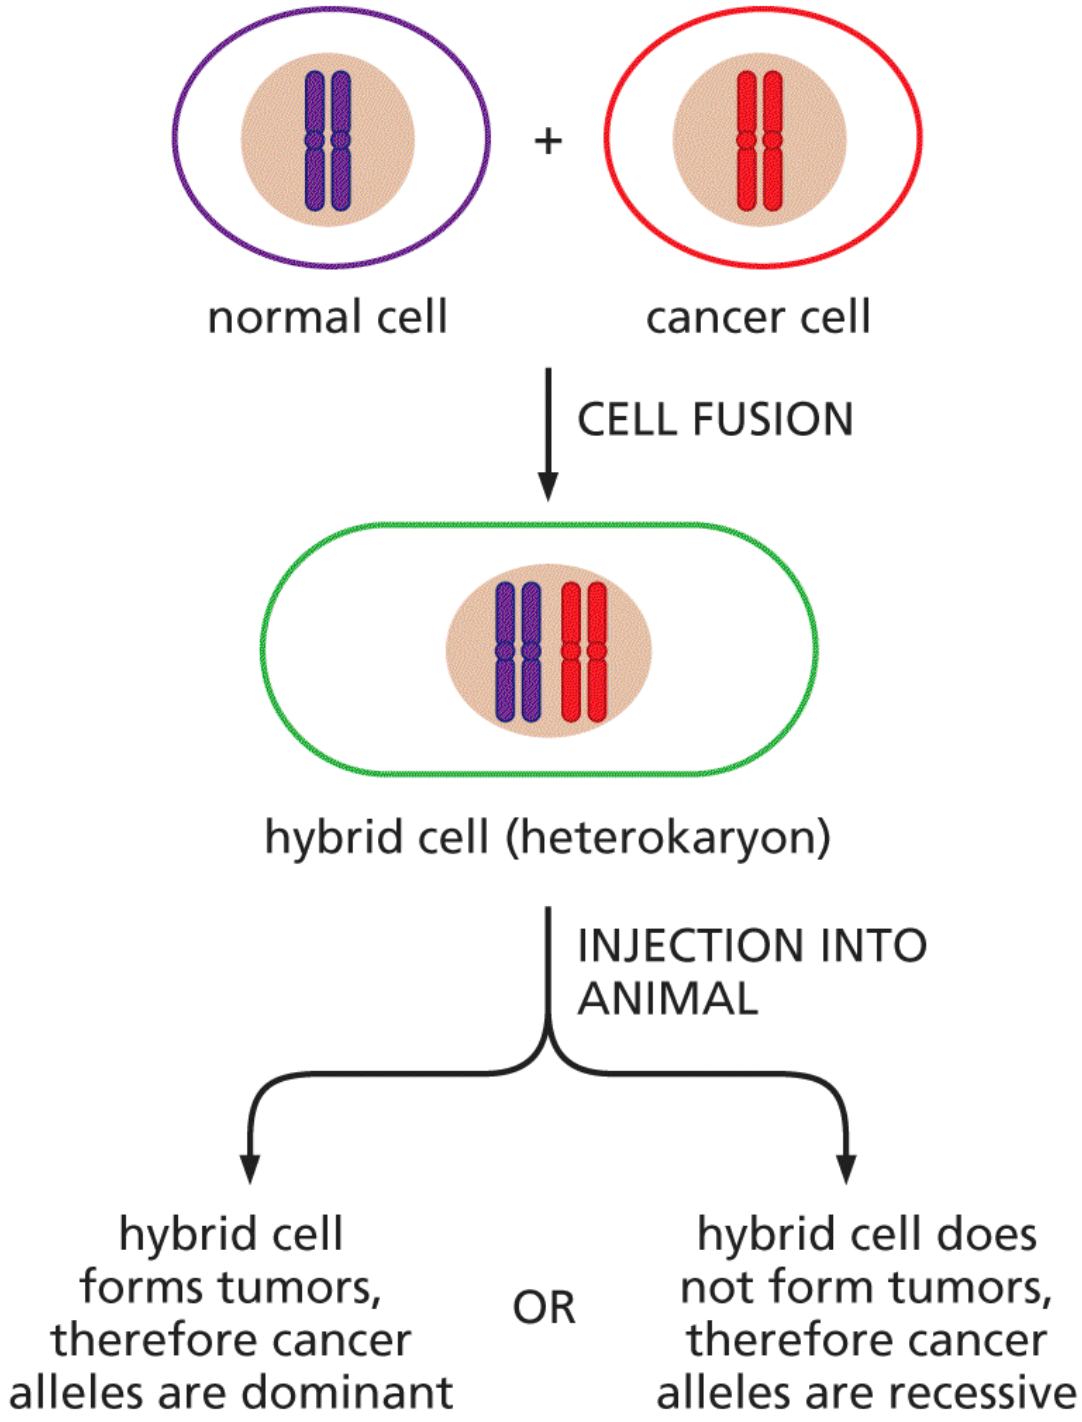
An initial hint of the importance of such recessive cancer-inducing alleles came from experiments undertaken initially at Oxford University in Great Britain. Based on the principles of Mendelian genetics, when an allele that specifies a dominant phenotype is juxtaposed with an allele specifying a recessive phenotype, the dominant allele, by definition, wins out and the cell will display the phenotype associated with the dominant allele. Such battles for phenotypic domination, it turns out, can be engineered experimentally by a technique called *cell fusion*. In this procedure, cells of two different phenotypes—for example, normal cells and cancer cells—are cultured together in a Petri dish. An agent is then used to induce fusion of the plasma membranes of cells that happen to be growing near one another. The result of such treatment is a large cell with a single cytoplasm and multiple nuclei, often termed a syncytium. Because these fusing agents act indiscriminately, they could join together cells of the same type—a pair of normal cells, for example—or cells of different types. If the participating cells happen to be of different origins, then the resulting hybrid cell

is termed a heterokaryon (**Figure 7.1A**), to indicate that it carries genetically distinct nuclei. Genetic techniques can then be used to select for a fused cell that has acquired two genetically distinct nuclei and, at the same time, to eliminate cells that have failed to fuse or happen to carry two identical nuclei. For example, each type of cell may carry a genetic marker that allows it to resist being killed by a particular antibiotic agent to which it would normally be sensitive; heterokaryons would therefore be resistant to killing by a mixture of the two antibiotics.



A micrograph image of a cell with a large, dark nucleus that looks like a prickly seed pod and a somewhat smaller, paler nucleus beside it. Other cytoplasmic structures are visible at the periphery of the image.

(A)



A diagram in which a normal cell and a cancer cell undergo cell fusion to form a hybrid cell (heterokaryon). When this is injected into an animal, either the hybrid cell forms tumors, meaning that the cancer alleles are dominant, or else the hybrid cell does not form tumors, in which case the cancer alleles are recessive.

(B)

Figure 7.1 Experimental fusion of cells (A) When cells growing adjacent to one another in culture are exposed to a *fusogenic* agent, such as the chemical polyethylene glycol (PEG) or a viral protein that triggers membrane fusion, they initially form a heterokaryon with multiple nuclei. In this experiment, radiolabeled mouse NIH 3T3 cells have been fused (using an inactivated Sendai virus) with monkey kidney cells. The resulting hybrid cell contains two distinct nuclei. The larger mouse nucleus is identified by the silver grains that were formed during subsequent autoradiography. The membrane surrounding this heterokaryon cannot be seen. (B) The use of cell fusion to test the dominance or recessiveness of the cancer cell phenotype can, in theory, yield two different outcomes: tumorigenic or non-tumorigenic hybrid cells. In fact, when cancer cells derived from most kinds of non-virus-induced human tumors (or from chemically induced rodent tumors) were used in these fusions, the hybrid cells were non-tumorigenic. In contrast, when the cancer cell derived from a virus-induced tumor, the hybrids were usually tumorigenic. (A, courtesy of S. Rozenblatt.)

Cells having large numbers of nuclei are generally inviable, whereas cells having only two nuclei are often viable and will proceed to grow. When these cells divide, the two nuclear membranes will break down, the two sets of chromosomes will intermingle, and each resulting daughter cell will receive a single nucleus with chromosome complements originating from both parental cell types.

Using this cell fusion technique, hybrid cells of disparate origins, including even chicken–human hybrids, could be made. Such hybrids were used to address many interesting biological questions. For our purposes, however, the results of only one type of experiment are of special interest: How did normal + cancer cell hybrids grow in culture and were they capable of forming tumors (Figure 7.1B)?

The smart money at the time bet that cancer, a potent, dominating phenotype, would come out on top when forced into a competition with the normal cell growth phenotype. However, in a number of experiments in which tumor cells were fused with normal cells, the hybrid cells that initially formed were found to have lost the ability to form tumors when injected into an appropriate host animal. This unexpected observation was interpreted to mean that the malignant, cancer cell phenotype was recessive to the phenotype of normal, wild-type growth. Alternative explanations could be proposed to explain this result: perhaps the dominant oncogene from the tumor cell failed to be expressed in the hybrid cell, or the hybrid cell might have been eliminated by the immune system of the host animal. Nevertheless, these early experiments were very influential in introducing the concept that the malignant phenotype might behave as a recessive trait.

There was, however, one notable exception to these observations: when the parental cancer cell in the two-cell hybrid had been transformed by tumor virus infection, the malignant phenotype would dominate (see Figure 7.1B). This behavior makes sense, given that tumor viruses are able to deploy the virus-associated oncogenes to transform normal cells. Such viral oncogenes are able, in a variety of ways, to dominate the behavior of the cells that they have infected and thereby act as dominant alleles (with respect to normal host cell genes that regulate related cell functions).

OceanofPDF.com

Glossary

syncytium
: Cell formed when the plasma membranes of two or more cells fuse, initially resulting in a multi-nucleated cell.

heterokaryon
: Cell carrying two (or more) genetically distinct nuclei, often arising from the experimental fusion of two cells.

OceanofPDF.com

7.2 The recessive nature of the cancer cell phenotype requires a genetic explanation

The results of the cell-fusion experiments led to the notion that normal cells carry functional alleles of genes that inhibit malignant growth and that these growth-inhibitory genes are somehow inactivated or lost in cancer cells.

Because human cells are diploid, normal cells would carry two copies of each of these genes, which help constrain or suppress their proliferation. During the development of a tumor, an evolving cancer cell would have to discard or otherwise inactivate both copies of one or more of these genes. Once these growth-suppressing genes were lost, the proliferation of the cancer cells would likely accelerate. However, re-introducing intact versions of these genes by cell fusion would restore their growth-inhibitory functions and cause the hybrid cells to slow or halt proliferation.

Because the wild-type versions of these (hypothetical) genes antagonize the cancer cell phenotype, they came to be called “tumor suppressor genes.” There were arguments both in favor of and against the existence of TSGs. The argument in their favor was that it is far easier to inactivate a gene by various mutational mechanisms than it is to hyperactivate its protein product through a mutation. For example, a *Ras* proto-oncogene can be converted into its hyperactivated oncogenic form only by a point mutation that affects certain specific codons, such as the 12th, 13th, or 61st (Section 4.3 and Figure 4.6). In contrast, a TSG—or, for that matter, any other gene—can readily be inactivated by point mutations that strike at many different sites in its protein-coding sequences, by insertions or deletions that alter its reading frame, or by large-scale chromosomal deletions.

The logical case against the existence of TSGs derived from the diploid state of the mammalian cell genome. If inactivation of TSGs really did play a role in enabling the growth of cancer cells, and if these inactive alleles

were recessive, an incipient tumor cell would seemingly reap no benefit from inactivating only one of its two copies of a TSG because a dominant, wild-type copy would remain. Hence, it seemed that both copies of a given TSG would need to be eliminated to produce a malignant phenotype.

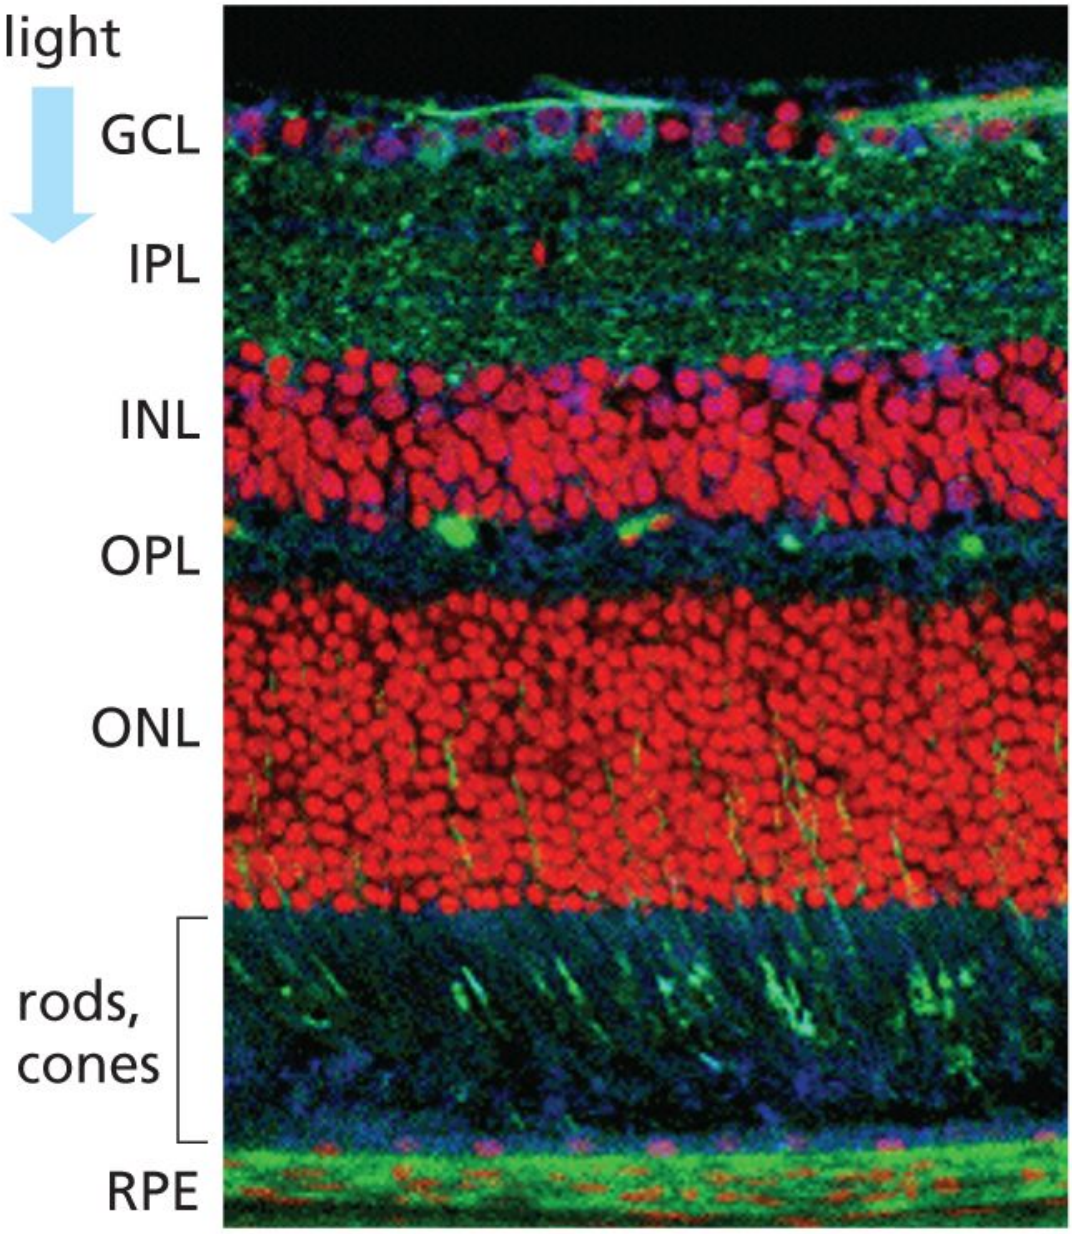
This requirement for two separate genetic alterations to the same gene seemed too complex and unwieldy and too improbable to occur during the lifetime of a cell. Because the likelihood of two mutations occurring is the square of the probability of a single mutation, this made it seem highly unlikely that TSGs could be fully inactivated in the time required for tumors to form. For example, if the probability of inactivating a single gene copy by mutation is on the order of 10^{-6} per cell generation, the probability of silencing both copies would be on the order of 10^{-12} per cell generation—exceedingly unlikely to occur in the early phases of tumor development.

OceanofPDF.com

7.3 The retinoblastoma tumor provides a solution to the genetic puzzle of TSGs

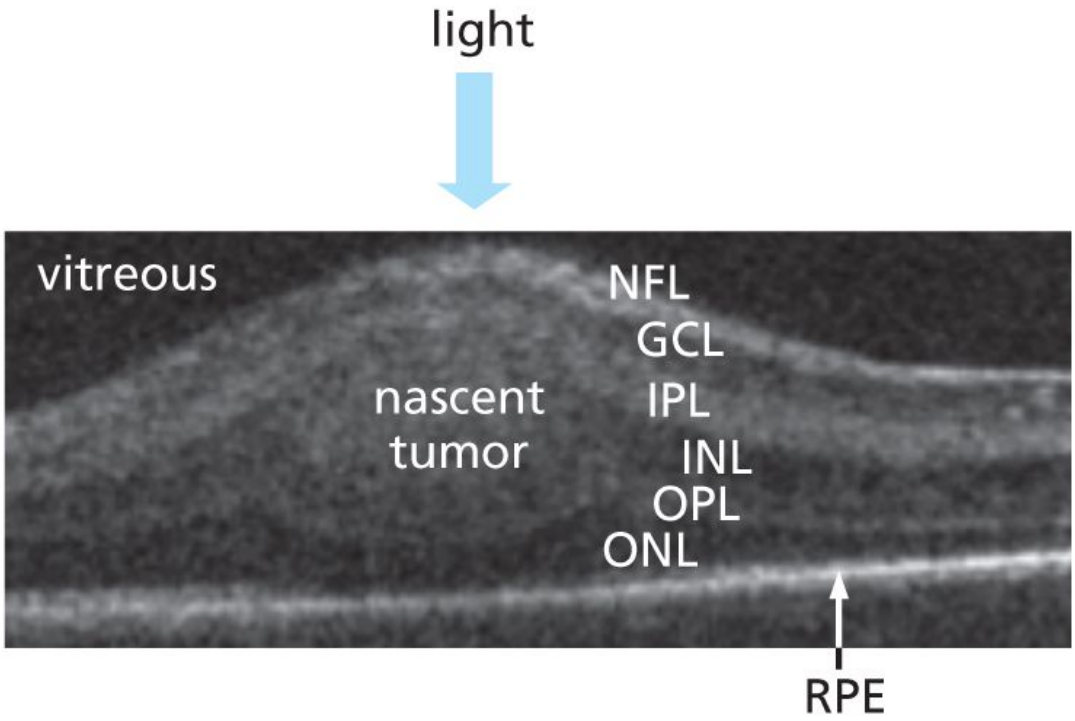
The arguments for and against the involvement of TSGs in tumor development could never be settled by the cell fusion technique. For one thing, this experimental strategy, on its own, offered little prospect of finding and isolating specific genes whose properties could be studied and used to support the TSG hypothesis. In the end, the important insights came from studying a rare childhood eye tumor, retinoblastoma.

Observed in about 1 in 20,000 children, this tumor of the retina arises in the precursors of photoreceptor cells (**Figure 7.2**). It is diagnosed anytime from birth to ages 6 to 8 years, after which the disease is rarely encountered. Retinoblastoma appears in two forms. Children who are born into families with no history of the disease present in the clinic with a single tumor in one eye, a condition termed unilateral retinoblastoma. If this tumor is eliminated—by radiation, cryoablation, or by removal of the affected eye—then the child usually has no further risk of retinoblastoma and no elevated risk of tumors elsewhere in the body. This form of retinoblastoma is considered sporadic.



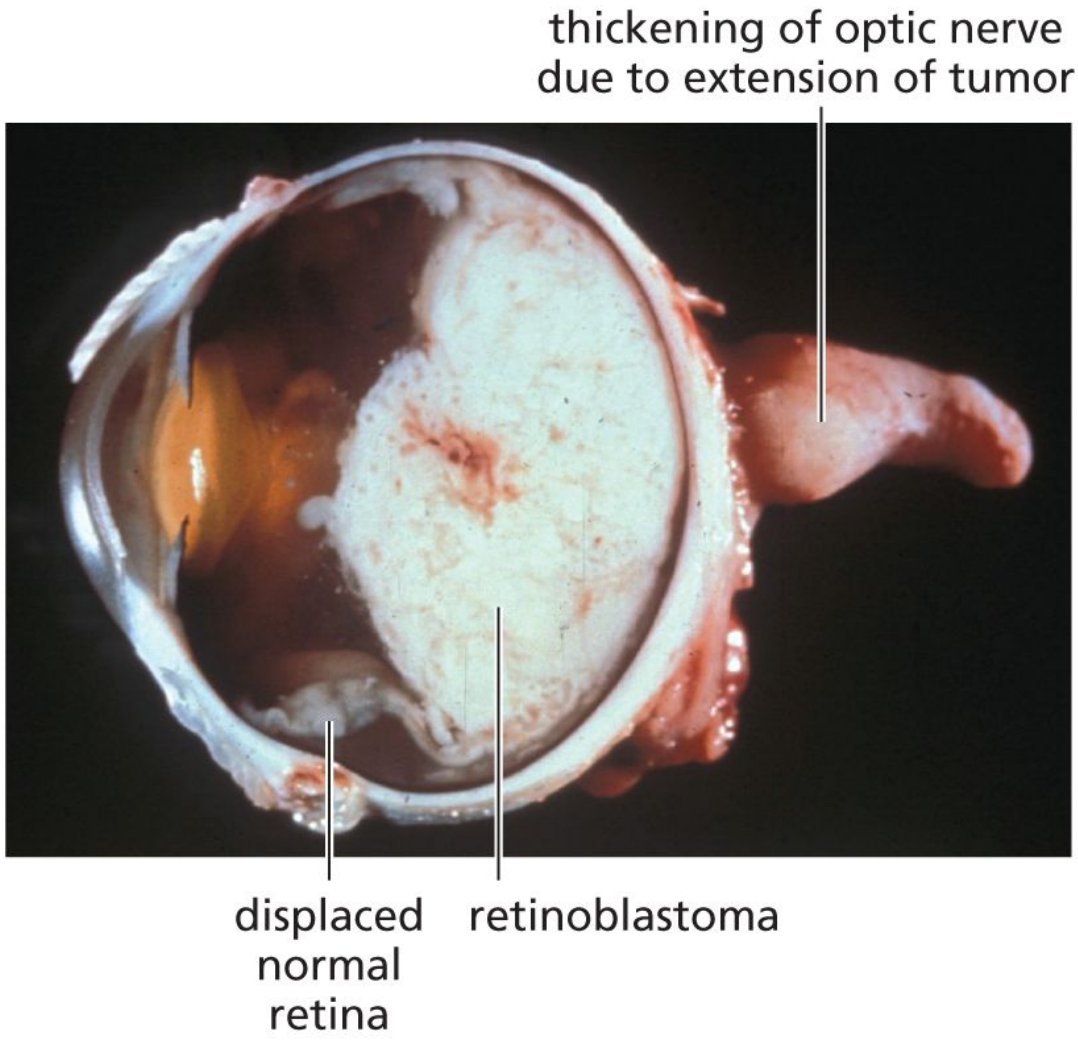
An enhanced color image showing a normal retina in cross section. Incoming light encounters tissue layers labeled G C L, I P L, I N L, O P L, O N L, rods and cones, and finally R P E.

(A)



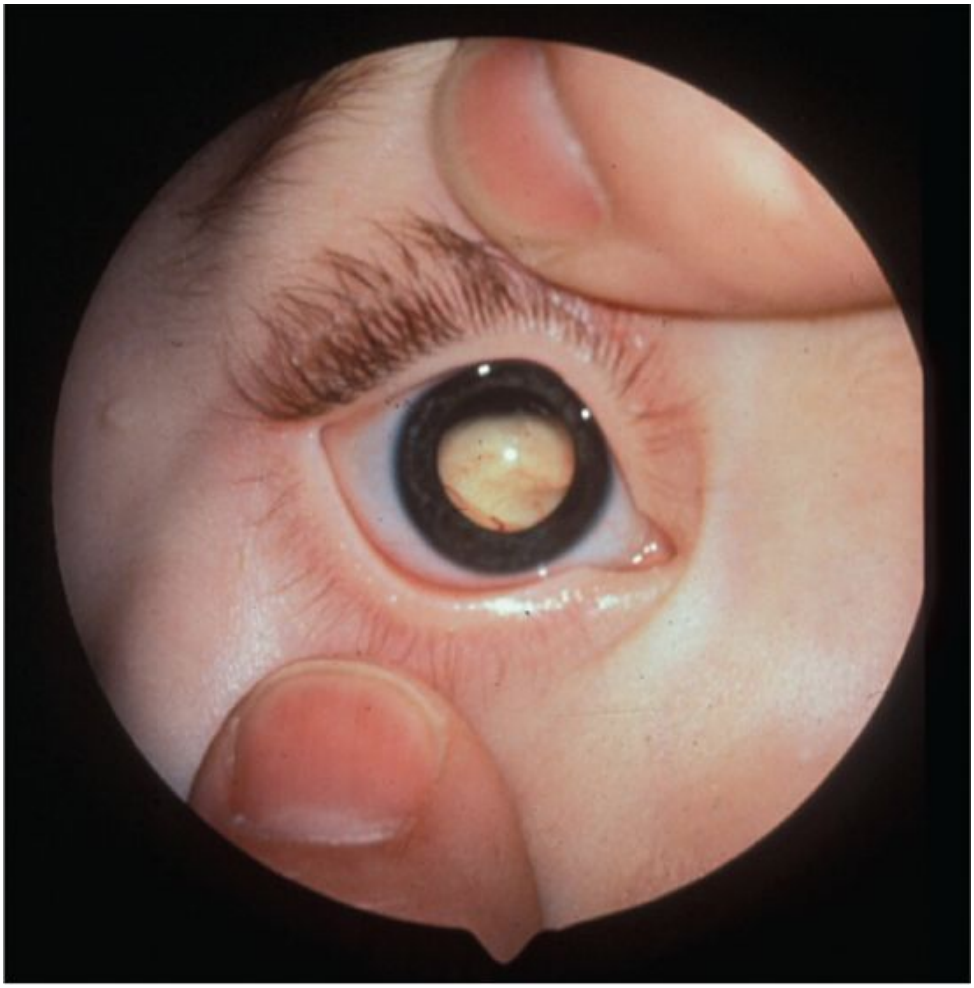
A black-and-white image of a nascent retinal tumor, growing within the layers named in Part A but also with an N F L layer above the G C L layer.

(B)



A color photo of a cross-sectioned eyeball in side view, showing a massive retinoblastoma, looking like a lump of cooked egg white in the back of the eyeball that has displaced the retina forward and has also caused thickening of the optic nerve that extends out the back of the eyeball.

(C)



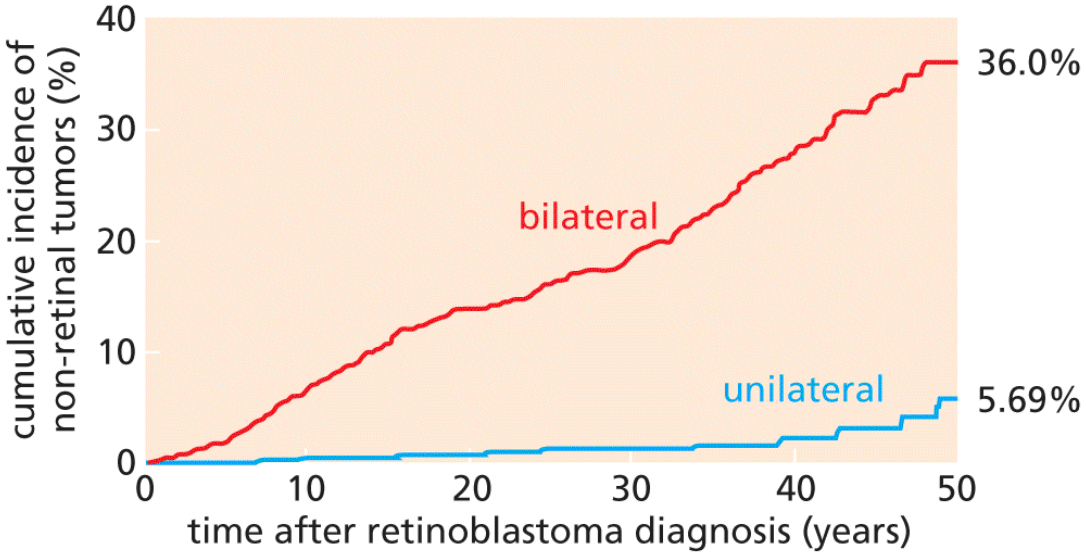
A frontal photograph of the eye of a living person suffering from a retinoblastoma. The highly dilated pupil appears shiny pale yellow instead of being dark.

(D)

Figure 7.2 Pediatric retinoblastomas Although the *Rb* gene regulates cell proliferation in most cell types throughout the body, inactivation of this TSG leads preferentially to the formation of pediatric tumors in the retina—a small, highly specialized tissue (A). The tumors arise from a stem cell precursor of the cone cells. In this micrograph, which shows a cross section of the retina, the nuclei of the rods and cones (*red*) are located in the outer nuclear layer (ONL), and their cell bodies (*dark green*) extend downward toward the retinal pigmented epithelium (RPE). Closer to the front of the eye are the outer plexiform layer (OPL), inner nuclear layer (INL), inner plexiform layer (IPL), and ganglion cell layer (GCL). (B) Created using Fourier domain optical coherence tomography, this image shows a nascent retinoblastoma in the eye of an $Rb^{+/-}$ infant. The

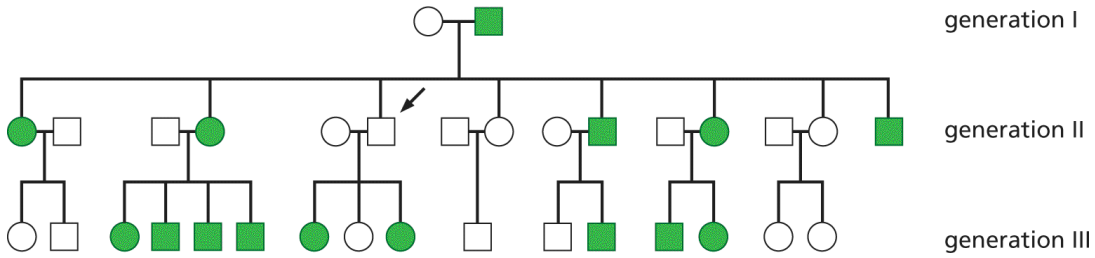
developing tumor appears to be emerging from the INL of the retina. NFL, nerve fiber layer. (C) A section of an eye in which a large retinoblastoma has developed and begun to invade the optic nerve. (D) A retinoblastoma may often initially present in the clinic as an opacity that obscures the retina. (A, from S.W. Wang et al., *Development* 129:467–477, 2002. With permission from the Company of Biologists. B, courtesy of A. Mallipatna, C. Vandenhoven, B.L. Gallie and E. Heon. C and D, courtesy of T.P. Dryja.)

A familial form of retinoblastoma occurs in children with a parent who also suffered from and was cured of the disease early in life. These children usually experience tumors arising in multiple sites in both eyes, a condition called *bilateral* retinoblastoma. Removal of these tumors does not protect these children from a greatly increased risk (more than 500 times above normal) of bone cancers (osteosarcomas) during adolescence and an elevated susceptibility to developing yet other, nonretinal tumors later in life (**Figure 7.3A**). Those who survive these tumors and grow to adulthood are usually able to reproduce; in half of their offspring, the familial form of retinoblastoma again rears its head (Figure 7.3B).



A line graph with two lines, with time after retinoblastoma diagnosis on the horizontal axis and cumulative incidence of non-retinal tumors in percent on the vertical axis. The line for unilateral rises very slowly for 40 years and then somewhat faster for 10 years to end at 5.69 percent after 50 years. The line for bilateral rises more steadily and faster, ending at 36.0 percent after 50 years.

(A)

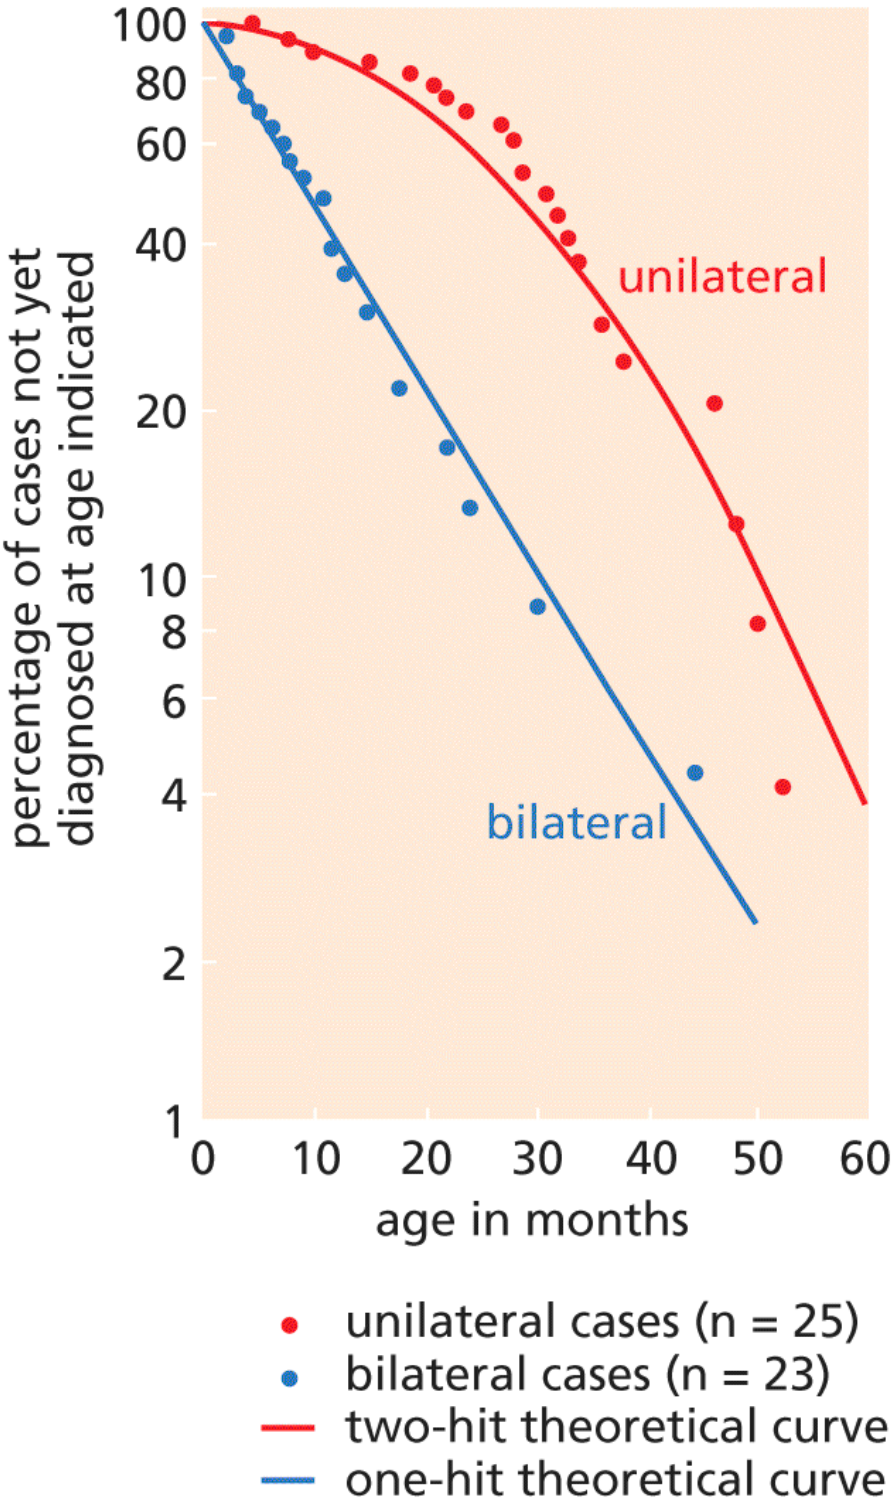


A family pedigree tree with three generations. he first generation is a single couple in which the male is affected by retinoblastoma. The second generation contains 3 affected and 2 unaffected female offspring and 1 unaffected and 2 affected male offspring. All married unaffected individuals except 1 affected male who did not marry. Of the females, only 2, both affected, passed the condition on to the third generation, and each of these two passed the condition on to all their offspring. Both married males passed the condition on to some of their offspring but not all, even though one of the married males did not manifest the condition himself.

(B)

Figure 7.3 Unilateral versus bilateral retinoblastoma (A) This graph shows the clinical courses of 1601 retinoblastoma patients who had been diagnosed between 1914 and 1984. Children diagnosed with bilateral tumors—those with familial retinoblastoma (*red line*)—have a dramatically higher risk of subsequently developing tumors in a variety of organ sites than those with unilateral tumors, who most often have the sporadic form of the disease (*blue line*). (A portion of this elevated risk is attributable to tumors that arose in the vicinity of the eyes because of the *radiotherapy* that was used to eliminate the retinoblastomas when these individuals were young.) (B) This pedigree shows multiple generations of a family with familial retinoblastoma. Males (*squares*), females (*circles*), affected individuals (*green*), unaffected individuals (*hollow shapes*). In one lineage, tumor development skipped a generation (*arrow*); this represents an example of *incomplete penetrance*, in which an individual carrying the mutant allele fails, for complex biological reasons, to develop retinoblastoma. (We can conclude that the indicated man carried the mutant allele because two of his daughters developed the disease.) Multi-generation pedigrees like this one were rarely observed before the advent of modern medicine, which allowed affected children to be cured of the disease, reach reproductive age, and transmit mutant alleles to the next generation. (A, from R.A. Kleinerman et al., *J. Clin. Oncol.* 23:2272–2279, 2005. With permission from the American Society of Clinical Oncology. B, courtesy of T.P. Dryja.)

Upon studying the kinetics with which retinal tumors appeared in children affected by both forms of the disease, Alfred Knudson concluded in 1971 that the rate of appearance of familial tumors was consistent with a single random event, whereas the sporadic tumors behaved as if two random events were required for their formation. These postulates have become known as Knudson's "one-hit" and "two-hit" hypotheses (**Figure 7.4**).

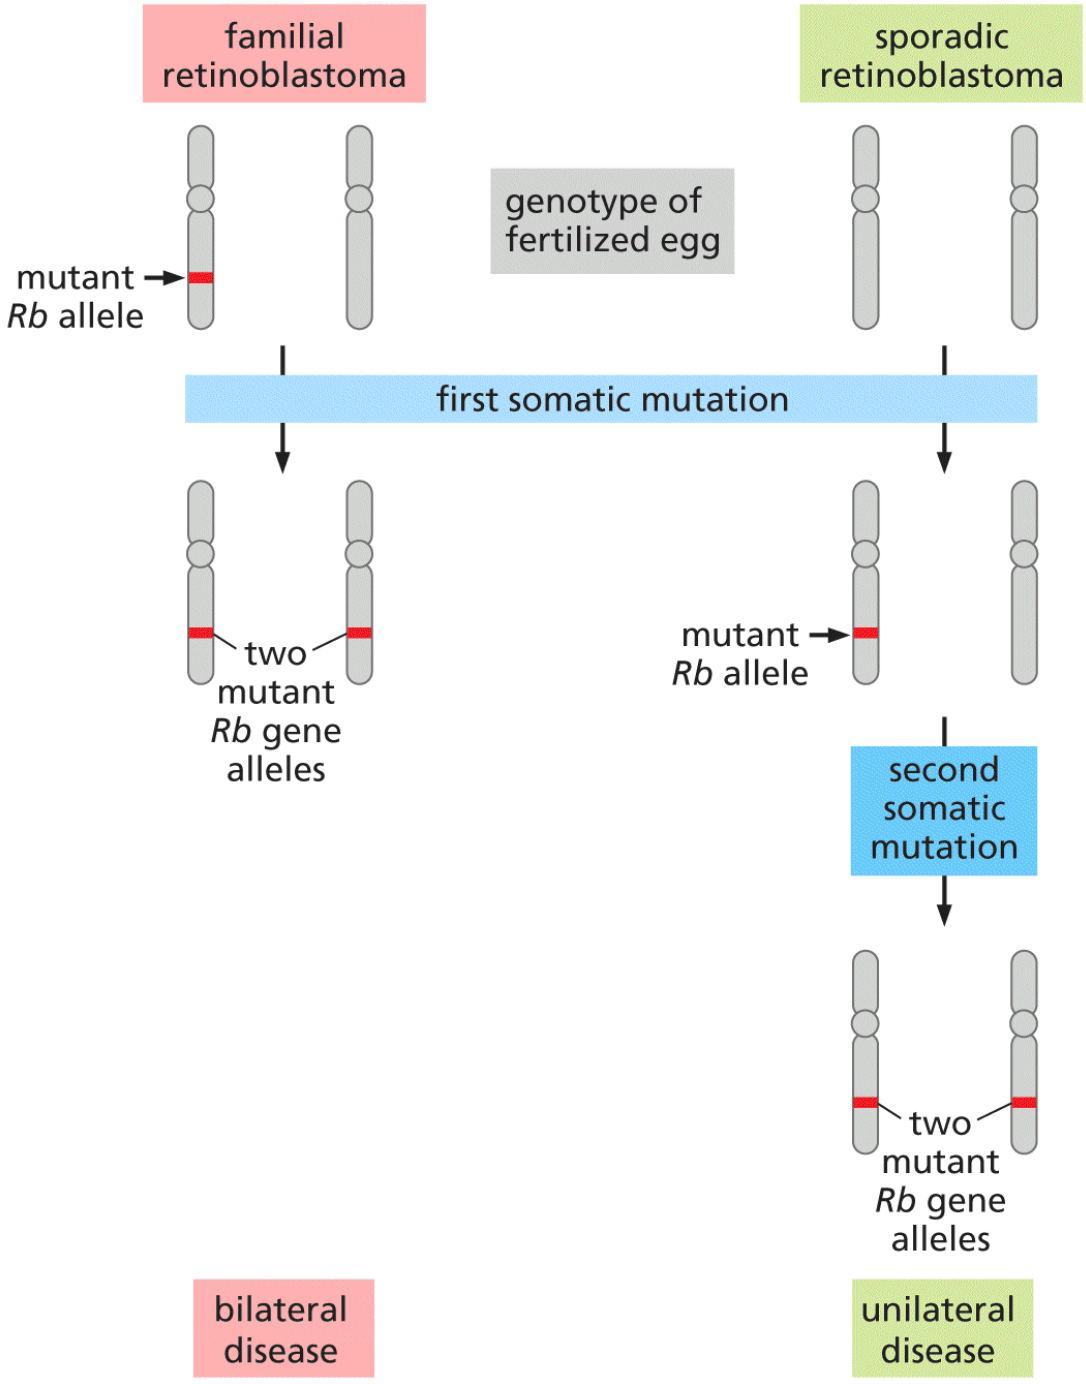


A line graph with two lines, with age on the horizontal axis and percentage of cases not yet diagnosed at age indicated on the vertical axis. The vertical scale is logarithmic, with 100 percent at the top and 10 percent halfway up. The so-called one-hit theoretical curve for bilateral retinoblastoma is a straight line sloping

steeply downward, from 100 percent at age 0 to about 20 percent at 20 months, to just over 2 percent at age 50 months. The two-hit curve for unilateral retinoblastoma is fairly level at first, so that at 20 months over 60 percent of cases are still undiagnosed. The curve bends downward, however, so that at 60 months only about 4 percent of cases remain undiagnosed. Real-world data points–23 for bilateral and 25 for unilateral–fit the theoretical curves fairly closely.

Figure 7.4 Kinetics of appearance of unilateral and bilateral retinoblastomas in children Knudson calculated that the bilateral tumors arose with one-hit kinetics (*blue*), whereas the unilateral tumors arose with two-hit kinetics (*blue red*). Each of these hits was presumed to represent a somatic mutation. It was realized only later that these two "hits" inactivated two copies of the same gene—*Rb*. (From A.G. Knudson Jr., *Proc. Natl. Acad. Sci. USA* 68:820–823, 1971. With permission from the author.)

The kinetics of tumor formation led to the deduction (or speculation, to be honest) that the development of retinoblastoma depended on the full loss of function of a TSG, which became known as the retinoblastoma gene or *Rb*. For children who inherit a defective allele of the *Rb* gene from one parent, a mutant version of the *Rb* gene will be present in all of the cells of the developing embryo, including the cells of the retina (**Figure 7.5**). Any one of these retinal cells needs to sustain only a single (somatic) mutation to inactivate the remaining wild-type allele; such cells, fully lacking this TSG function, could then spawn a retinoblastoma. Given the need for only one somatic mutational event and the large number of vulnerable retinal cells, children with the familial form of the disease typically develop multiple tumors usually affecting both eyes, that is, the bilateral form of the disease.



A diagram of the dynamics of retinoblastoma formation. In familial retinoblastoma, the genotype of a fertilized egg already contains a single mutant R b allele on one of the two chromosomes. Then a single somatic mutation is sufficient to introduce a mutant R b allele on the other chromosome. The typical consequence is bilateral disease. By contrast, in sporadic retinoblastoma, one somatic mutation produces a mutant R b allele on one of the two chromosomes,

and a second somatic mutation is required to produce a mutant R b allele on the other chromosome. The typical consequence is unilateral disease.

Figure 7.5 Dynamics of retinoblastoma formation In familial retinoblastoma (*left*), the fertilized egg from which a child develops carries one defective copy of the *Rb* gene; all of this child's retinal cells will therefore carry only a single functional *Rb* gene copy. If this surviving copy of the *Rb* gene is eliminated in a retinal cell by a somatic mutation, that particular cell will lack all *Rb* gene function and will be poised to proliferate into a mass of tumor cells. In sporadic retinoblastoma (*right*), the fertilized egg is genetically wild type at the *Rb* locus, and retinoblastoma development therefore will require two successive somatic mutations striking the two copies of the *Rb* gene carried by a lineage of retinal precursor cells. Because only a single somatic mutation is needed to eliminate *Rb* function in familial cases, multiple cells in both eyes are typically affected. However, the convergence of two somatic mutations—each a rare event—on a single cell, thus its descendants, is mathematically unlikely, explaining why children with sporadic retinoblastoma generally develop only a single tumor, that is, unilateral disease.

Of note, some children with no family history of the disease also develop bilateral retinoblastoma and other cancers characteristic of the familial syndrome. In these cases, a mutation must have arisen during the formation of a parental germ cell. The child would thus inherit a defective allele that would be present in all cells of the body and, like the children with the familial form of the disease, have a higher risk of tumor development.

The dynamics differ for children with the sporadic form of the disease. In these cases, both copies of the *Rb* gene must be inactivated independently, one after the other, before a retinal cell can reach the uncontrolled proliferation that eventually results in a tumor (see Figure 7.5). Because this chain of events is expected to be rare, affected children tend to have just a solitary tumor affecting one eye (unilateral retinoblastoma).

Strikingly, this depiction of *Rb* gene behavior corresponded exactly to the recessive attributes of TSGs whose existence had been postulated from results of the cell fusion studies (see Figure 7.1). Still, all this remained no more than an attractive hypothesis, because the *Rb* gene had not yet been cloned and no molecular evidence was available demonstrating that *Rb* gene copies had been rendered inactive by mutation. This behavior seemed to create a puzzle: although the inherited, TSG-inactivating mutations associated with retinoblastoma are *recessive* when it comes to the phenotype of a cell, the familial form of the disorder is passed from one generation to the next in a fashion that conforms to the behavior of a Mendelian *dominant* allele. This apparent conundrum is discussed in detail in **Sidebar 7.1**.

Sidebar 7.1 Mutant *Rb* alleles are both dominant and recessive

Although we have not yet presented the molecular underpinnings of retinoblastoma, our discussion has already raised an apparent contradiction. At the level of the whole organism, an individual who inherits a mutant, defective allele of *Rb* is almost certain to develop retinoblastoma at some point in childhood, usually multiple tumors affecting both eyes. Hence, the disease-causing *Rb* allele is considered to act dominantly at the level of the *whole organism*. However, if we were to study the behavior of the mutant allele *within a cell* from this individual, we would conclude that the mutant allele acts recessively, because a cell carrying a mutant and a wild-type *Rb* gene copy would behave normally. How can we explain this genetic paradox?

The dominant behavior of the mutant *Rb* allele at the organismic level is determined by the likelihood that one or more cells in the retina of a person who inherits a mutant allele of *Rb* (hence has the genotype $Rb^{+/-}$) will lose the remaining wild-type *Rb* allele and become $Rb^{-/-}$. The likelihood that such a loss will take place depends on the size of the target cell population in the developing retina. For example, if the average retina contains 5×10^6 cells that are susceptible to transformation, and if the rate of loss of the surviving wild-type allele in the cells of an $Rb^{+/-}$ heterozygous individual is 1 per 10^6 cells, then on average 5 cells in each of this individual's eyes will lose the surviving *Rb* allele and therefore all *Rb* gene function. Each of these $Rb^{-/-}$ cells will then be primed to spawn a retinoblastoma, producing multiple ($\sim$5) tumors in each eye. Hence the inheritance of a defective *Rb* allele, which produces heterozygous cells in both retinas, virtually preordains disease development.

Glossary

retinoblastoma
: Pediatric tumor of the oligopotential stem cells of the retina.

cryoablation
: The elimination of a tissue or a group of cells by directed localized freezing.

sporadic
: Describing a disease or condition that appears to occur randomly in a large population without any apparent inborn predisposition.

familial
: Referring to an organismic trait or a syndrome that is heritable and therefore found in clusters in certain families.

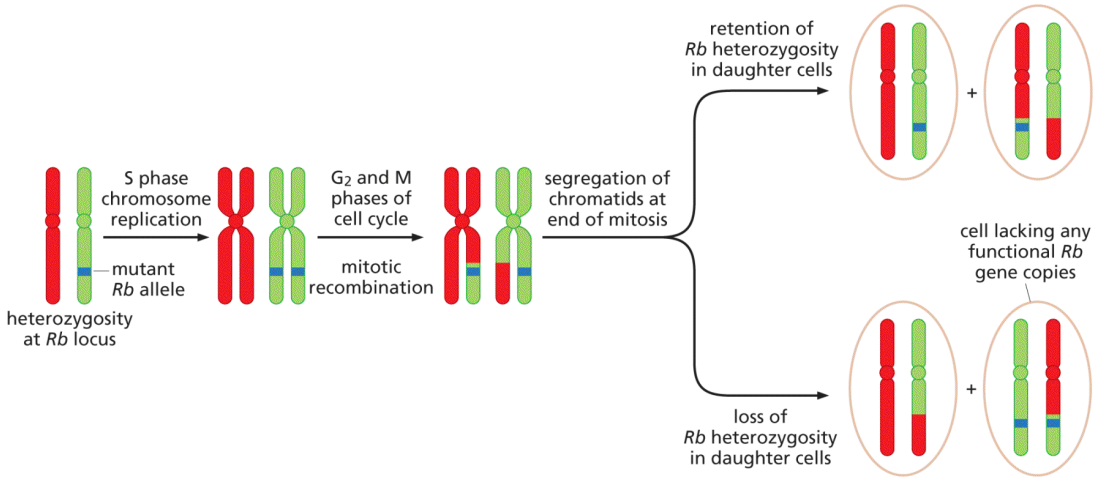
7.4 Incipient cancer cells eliminate wild-type copies of TSGs by a variety of mechanisms

The findings with retinoblastoma reinforced the notion that anti-proliferative genes, like the proposed *Rb* gene, might be important regulators of tumorigenesis. Still, for the sporadic form of the disease, the vexing question of how single cells could acquire the necessary “two hits” remained. A solution to this dilemma is provided by a broader look at how gene function can be lost.

Imagine a cell in which one of the two *Rb* gene copies had been inactivated by some type of mutational event that occurs with a frequency comparable to that associated with most mutational events—about 10^{-6} per cell generation. A cell with this mutation would now be in a heterozygous configuration, having one wild-type and one defective gene copy, that is, $Rb^{+/-}$. Because the mutant *Rb* allele is recessive at the cellular level, this heterozygous cell would continue to exhibit a wild-type phenotype. Now, what if the second, wild-type gene copy of *Rb* were inactivated by a mechanism that did not depend on its being struck directly by a second, independent, rare mutational event? Instead, perhaps some exchange of genetic information took place between homologous chromosomes, one of which carried the wild-type *Rb* allele, whereas the other carried the mutant, inactive allele. Such recombination takes place during meiosis, when sperm and eggs are formed. It can also occur in actively proliferating cells as they prepare their chromosomes for division—a form of genetic exchange called mitotic recombination.

In this fashion, the chromosomal arm carrying the wild-type *Rb* allele might be replaced with a chromosomal arm carrying the mutant allele derived from the paired homologous chromosome. Because this process depends upon reciprocal exchange of genetic information between chromosomal arms, the participating chromosomes would both remain full-length and therefore indistinguishable from their normal counterparts when viewed in the microscope. However, at the genetic and molecular level, one of the cells emerging from this recombination event would have replaced its remaining wild-type *Rb* allele and would therefore have become $Rb^{-/-}$. Importantly, such mitotic recombination is found to occur at a frequency of 10^{-5} to 10^{-4} per cell generation; it therefore provides a far more probable way for a cell to rid itself of the remaining wild-type copy of the *Rb* gene than direct mutational inactivation.

Prior to undergoing mitotic recombination, two homologous chromosomes (in the case of the *Rb* gene, the two human Chromosomes 13) will contain many different alleles, leading them to be heterozygous at many genetic loci (**Supplementary Sidebar 7.1**). However, following the mitotic recombination that leads to homozygosity at the *Rb* locus (with the resulting homologous chromosomes within a daughter cell possessing either an $Rb^{-/-}$ or an $Rb^{+/+}$ genotype), a number of the alleles of genes that are physically close to *Rb* on Chromosome 13 will be carried along during the exchange, and thus will also become homozygous. This genetic alteration of a gene or an extended chromosomal region is usually termed loss of heterozygosity, or simply LOH (**Figure 7.6**).

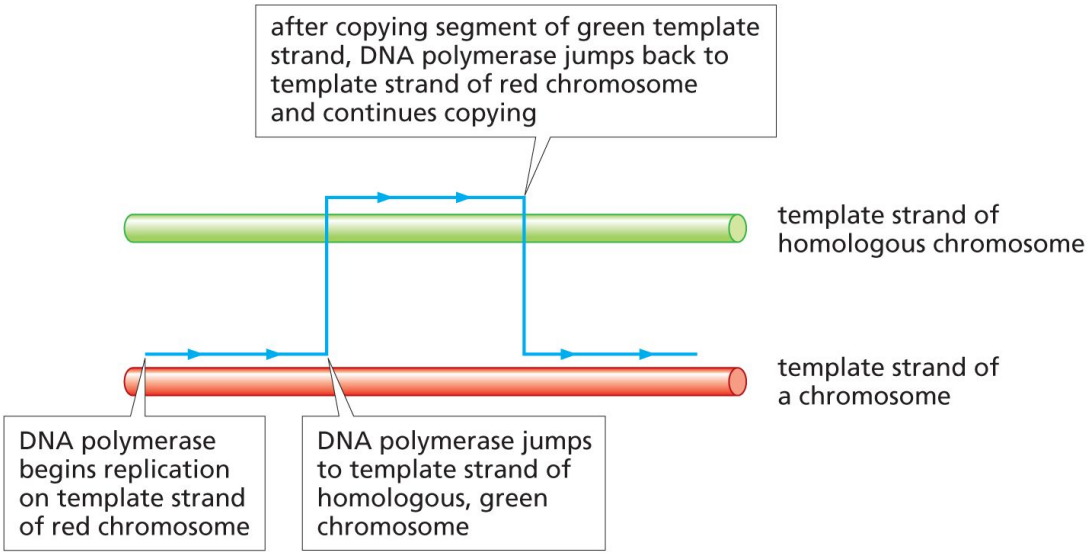


A diagram illustrating the elimination of wild-type R b gene copies. Initially, only one of two paired chromosomes has a mutant R b allele. This is heterozygosity at the R b locus. In S phase chromosome replication, each chromosome doubles up, so now there is an X-shaped chromosome with no mutant allele on either chromatid and an X-shaped chromosome with a mutant allele on each chromatid. Mitotic recombination during the G 2 and M phases of the cell cycle causes the two chromosomes to end up each with a wild-type allele one chromatid and a mutant allele on the other. Depending on how the four chromatids pair up during segregation at the end of mitosis, one of two outcomes is will result. First, there may be two pairs of chromosomes each with a wild-type allele on one chromosome and a mutant allele on the other. This is retention of R b heterozygosity in daughter cells. Second, one pair of chromosomes may have a mutant allele on each chromosome and the other pair only wild-type alleles. This is loss of R b heterozygosity in daughter cells.

Figure 7.6 Elimination of wild-type *Rb*gene copies Mitotic recombination can lead to loss of heterozygosity (LOH) of a gene such as *Rb*. During the G2 phase of the cell cycle, genetic material can be exchanged between the chromatids of two

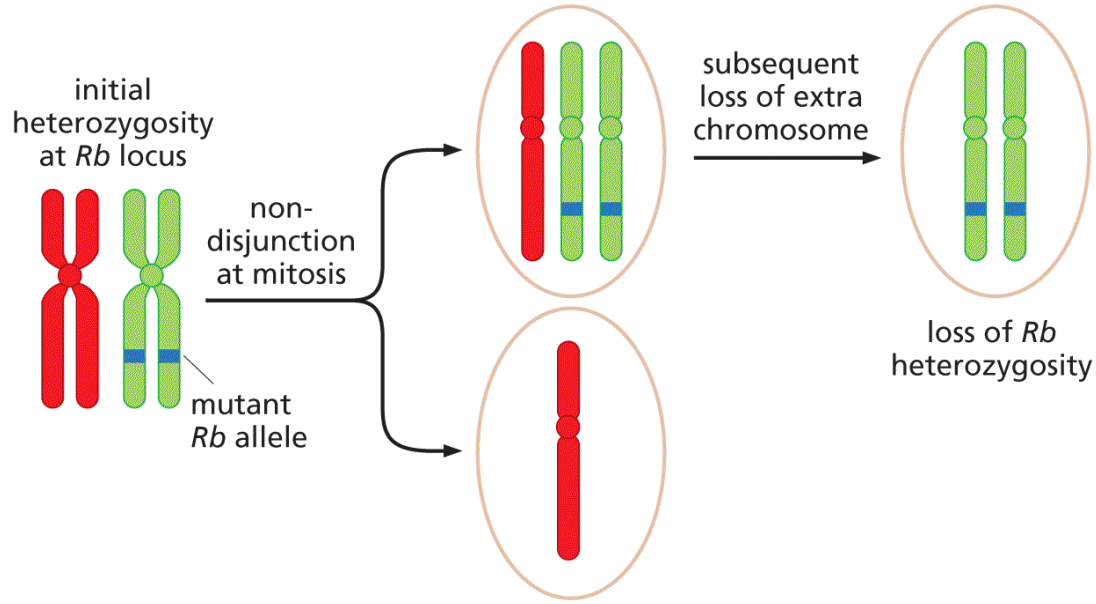
homologous chromosomes (for example, the two Chromosomes 13) through the process of genetic crossing over. The subsequent segregation of chromatids may yield a pair of daughter cells that both retain heterozygosity at the *Rb* locus. (The mutant *Rb* allele is indicated here as a *blue line*.) With equal probability, the process could alternatively yield two daughter cells that have undergone LOH at the *Rb* locus (and other nearby loci on the same chromosomal arm). One of these cells will be homozygous for the wild-type *Rb* gene, and the other will be homozygous for the mutant *Rb*.

LOH and the elimination of TSGs such as *Rb* can be achieved in many other ways. One of these derives from the process of gene conversion (**Figure 7.7A**). In this mechanism, the enzyme replicating a DNA strand on one chromosome temporarily switches templates and begins to replicate the DNA strand belonging to the homologous chromosome. After progressing some distance along this strand, it disentangles and reverts to using the template strand on which it started (a mechanism sometimes termed copy choice). In this manner, this newly synthesized strand of DNA will now contain DNA sequences identical to a stretch on the homologous chromosome, again resulting in LOH. Such gene conversion is known to occur even more frequently per cell generation than mitotic recombination.



A template strand of a chromosome is shown in red and a template strand of a homologous chromosome is shown in green. D N A polymerase begins replication on the red template strand. Then D N A polymerase jumps to the green, homologous template strand. After copying a segment of the green strand, D N A polymerase jumps back to the red template strand and continues copying.

(A)



A diagram that begins with two X-shaped chromosomes after S phase chromosome replication, one of which has the mutant R b allele on both chromatids. Following non-disjunction at mitosis, one of the daughter cells ends up with three chromatids instead of two, including both chromatids with the mutant alleles. The other daughter cell receives just one chromatid. If the daughter cell with three chromosomes loses the one without the mutation, it is left with two chromosomes that both have the mutation. Then loss of R b heterozygosity has occurred.

(B)

Figure 7.7 Loss of heterozygosity via gene conversion and chromosomal nondisjunction (A) During the process of gene conversion, a DNA polymerase initially begins to use a DNA strand on one chromosome (*red*) as a template for the synthesis of a new daughter strand (*blue*). After advancing some distance down this template strand, the polymerase jumps to the other (homologous) chromosome (*green*) and uses one of its strands as a template for further elongation of the nascent daughter strand. After progressing some distance down this strand, the polymerase may jump back to the originally used template strand and continue replication. In this manner, a mutant TSG allele, such as a mutant allele of *Rb*, may be transmitted from one chromosome (*green*) to its homolog (*red*), replacing the wild-type TSG allele that was previously residing there. (B) LOH can occur through the mis-segregation of chromosomes during mitosis. When such chromosomal nondisjunction takes place, one daughter cell will retain

both chromatids of a chromosome rather than the usual allotment of a single chromatid. The resulting triploidy of this chromosome in one daughter cell (*top*) may be disadvantageous, so descendants of this cell may shed an extra chromosome and revert to a diploid state. Because the chromosome to be lost will likely be selected at random, this reversion to diploidy may result in homozygosity for the Rb^{-} chromosome and loss of the wild-type allele (carried by the *red* chromosome).

LOH can also be achieved by large chromosomal deletions or by simply breaking off and discarding an entire chromosomal region without replacing it with a copy derived from the other homologous chromosome. These events result in hemizygosity of the chromosomal region, in which now all the genes on this chromosomal arm or segment are present in only a single copy rather than the usual two copies per cell. (Cells can survive with only one copy of certain chromosomal regions, but the loss of a single copy of other chromosomal regions seems to put cells at a distinct biological disadvantage.) Such hemizygosity is counted as an LOH, because only one allelic version of a gene in this chromosomal region can be detected.

In many tumors, LOH is achieved through the loss of an entire chromosome as a result of inaccurate chromosomal segregation at mitosis, a process called nondisjunction (Figure 7.7B). In the descendant cell that incorrectly receives three chromosomes, one may subsequently be shed, leaving two identical copies of one of the homologous chromosomes behind.

A detailed examination of chromosomal complements in human colon carcinoma cells has shown that, at least in these cancers, LOH is frequently achieved via genetic alterations that change the overall structure of chromosomes—an event that can be observed in the karyotype of the affected cells. Many of these events appear to be translocations, in that they involve recombination between chromosomal arms on nonhomologous chromosomes. Such recombination events might be triggered by double-stranded DNA breaks followed by fusion of the resulting ends with DNA sequences originating in other chromosomes. In this fashion, some genetic regions may be duplicated and others lost altogether. In Chapter 10 (see Section 10.4) we will discuss in greater detail one specific molecular mechanism in which such nonhomologous recombination events may occur during the development of a tumor.

Because LOH is thought to occur at a far higher frequency than mutational alteration of genes in cells that are $Rb^{+/-}$, the second, surviving wild-type copy of the *Rb* gene would be far more likely to be lost through LOH than through a mutation directly striking this gene copy (**Supplementary Sidebar 7.2**). Consequently, most retinoblastoma tumor cells would be predicted to show LOH at the *Rb* locus and at genetic markers that reside nearby on Chromosome 13; conversely, the cells in only a

small minority of tumors would be predicted to carry two distinct mutant alleles of *Rb*, each inactivated by an independent mutational event.

OceanofPDF.com

Glossary

mitotic recombination
: Recombination between homologous chromosomal arms occurring during somatic cell proliferation, often during the G2 phase of the cell cycle (rather than during mitosis).

loss of heterozygosity
: A genetic event in which one of two alleles at a heterozygous locus is lost; the lost allele may simply be discarded or be replaced with a duplicated copy of the surviving allele. *See also* **allelic deletion**.

gene conversion
: Process whereby the genetic information on one chromosome is transferred to the homologous chromosome without genetic recombination or crossing over occurring between the two chromosomes.

copy choice
: Genetic recombination mechanism whereby, during the replication of DNA on one chromosome, the replication machinery switches to using the DNA sequences on another chromosome as template.

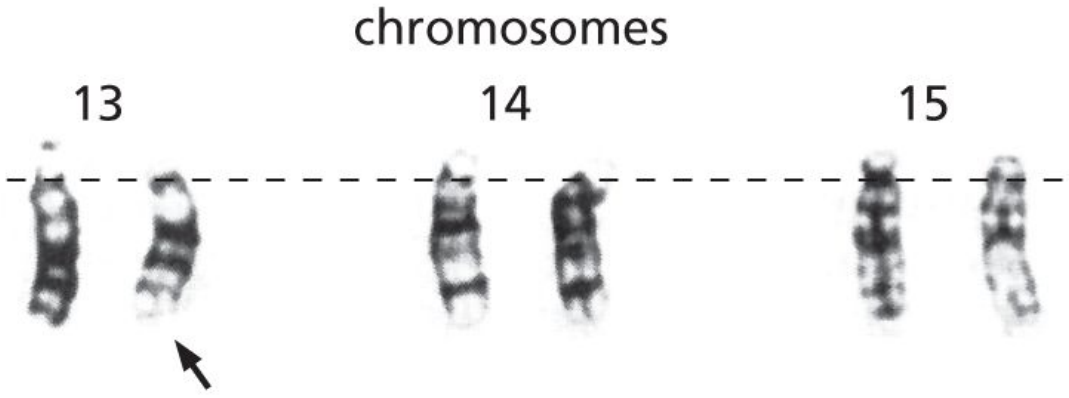
hemizygosity
: Presence of only one copy of an autosomal gene per cell.

nondisjunction
: (1) Failure of two chromatids to separate from one another during mitosis or two homologous chromosomes to separate from one another during meiosis. (2) State created by this failure of separation.

OceanofPDF.com

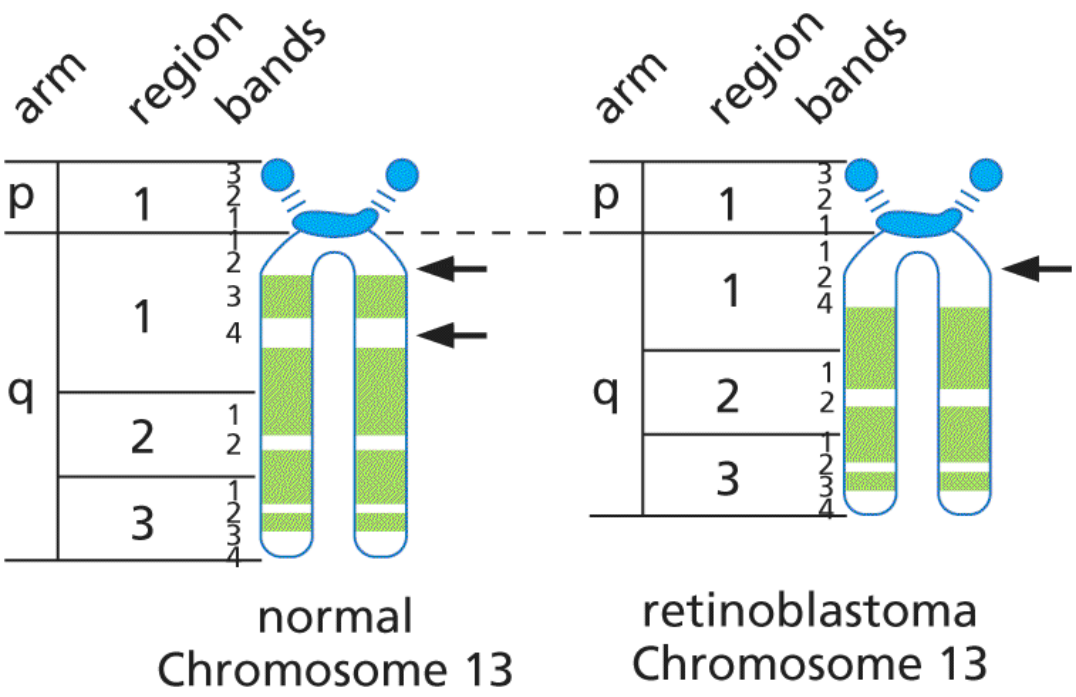
7.5 The Rb gene often undergoes loss of heterozygosity in tumors

In 1978, the chromosomal localization of the *Rb* gene was determined by examining the chromosomes present in retinoblastomas. In a small number of retinal tumors, careful analysis of chromosomal karyotypes (see Sidebar 1.2) revealed interstitial deletions within the long arm (q) of Chromosome 13. Even though each of these deletions began and ended at different sites within this chromosomal arm, they shared in common the loss of chromosomal material in the 4th band within the 1st region of this chromosomal arm, that is, 13q14 (**Figure 7.8**). These interstitial deletions eliminated many hundreds, often thousands, of kilobases of DNA, indicating that a number of genes in this region had been jettisoned simultaneously by the developing retinal tumor cells. These changes involved the *loss* of genetic information, providing evidence that the *Rb* gene, which was imagined to lie somewhere in this chromosomal region, had been discarded—precisely the outcome predicted by the tumor suppressor gene theory. (Such large-scale deletions are actually rare. In most retinoblastomas, the mutations that knock out the *Rb* gene affect far smaller segments of chromosomal DNA and are therefore submicroscopic, that is, invisible upon microscopic analysis of metaphase chromosome spreads.)



Human chromosome pairs 13, 14 and 15, stained. They look like maggots with irregular dark banding. In pair 13, the right chromosome is shorter than the left one and is missing a dark band.

(A)



A diagram showing the precise difference between normal Chromosome 13 and retinoblastoma Chromosome 13. On both chromatids, the normal chromosome has bands 3, 2 and 1 in region 1 of the short p arm. In the long q arm, it has bands 1 through 4 in region 1, bands 1 and 2 in region 2, and bands 1 through 4 in region 3. The retinoblastoma chromosome is missing band 3 in q arm region 1.

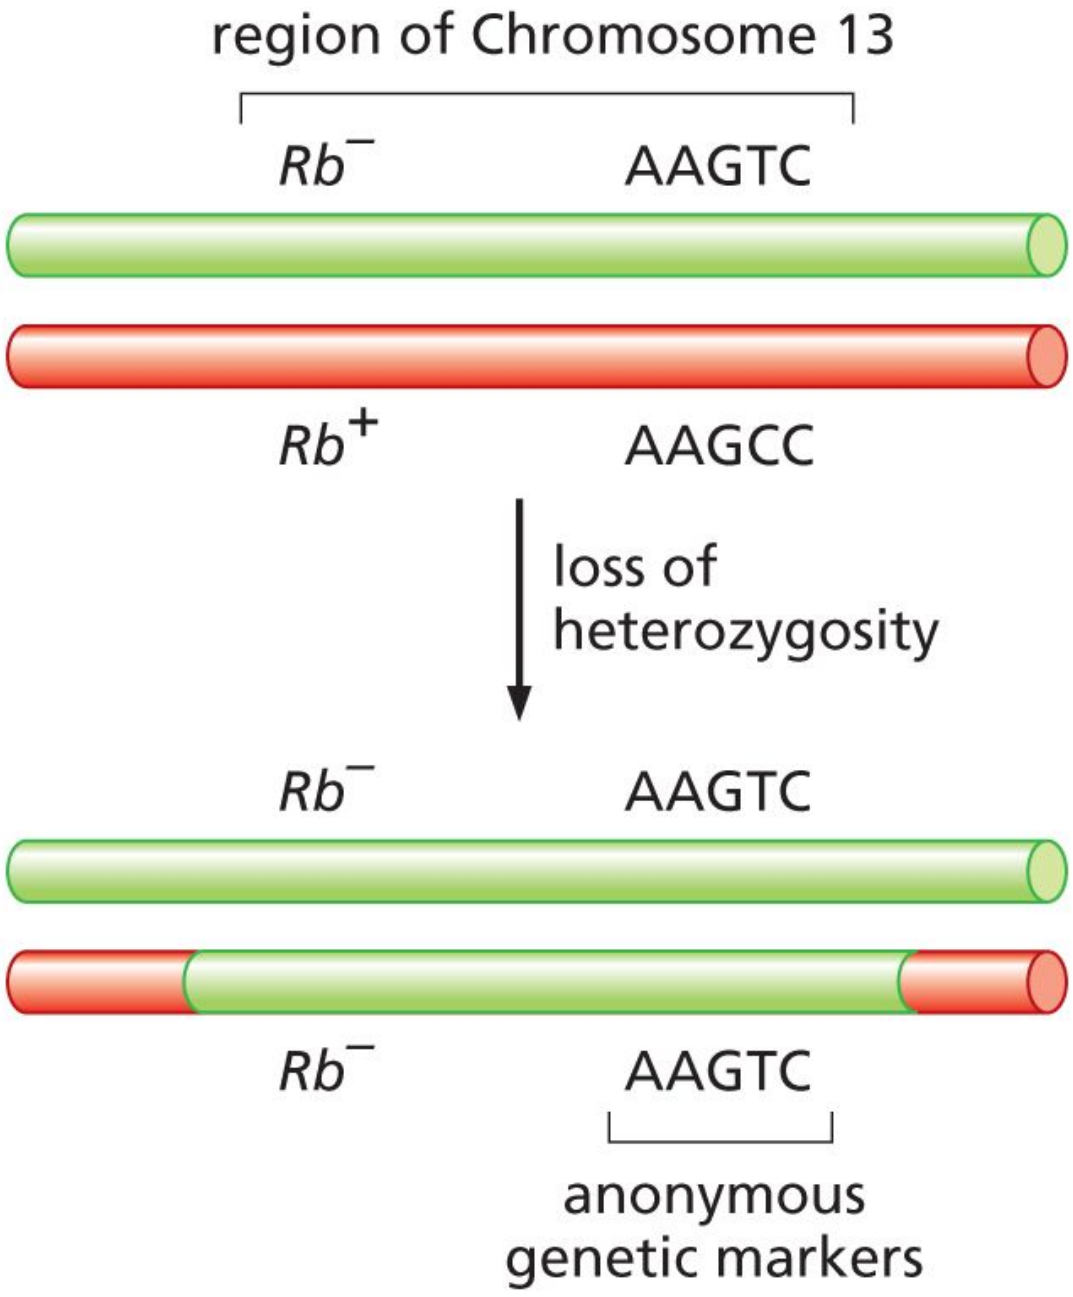
(B)

Figure 7.8 Chromosomal localization of the *Rb* locus (A) The characteristic darkly staining bands of each human chromosome delineate that chromosome's specific subregions. In this case, careful study of the karyotype of retinoblastoma cells, performed on the condensed mitotic chromosomes, revealed a deletion in the long arm (q) of Chromosome 13 in a 6-year-old child with retinoblastoma (*arrow*). Note that while the loss of the darkly staining band at 13q13 (*green*) is easily observed, a significant portion of 13q14 (where *Rb* is present) is also lost. For comparison, Chromosomes 14 and 15 in the same cell appeared normal. (B) Careful cytogenetic analysis revealed that the deletion was localized between bands 13q12 and 13q14, that is, between the 2nd and 4th bands of the 1st region of the long arm of Chromosome 13. (A, from U. Francke, *Cytogenet. Cell Genet.* 16:131–134, 1976. With permission from Karger.)

Through good fortune, a second gene lying in the 13q14 chromosomal region had already been reasonably well characterized. This gene, which encodes the enzyme esterase D, is represented in the human gene pool by two distinct alleles whose protein products migrate at different rates in gel electrophoresis. The esterase D locus thus presented geneticists with a golden opportunity to test the LOH theory. Recall that when LOH occurs, an entire chromosomal region is usually affected. Because the esterase D locus had been mapped close to the *Rb* gene locus on the long arm of Chromosome 13, if the *Rb* locus suffered LOH during tumor development, then the esterase D locus should frequently suffer the same fate. In effect, the esterase D locus could act as a surrogate marker for the still-mysterious, yet-to-be-cloned *Rb* gene.

Indeed, when researchers scrutinized the cells of several children afflicted with retinoblastoma who were born heterozygous at the esterase D locus (having inherited two distinct esterase D alleles from their parents), they found that their tumor cells had lost the protein product of one esterase D allele and thus must have undergone LOH. This finding suggested that the closely linked *Rb* gene had also undergone LOH. Such a change conformed to the theorized behavior ascribed to a growth-suppressing gene, both of whose wild-type alleles needed to be jettisoned before a cell could proliferate uncontrollably.

In a more general sense, the swapping of information between two chromosomes was likely to involve not only the *Rb* gene but also, as argued above, a large number of genes and genetic markers flanking the *Rb* locus on both sides. Such genetic markers might be short nucleotide base sequences that are not themselves components of any gene. For example, a genetic marker sequence in a neighboring region of Chromosome 13 that was initially AAGCC/AAGTC (hence heterozygous) might now become either AAGCC/AAGCC or AAGTC/AAGTC (and therefore homozygous; **Figure 7.9**). Like the esterase D gene, this neighboring oligonucleotide segment has been “carried along for the ride” with the nearby *Rb* gene during the swapping of sequences between the two homologous chromosomes. Indeed, precisely this type of analysis was performed in 1982, and the results reinforced the conclusion reached from analysis of the esterase D locus. Note, by the way, that such genetic marker sequences could lie many kilobases distant from the *Rb* locus in an intergenic region of Chromosome 13q14. Because they are not known to be associated with any biological function, these marker sequences are termed anonymous, and their conversion from a heterozygous to a homozygous configuration needs to be determined by nucleotide sequencing or by hybridization with an appropriate sequence-specific DNA probe (see **Supplementary Sidebar 7.1**).

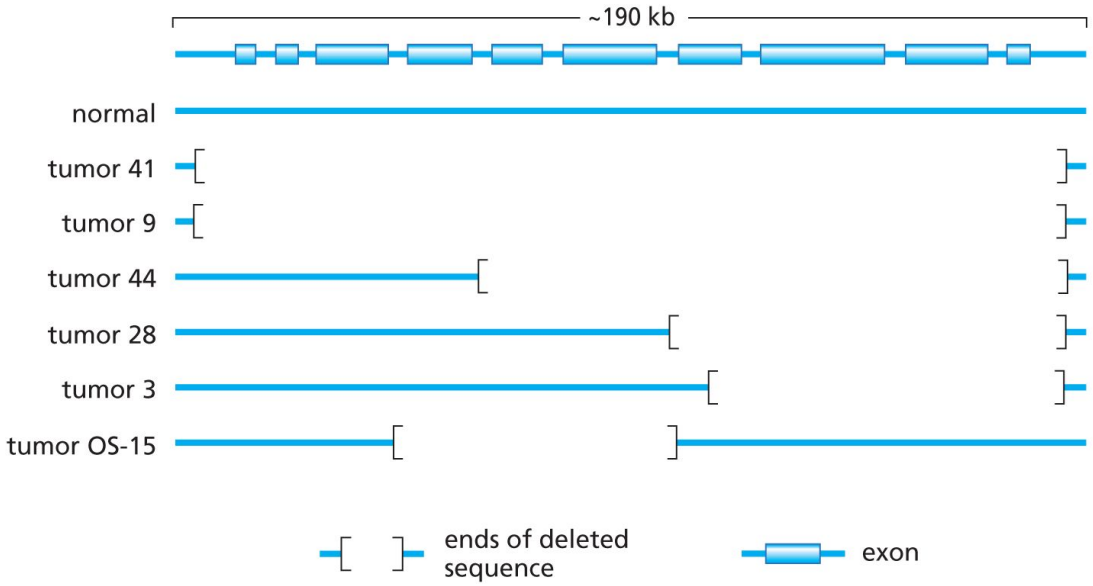


An illustration of tracking loss of R b heterozygosity. Initially, one copy of chromosome 13 is R b positive and in the same segment there is a base sequence A A G C C, while the other copy is R b negative and the nearby base sequence is A A G T C. The base sequences are anonymous genetic markers. After loss of heterozygosity, both copies are R b negative and with base sequence is A A G T C.

Figure 7.9 Demonstrations of loss of heterozygosity at the *Rb* locus A genetic marker sequence, which is linked to the *Rb* locus but is not part of any known gene,

can also be used to follow changes in this chromosomal region. The pentanucleotide shown here may initially be in a heterozygous configuration (*top*) and during the process that leads to LOH at the *Rb* locus may also undergo LOH.

In 1986 the *Rb* gene was cloned with the aid of a DNA probe that recognized an anonymous genomic sequence that turned out to be located within the *Rb* gene itself. Additional DNA probes derived from different portions of the cloned gene revealed, as was previously speculated, that the *Rb* gene in retinoblastomas suffered mutations that resulted in its inactivation (**Figure 7.10**). In some retinoblastomas, these mutations involve large deletions within the *Rb* gene and its flanking DNA sequences. Analysis of the DNA from these tumors by Southern blotting (**Supplementary Sidebar 4.3**) revealed that the mutant *Rb* allele resulting from these deletions was usually present in homozygous configuration. This meant that after the creation of an inactive or null allele of *Rb* on one chromosome, the corresponding region on the other, homologous chromosome was discarded or replaced, leading to hemizygosity or LOH at this locus. These data directly validated many of the predictions of the theoretical models that had been proposed to explain how TSGs behave during the development of cancers.



Six mutations of the R b gene. The normal gene contains ten protein-coding segments containing a total of about 190 kilobases. In the tumor 41 and tumor 9 mutations, all ten segments are deleted. In the tumor 44 mutation, segments 5 through 10 are deleted. In the tumor 28 mutation, segments 7 through 10 are deleted. In the tumor 3 mutation, segments 8 through 10 are deleted, along with part of segment 7. In the tumor O S-15 mutation, segments 4 through 6 are deleted.

Figure 7.10 Mutations of the *Rb* gene A cloned *Rb* cDNA was used as a probe in a Southern blot analyses of genomic DNAs from a variety of retinoblastomas and an osteosarcoma. Shown are the 10 protein-coding segments (exons) of the *Rb* gene (*blue cylinders*). The normal version of the gene encompasses a chromosomal region of approximately 190 kb. However, analysis of a subset of retinoblastoma DNAs indicated that significant portions of this gene had undergone homozygous deletion (the segments within each pair of brackets). Thus, tumors 41 and 9 lost the entire *Rb* gene, apparently together with flanking chromosomal DNA segments on both sides. Tumors 44, 28, and 3 lost, to differing extents, the right half of the gene together with rightward-lying chromosomal segments. The fact that an osteosarcoma (OS-15) lost a portion of this gene that was contained entirely within the left and right boundaries of the gene argued strongly that this 190-kb chromosomal DNA segment, and not leftward- or rightward-lying DNA segments, was the repeated target of mutational inactivation occurring during the development of these tumors. (From S.H. Friend et al., *Nature* 323:643–646, 1986. With permission from Nature.)

As mentioned earlier, children who inherit a defective *Rb* gene copy are also predisposed to osteosarcomas (bone tumors) as adolescents. With an *Rb* gene probe in hand, it became possible to demonstrate that certain osteosarcomas also carried structurally altered *Rb* genes (see Figure 7.10). At the same time, these findings highlighted a puzzle that remains largely unsolved to this day: Why does inheritance of an inactive mutant gene such as *Rb*, which encodes a protein that operates in a wide variety of cell types and tissues throughout the body (as we will learn in Chapter 8), predispose individuals predominantly to retinal and bone tumors? Why are not all tissues at equal risk? One answer to this question is that mutation of *Rb* appears to be sufficient to initiate the development of tumors in the cells that give rise to retinoblastoma. In other tissues, multiple mutational events are required to form tumors (as we discuss in Chapter 11). Interestingly, we now know that *Rb* is widely inactivated in human cancers, although in each tumor it is typically mutated along with other unrelated genes located elsewhere in the genome. Thus, in such settings, *Rb* mutation is not sufficient, on its own, to trigger tumor development.

Glossary

interstitial deletion
: Genetic alteration, often observed through analysis of karyotype, that causes deletion of an internal segment of a chromosomal arm.

submicroscopic
: Too small to be seen through the light microscope.

surrogate marker
: A measurable parameter, often a diagnostic parameter, that serves to indicate the behavior of another process or agent whose behavior it parallels and reflects.

anonymous (marker)
: Referring to a segment of genomic DNA that is not affiliated with any known gene or biological function.

null allele
: An allele of a gene that lacks all normal functions of the gene. *See also* **hypomorphic**.

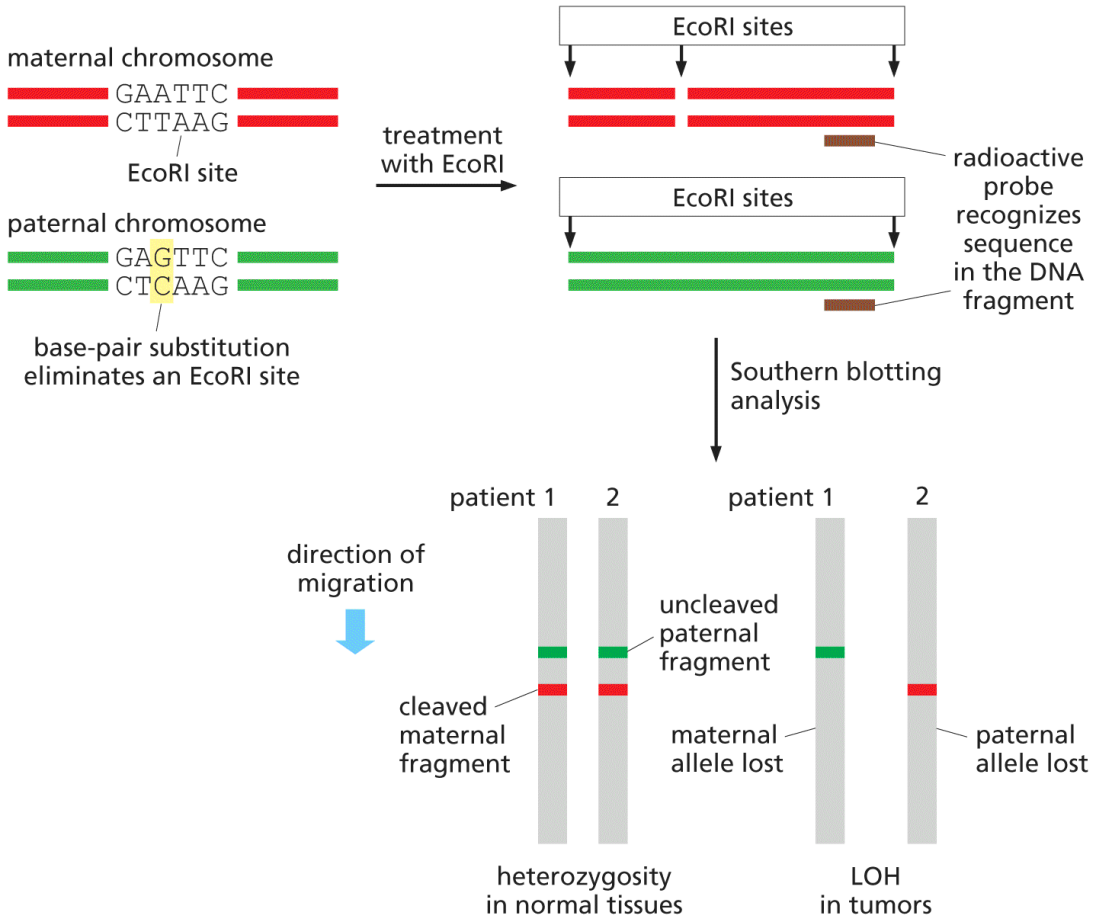
7.6 Loss-of-heterozygosity events can be used to find TSGs

Numerous TSGs that operate like the *Rb* gene were presumed to lie scattered around the human genome and to play a role in the pathogenesis of many types of human tumors. In the late 1980s, researchers interested in finding these genes were confronted with an experimental quandary: How could one find genes whose existence is most apparent when they are missing from a cell's genome? Dominantly acting oncogenes could be detected readily through their ability to transform normal cells in a transfection-focus assay (see Figure 4.1) or through their presence in a retrovirus genome or within a chromosomal segment that repeatedly underwent gene amplification in a number of independently arising tumors.

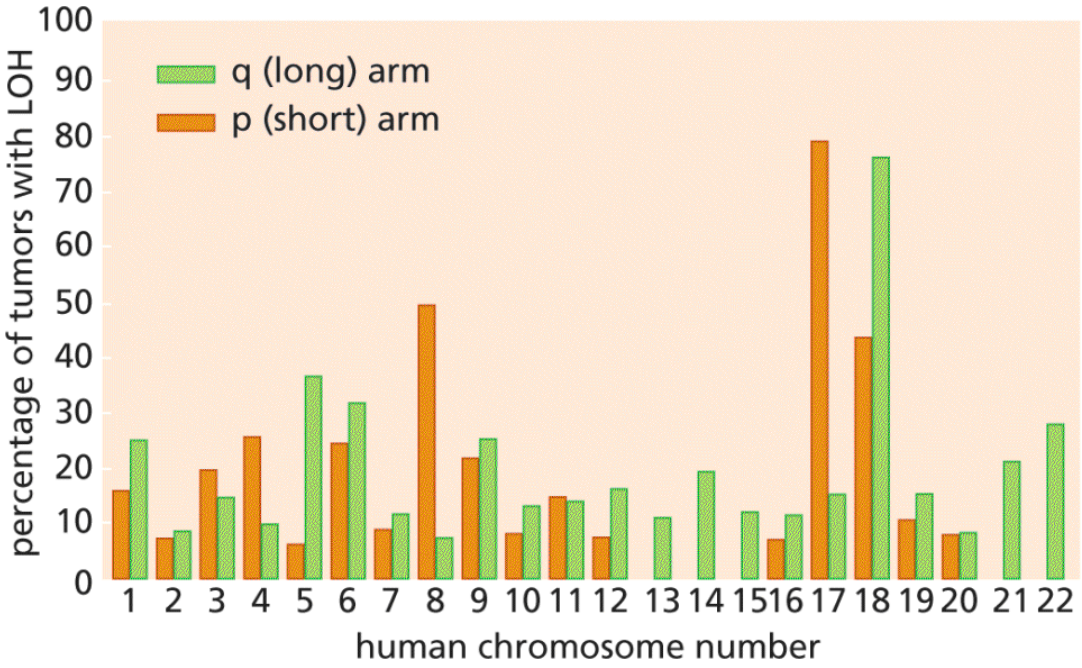
To locate TSGs, however, researchers needed a more generalizable strategy—one that did not depend on the chance observation of interstitial chromosomal deletions or the presence of a known gene (for example, esterase D) that, through good fortune, lay near a TSG on a chromosome.

The tendency of TSGs to undergo LOH during tumor development provided cancer researchers with a novel genetic strategy for tracking these genes down. Because the chromosomal region flanking a TSG often experienced LOH along with the TSG itself, investigators should be able to detect the existence of a still-unknown TSG by searching for anonymous genetic markers that repeatedly undergo LOH during the development of a specific type of human tumor. This strategy, which was used to follow the behavior of the *Rb* gene (see Figure 7.9), could be generalized by exploiting DNA segments that were mapped to sites throughout the human genome. Once again, these DNA segments had no obvious affiliations with specific genes. In some cases, one version of the segment contained a nucleotide sequence that could be recognized by a restriction enzyme, whereas another variant possessed a single base-pair substitution that eliminated this sequence, rendering the surrounding DNA segment resistant to cleavage (**Figure 7.11A**). Because such sequence variability occurs as a consequence of normal genetic variability in the human gene pool, such sites were said to represent polymorphic genetic markers (see Section 1.2). When the allelic versions of such polymorphic sequences either permit or disallow cleavage by a restriction enzyme, the marker is called a restriction fragment length polymorphism (RFLP).



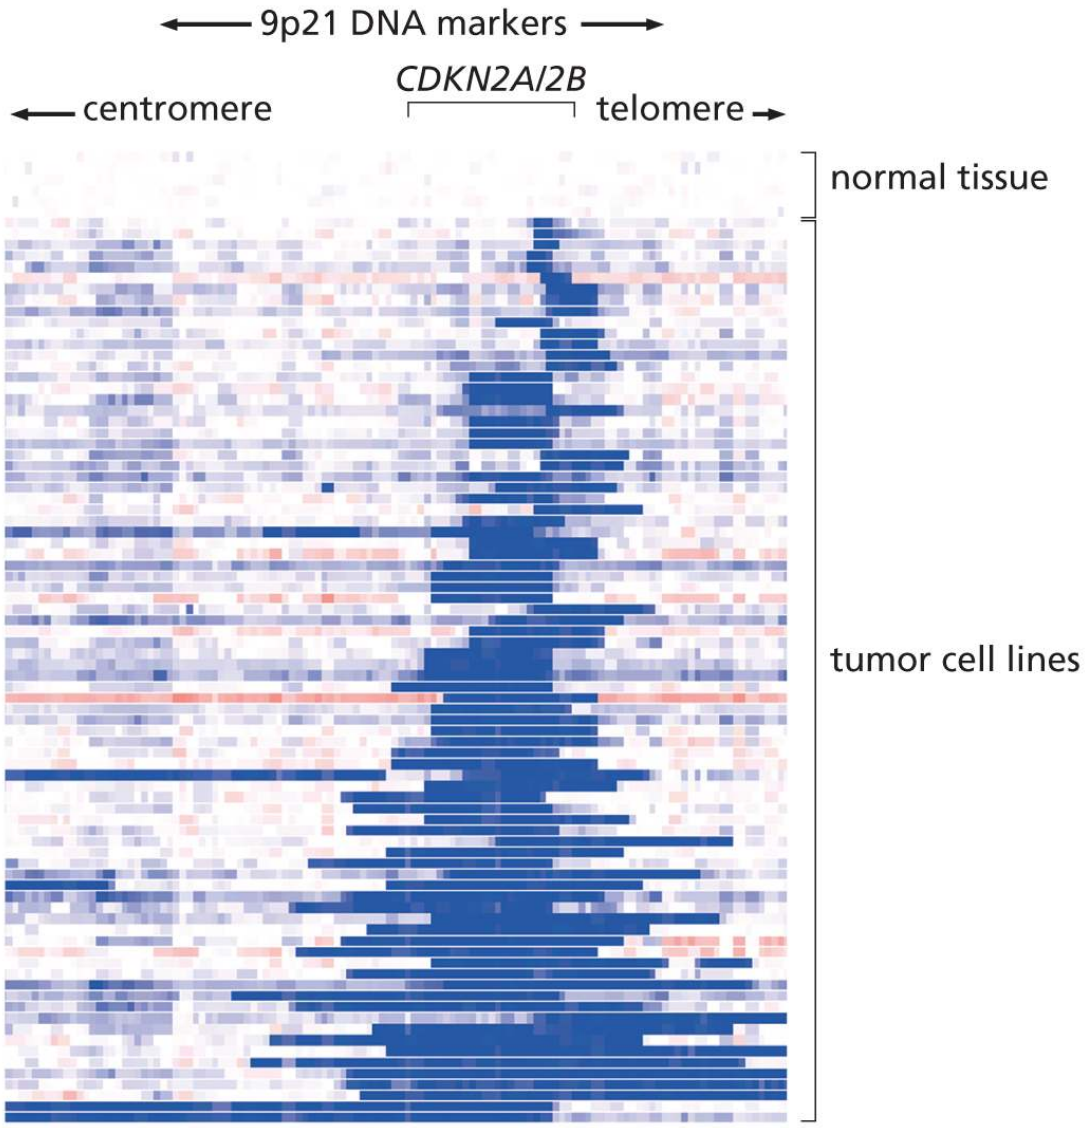
A maternal chromosome segment has an Eco R I site in the middle consisting of the base sequence G A A T T C on one strand and the paired sequence C T T A A G on the other. Also shown is a corresponding paternal chromosome segment in which the second A T pair has been replaced by G C. This base-pair substitution eliminates the middle Eco R I site. The two ends of each chromosome segment are also Eco R I sites. Treatment with Eco R I produces one long paternal segment and two shorter maternal segments. One end of the paternal segment and one end of one of the material segments contains a sequence that is recognized by a radioactive probe. When southern blotting analysis is performed on two cancer patients, heterozygosity in normal tissue results in display of both the cleaved maternal fragment and the uncleaved paternal fragment. L O H in tumors, by contrast, results in display of only the uncleaved paternal fragment in Patient 1 and only the cleaved maternal fragment in Patient 2. The other alleles have been lost.

(A)



A histogram with human chromosome number on the horizontal axis and percentage of tumors with L O H on the vertical axis. Over 70 percent of tumors have a mutation on the short p arm of chromosome 17, and over 70 percent of tumors have a mutation on the long q arm of chromosome 18. Chromosomes 13, 14, 15, 21 and 22 never have a mutation on the short arm. Other locations vary from 5 to 50 percent.

(B)



A map of deletions in various tumor cell lines, listed vertically. The horizontal axis represents 9 p 21 D N A markers between the centromere on the left and the telomere on the right. A section down the middle is labeled C D K N 2 A slash 2 B. This section contains dark blue bands that get increasingly wider toward the bottom of the map.

(C)

Figure 7.11 Localization of TSGs (A) Genetic markers that are defined by the presence or absence of a restriction endonuclease cleavage site can be used to analyze chromosomal regions. In this illustration, the DNA segment in the chromosome of maternal origin (*red*) can be cleaved by the enzyme EcoRI, while the homologous, paternally derived segment (*green*), contains a single base-pair

substitution that renders it resistant to cleavage. This variation represents a restriction fragment length polymorphism (RFLP), and a radioactive probe that recognizes the right end of both DNA fragments can be used in Southern blot analysis to determine whether cleavage has occurred (*below*). The presence or absence of a cleavage fragment makes it possible, in turn, to track the inheritance of DNA sequences that behave genetically like Mendelian alleles. In this example, the DNAs from the normal tissues of two cancer patients (1 and 2) both show heterozygosity in this chromosomal region. However, loss of heterozygosity (LOH) has occurred in their tumor DNAs, with patient 1 showing loss of the maternal allele and patient 2 shows loss of the paternal allele. ((B) RFLP analysis was used to survey the LOH in entire chromosomal arms in a series of human colon cancers. The long (q) and short (p) arms of the chromosomes are indicated by *green bars* and *orange bars*, respectively. The “allelic deletions” indicated on the ordinate are equivalent to LOH. Although these analyses were imprecise, because very few probes were available at the time to gauge the extent of LOH, Chromosomes 17 and 18 were nevertheless obvious targets of LOH and thus likely to harbor TSGs. Chromosome 8p is also a target of LOH, but its TSG has never been identified. Another TSG inactivated in almost all colorectal cancers, *Apc*, is located on Chromosome 5q. Because this gene is so large (creating a large target of random mutations), both copies are often lost through independent, random mutation, rather than mutation followed by LOH; thus, its importance in the development of colorectal cancer is underestimated in this analysis. The short arms of Chromosomes 13, 14, 15, 21, and 22 contain only ribosomal genes and thus were not included in this analysis. (C) The locations of deleted chromosomal segments reveal the locations of TSGs. Thus, another strategy for localizing and identifying TSGs depends on mapping overlapping regions of relatively small deletions that affect a chromosomal arm. In this analysis, DNAs of 80 tumor cell lines (arrayed top to bottom, names deleted) were analyzed for the presence or absence of sequences recognized by 250,000 probes, present at an average density of one per 12 kb across the genome. Short homozygous deletions (*dark blue bars*) frequently eliminate one or both copies of *CDKN2A* and *CDKN2B*, an adjacent pair of TSGs that map to Chromosome 9p21. In contrast, nearby chromosomal sequences to the right and left are rarely affected by either significant amplification (*light red squares*) or deletions (*light blue squares*). (B, from B. Vogelstein et al., *Science* 244:207–211, 1989. With permission from AAAS. C, from S.M. Rothenberg et al., *Cancer Res.* 70:2158–2164, 2010. With permission from American Association for Cancer Research.)

Cancer geneticists used RFLP markers to determine whether various chromosomal regions frequently underwent LOH during the development of certain types of tumors. Figure 7.11B shows the results of using RFLPs to search for regions of LOH arising in

a group of human colorectal tumors, that is, carcinomas of the colon and rectum. In this case, the long and short arms of most chromosomes were represented by at least one RFLP marker, allowing investigators to track their fate. The results indicate that the short (p) arm of Chromosome 17 and the long (q) arm of Chromosome 18 suffered unusually high rates of LOH in this series of tumors—rising far above the background level of the 15–20% LOH that befell most of the remaining chromosomal arms in the cells of these tumors. (This background level of LOH reveals that all chromosomal regions within developing tumors have some tendency to undergo LOH at a certain rate. However, if the LOH happens to occur in a region harboring a TSG, the proliferation or survival of the cells in which this has occurred may be favored, leading to high numbers of tumors carrying this particular LOH.) The fact that specific arms of Chromosomes 17 and 18 frequently underwent LOH in tumors provided strong evidence that both arms harbored still-unknown TSGs. Thus, this genetic localization provided the investigators with a clear indication of where in the genome they should search for the culprit TSGs.

Another strategy to identify regions of LOH and suspected TSGs depends on the detection of single-nucleotide polymorphisms (SNPs, pronounced “snips”) in normal and cancer cell genomes. These SNPs are detected by DNA sequencing or by other methods, such as using polymerase chain reaction (PCR) primers that are complementary to one or the other polymorphic allele (**Supplementary Sidebar 7.3**). Based on large-scale genome sequencing of the human population, we now know of more that 100 million SNPs in the human genome, which represent a significant fraction of the genetic variation that exists in our species.

Of course, these SNP markers are useful for LOH analyses only if a significant proportion of individuals are heterozygous at these marker loci in their normal tissues. Because about 1 in 10 known SNPs has an allele frequency of greater than 5% across human populations, the average person’s genome is likely to harbor a SNP marker in heterozygous configuration every few kilobases of DNA. Such greatly increased density, compared with that of the earlier RFLP markers, allows regions of LOH to be localized far more precisely to chromosomal segments that may contain a relatively small number of genes, greatly facilitating the identification of candidate TSGs within these regions. Nonetheless, even prior to the introduction of these and other more powerful mapping techniques, LOH analyses allowed the identification and subsequent cloning of more than 30 TSGs.

SNP-based analysis of collections of tumors has identified many regions of frequent deletion across cancer genomes, indicative of TSG loss. The fruits of one such study can be seen in Figure 7.11C, in which relatively small deletions of a region of human Chromosome 9 were frequently detected in the genomes of 80 cancer cell lines. The relatively short chromosomal DNA segment that was targeted, time after time, by these

deletions is known from other work to encode two well-studied TSGs, *CDKN2A*, and *CDKN2B*, which will be discussed in detail in Chapters 8 and 9.

In the current era of genomics, in which cancer cell genomes can be rapidly sequenced and compared with the genome sequences of normal tissues, the identification of candidate TSGs is more straightforward. Such sequencing studies not only reveal regions of chromosomal deletion or LOH, but they can be used to tentatively identify TSGs based on the observation of frequent loss-of-function mutations in these genes across multiple patients with a given cancer type (as discussed in Chapter 12). As an example, the connection to cancer of *Keap1*, a TSG that we will discuss shortly, was revealed by direct DNA sequencing.

Together, these various techniques have uncovered at least two hundred TSGs in the human genome. A representative handful of these TSGs, which have been found on almost every chromosome, is presented in **Table 7.1**. As shown, several of these TSGs are also responsible for important familial cancer syndromes through mutation in the germ line of affected individuals.

Table 7.1 Examples of human tumor suppressor genes

Name of gene	Chromosomal location	Familial cancer syndrome	Sporadic cancer	Function of gene product
CHD5	1p36.31	cutaneous melanoma	many types	histone reader, transcriptional inducer
FH	1q42.3	familial leiomyomatosis[a]	—	fumarate hydratase
BAP1	3p21.1	mesothelioma, melanoma	mesothelioma, uveal melanoma	ubiquitin hydrolase
RASSF1A	3p21.3	—	many types	multiple functions

Name of gene	Chromosomal location	Familial cancer syndrome	Sporadic cancer	Function of gene product
TGFB2	3p2.2	HNPCC	colon, gastric, pancreatic carcinomas	TGF-β receptor
VHL	3p25–26	von Hippel–Lindau syndrome	renal cell carcinoma	ubiquitylation of HIF
hCDC4	4q32	—	endometrial carcinoma	ubiquitin ligase
APC	5q21–22	familial adenomatous polyposis coli	colorectal, pancreatic, and stomach carcinomas; prostate carcinoma	β-catenin degradation
miR-124a[b]	8p23.1	—	many types	suppresses CDK6
p16^{INK4A}[c]	9p21	familial melanoma	many types	CDK inhibitor
p14^{ARF}[d]	9p21	—	all types	p53 stabilizer
PTC	9q22.3	nevoid basal cell carcinoma syndrome	medulloblastomas	receptor for hedgehog GF

Name of gene	Chromosomal location	Familial cancer syndrome	Sporadic cancer	Function of gene product
TSC1	9q34	tuberous sclerosis	—	inhibitor of mTOR[e]
PTEN[f]	10q23.3	Cowden's disease, breast, and gastrointestinal carcinomas	glioblastoma; prostate, breast, and thyroid carcinomas	PIP_3 phosphatase
WT1	11p13.5–6	Wilms tumor	Wilms tumor	TF
MEN1	11p13	multiple endocrine neoplasia	—	histone modification, transcriptional repressor
BWS/CDKN1C	11p15.5	Beckwith–Wiedemann syndrome	—	$p57^{Kip2}$ CDK inhibitor
CBL	11q23.3	juvenile myelomonocytic leukemia	adult myelomonocytic leukemia	SH2-containing ubiquitin ligase
RB	13q14.2	retinoblastoma, osteosarcoma	retinoblastoma; sarcomas; bladder, breast, esophageal, and lung carcinomas	transcriptional repression; control of E2Fs

Name of gene	Chromosomal location	Familial cancer syndrome	Sporadic cancer	Function of gene product
miR-15a/16-1	13q14.3	—	B-cell lymphoma	suppresses Bcl-2, Mcl-1, cyclin D1, Wnt3a
miR-127	14q32.31	—	many types	suppresses Bcl-6
TSC2	16p13.3	tuberous sclerosis	—	inhibitor of mTOR[e]
CBP	16p13.3	Rubinstein–Taybi syndrome	AML[g]	TF co-activator
CYLD	16q12–13	cylindromatosis	—	deubiquitinating enzyme
CDH1	16q22.1	familial gastric carcinoma	invasive cancers	cell–cell adhesion
BHD/FLCN	17p11.2	Birt–Hogg–Dube syndrome	kidney carcinomas, hamartomas	regulator of mTOR[e]
TP53	17p13.1	Li–Fraumeni syndrome	many types	TF
NF1	17q11.2	neurofibromatosis type 1	colon carcinoma, astrocytoma, acute	Ras-GAP

Name of gene	Chromosomal location	Familial cancer syndrome	Sporadic cancer	Function of gene product
			myelogenous leukemia	
DPC4[h]	18q21.1	juvenile polyposis	pancreatic and colon carcinomas	TGF-β TF
KEAP1	19p13.2	—	many types	suppresses anti-oxidant response
LKB1/STK11	19p13.3	Peutz–Jegher syndrome	hamartomatous colonic polyps	serine/threonine kinase
RUNX1	21q22.12	familial platelet disorder	AML	TF
SNF5 [i]	22q11.2	rhabdoid predisposition syndrome	malignant rhabdoid tumors	chromosome remodeling
NF2	22q12.2	neurofibroma-predisposition syndrome	schwannoma, meningioma; ependymoma	cytoskeleton–membrane linkage
WTX	Xq11.1	—	Wilms tumor	β-catenin degradation

Glossary

restriction fragment length polymorphism
: Variation in DNA sequence that can be detected through its effect of allowing or preventing cleavage of a chromosomal DNA segment by a restriction enzyme.

polymorphism
: A variant genetic allele or phenotype that does not appear to be associated with any pathology and, by implication, is a reflection of normal intraspecies variability and thus normal function.

colorectal
: Referring to the lower gastrointestinal tract including the colon and rectum.

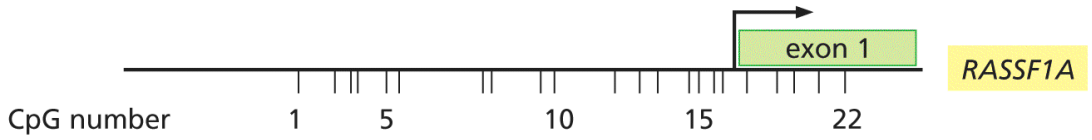
7.7 Promoter methylation represents an important mechanism for inactivating TSGs

DNA molecules can be altered covalently by the attachment of methyl groups to cytosine bases (as described in Section 1.8). In mammalian cells, this methylation is found only when cytosine bases are located in a position that is 5′ to guanosines, that is, in the sequence CpG. This modification is often termed “methylated CpG” (meCpG), even though only the cytosine is methylated. When CpG methylation occurs in the vicinity of a gene promoter, it can cause repression of transcription of the associated gene, and conversely, when methyl groups are removed, transcription of the gene is often de-repressed. The means by which this modification influences gene expression is an active area of research, but it appears that methylation attracts proteins that control the packaging of DNA (as discussed in Section 1.8). In any case, extensive research indicates that the methylation of CpGs and the accessibility of promoter DNA are as important as are mutations in shutting down TSGs.

During the development of all animal species, decisions concerning the transcriptional state of many genes are made early in embryogenesis. Once made, these decisions must be passed on to the descendant cells in various parts of the growing embryo. Because CpG methylation can be transmitted from cell to cell heritably (see Section 1.8), it represents a highly effective way to ensure that descendant cells, many cell generations removed from an early embryo, continue to respect and enforce the methylation decisions made by their embryonic ancestors.

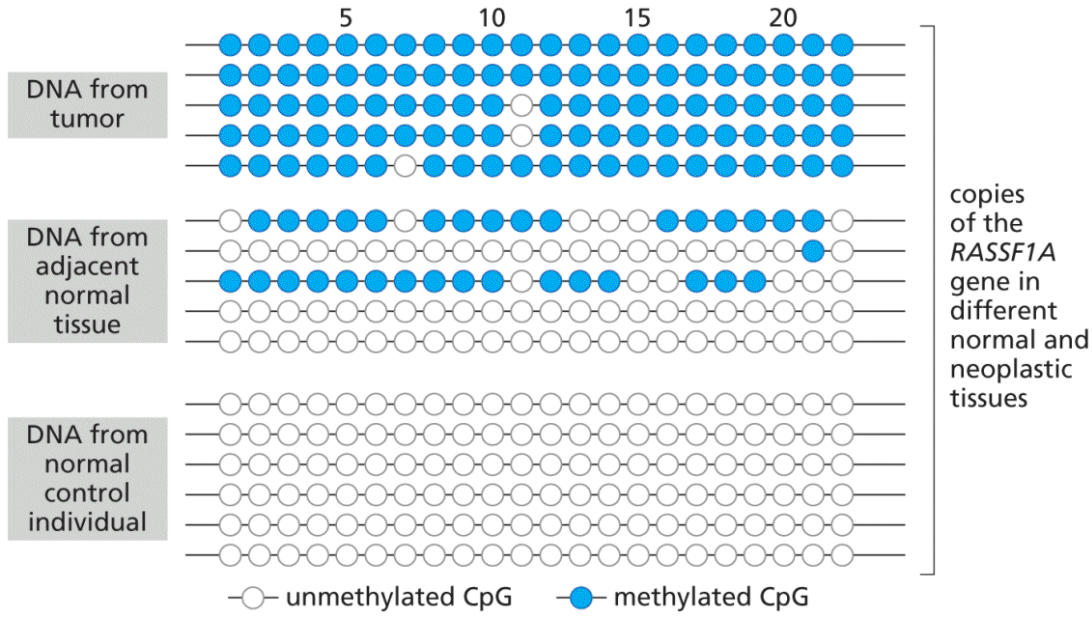
The enzymes that are responsible for methylating CpGs—called DNA methyltransferases—are themselves altered in cancer, as are the enzymes involved in regulating the removal of this 5′ methyl group. The end result is that the methylation state of cancer genomes differs from that of the corresponding normal cell. Indeed, in developing cancers, DNA methylation is altered in two opposing directions. In the early stages of tumor development, methylation throughout the cancer cell genome is often found to decrease progressively (as determined by the technique described in **Supplementary Sidebar 7.4**). This decline could result from the failure of DNA methyltransferases to maintain methylation levels or to an active process of demethylation. Much of this “global hypomethylation” takes place within highly repeated DNA sequences that do not specify biological functions; although such hypomethylation is correlated with chromosomal instability, it remains unclear whether it directly causes this instability.

Apart from this global hypomethylation, there are also localized regions of DNA—segments with a high density of CpGs called “CpG islands”—that become excessively methylated in the genomes of cancer cells. These CpG islands are often associated with the promoters of genes (**Figure 7.12**), and their methylation by DNA methyltransferases silences transcription, resulting in the shutdown of gene expression. (A recent survey indicated that 60–70% of all genes in the human genome have CpG islands affiliated with their promoters, yielding a total of 12,000 to 14,000 genes that are, in principle, vulnerable to inappropriate shutdown by methylation.)



A map of the R A S S F 1 A promoter region, showing the locations of C p G dinucleotides numbered 1 through 22 from left to right. Exon 1 starts between numbers 17 and 18 and runs rightward to the end of the region.

(A)



A diagram shows the methylation state of each C p G in 16 different normal and neoplastic tissue samples, 5 of which are from a tumor, 5 of which are from adjacent normal tissue, and 6 of which are from a normal control individual. In the tumor D N A, all or all but one of the C p Gees are methylated. In adjacent normal tissue, the number of methylated C p Gees is highly variable–anywhere from 0 to 16. In the control individual, none of the C p Gees are ever methylated.

(B)

Figure 7.12 Methylation of the *RASSF1A* promoter (A) A map of the structure of the *RASSF1A* promoter region shows the location of the CpG dinucleotides (ticks) in the CpG island in which the promoter is embedded. (B) A diagram depicts the state of methylation of each CpG dinucleotide (circle) in this island. Filled circles (*blue*) indicate that a CpG has been found to be methylated, whereas open circles indicate that it is unmethylated. Analyses of five DNA samples from a prostate tumor indicate methylation at almost all CpG sites in the *RASSF1A* CpG island; this CpG island is unmethylated in most, but not all, samples of adjacent, ostensibly normal tissue. Analyses of control DNA from a normal individual indicate the absence of any methylation of the CpGs in this CpG island. (These data suggest the presence of some abnormal cells with methylated DNA in the ostensibly normal tissue adjacent to tumor 232.) Analysis was performed by bisulfite sequencing (see **Supplementary Sidebar 7.4**). (Courtesy of W.A. Schulz and A.R. Florl.)

CpG methylation is effective in shutting down the expression of a gene only if it occurs within the promoter or other regulatory sequences of the gene; conversely, methylation of DNA sequences in the body of the gene, including exonic sequences, seems to have little if any effect on the level of transcription. Because promoter methylation can silence a gene as effectively as a mutation of its nucleotide sequences, we might predict that methylation plays a role in the silencing of TSGs that occurs during tumor progression. In fact, this has proven to be the case. More than half of the TSGs that are inactivated by germ-line mutations in familial cancer syndromes have been found to be silenced in sporadic cancers by promoter methylation. For example, when the TSG *Rb* is mutated in the germ line, it leads to familial retinoblastoma. In sporadic retinoblastomas, however, *Rb* is inactivated either by somatic mutations or by promoter methylation. In addition, the promoters of a variety of other genes that are known or thought to inhibit tumor formation have been found in a methylated state (**Table 7.2**).

Table 7.2 Examples of hypermethylated genes found in human tumor cell genomes

Name of gene	Nature of protein function	Type of tumor
AR	androgen receptor signaling	prostate

Name of gene	Nature of protein function	Type of tumor
RARβ2	nuclear receptor for differentiation	breast, lung
$p57^{Kip2}$	CDK inhibitor	gastric, pancreatic, hepatic; AML
IGFBP	sequesters IGF-1 factor	diverse tumors
BRCA1	DNA damage response	breast, ovarian
$CDKN2A/p16^{INK4A}$	inhibitor of CDK4/6	diverse tumors
$CDKN2B/p15^{INK4B}$	inhibitor of CDK4/6	diverse tumors
APC	inducer of β-catenin degradation	colon carcinomas
miR-200s	inhibitor of epithelial-mesenchymal transition	colon, bladder, squamous cell carcinoma
ESR1	estrogen receptor signaling	breast
p73	aids p53 to trigger apoptosis	diverse tumors
GSTP1	mutagen inactivator	breast, liver, prostate

Name of gene	Nature of protein function	Type of tumor
MGMT	DNA repair enzyme	colorectal
CDH1	cell–cell adhesion receptor	bladder, breast, colon, gastric
DKK1	Wnt inhibitor	colon
MLH1	DNA mismatch repair enzyme	colon, endometrial, gastric
PTEN	degrades PIP_3	diverse tumors
TGFBR2	TGF-β receptor	colon, gastric, small-cell lung
VHL	ubiquitin ligase	kidney, hemangioblastoma
RB	cell cycle regulator	retinoblastoma
CASP8	apoptotic caspase	neuroblastoma, SCLC
APAF1	pro-apoptotic cascade	melanoma

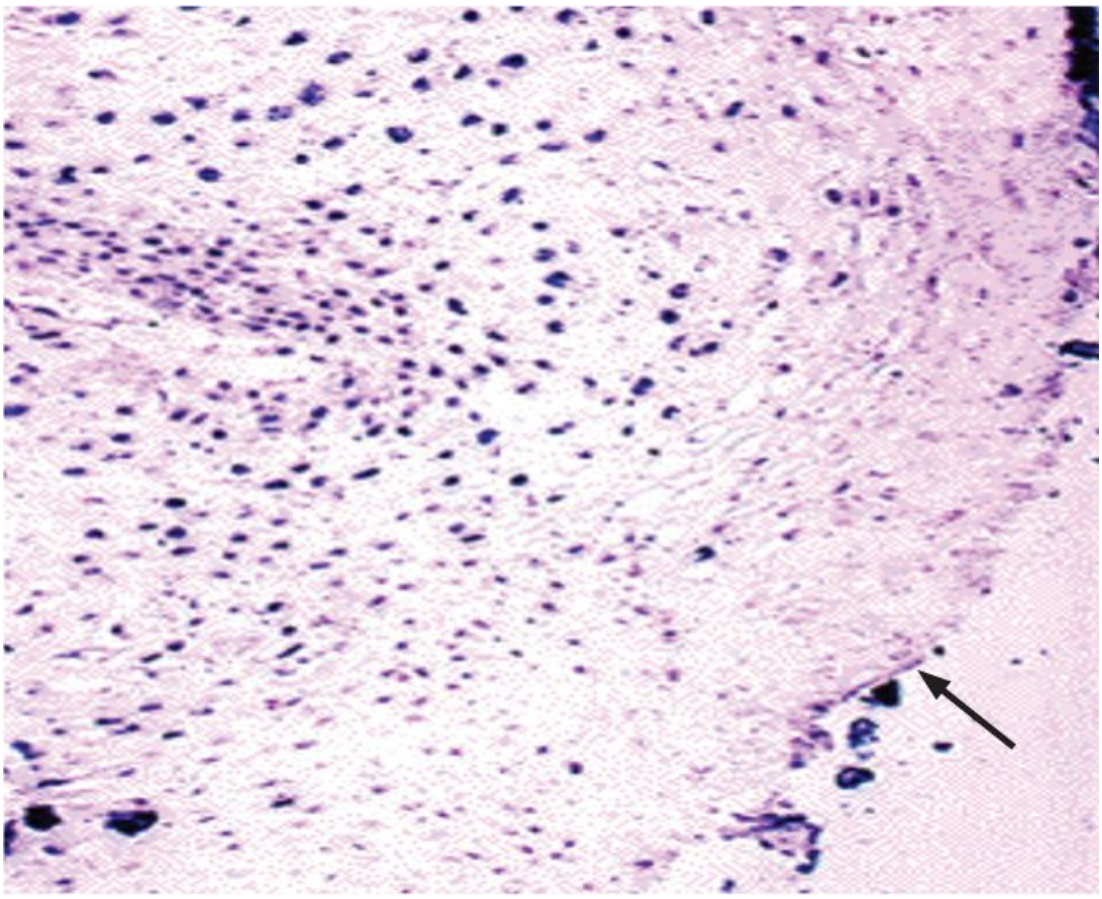
Adapted from H. Heyn and M. Esteller, *Nat. Rev. Genet.* 13:679–692, 2012.

The extent of CpG island methylation varies greatly from one tumor genome to the next. In some tumors, the hypermethylation is so extensive that such tumors are said to exhibit the “CpG island methylator phenotype” (CIMP). In the cells of these tumors, as many as 5% of the genes (that is, about 1000 genes) may possess hypermethylated

CpG islands. The molecular mechanisms driving this runaway CpG methylation remain under active investigation.

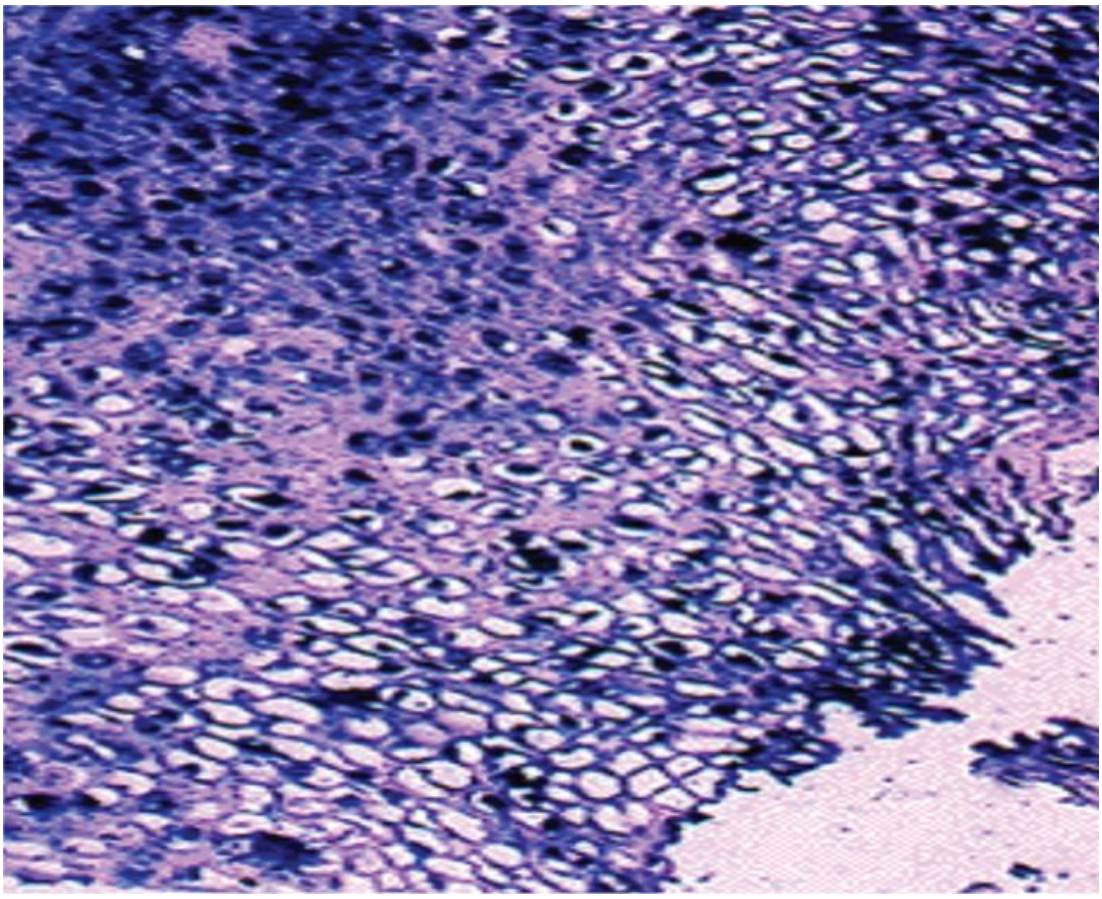
Some candidate TSGs are rarely inactivated by somatic mutations, and their involvement in creating cancer is suggested only by the finding that their promoters are methylated in large numbers of independently arising tumors. The absence of defined mutations makes it challenging to verify that inactivation of a candidate TSG actually contributes causally to cancer formation. Nevertheless, even in the absence of direct evidence of mutational inactivation, the recurring functional silencing of these genes by CpG methylation is now well accepted as proof of their roles as TSGs.

The elimination of TSG function by promoter methylation might, in principle, occur through either of two routes. Both copies of a TSG might be methylated independently of one another. Alternatively, one copy might be methylated and the second might then suffer an LOH accompanied by a duplication of the already-methylated TSG copy. Actually, this second mechanism seems to operate quite frequently. For example, one study found that a TSG called $p16^{INK4A}$ (which will be described in Section 8.4) was methylated in 44% of the (ostensibly) normal lung epithelial cells cultured from current and former smokers and not at all in the comparable cells prepared from those who had never smoked. LOH in this chromosomal region was found in 71 to 73% of the two smoking populations and in 1.5 to 1.7% of nonsmokers. This study also teaches us a second lesson: methylation of critical growth-controlling genes often occurs early in the complex, multi-step process of tumor formation—long before histological changes are apparent in a tissue. These populations of outwardly normal cells presumably provide a fertile soil for the eventual eruption of premalignant and malignant growths. This point is borne out in other tissues as well, such as the histologically normal breast tissues analyzed in **Figure 7.13**.



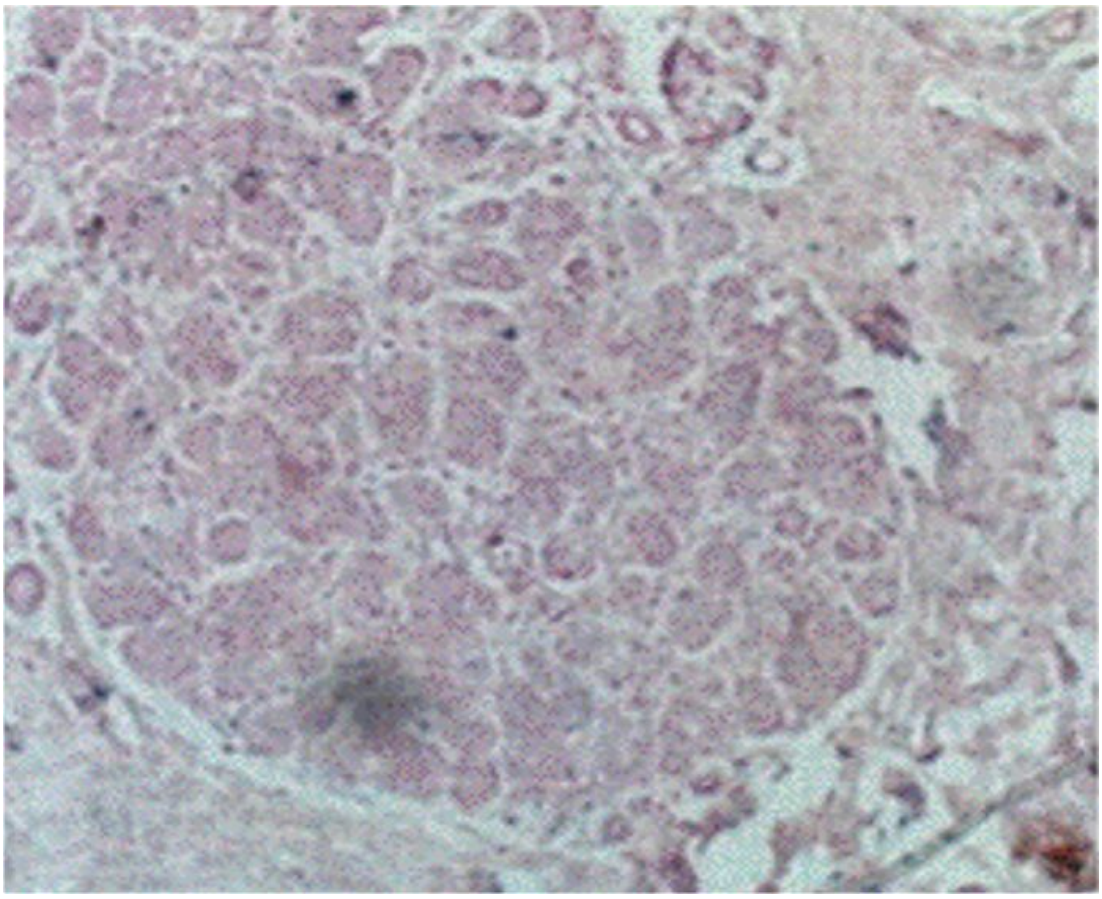
A tissue sample in which the cells are generally light in color and in some, near the edge of the sample (as marked by an arrow), the nuclei are hardly visible.

(A)



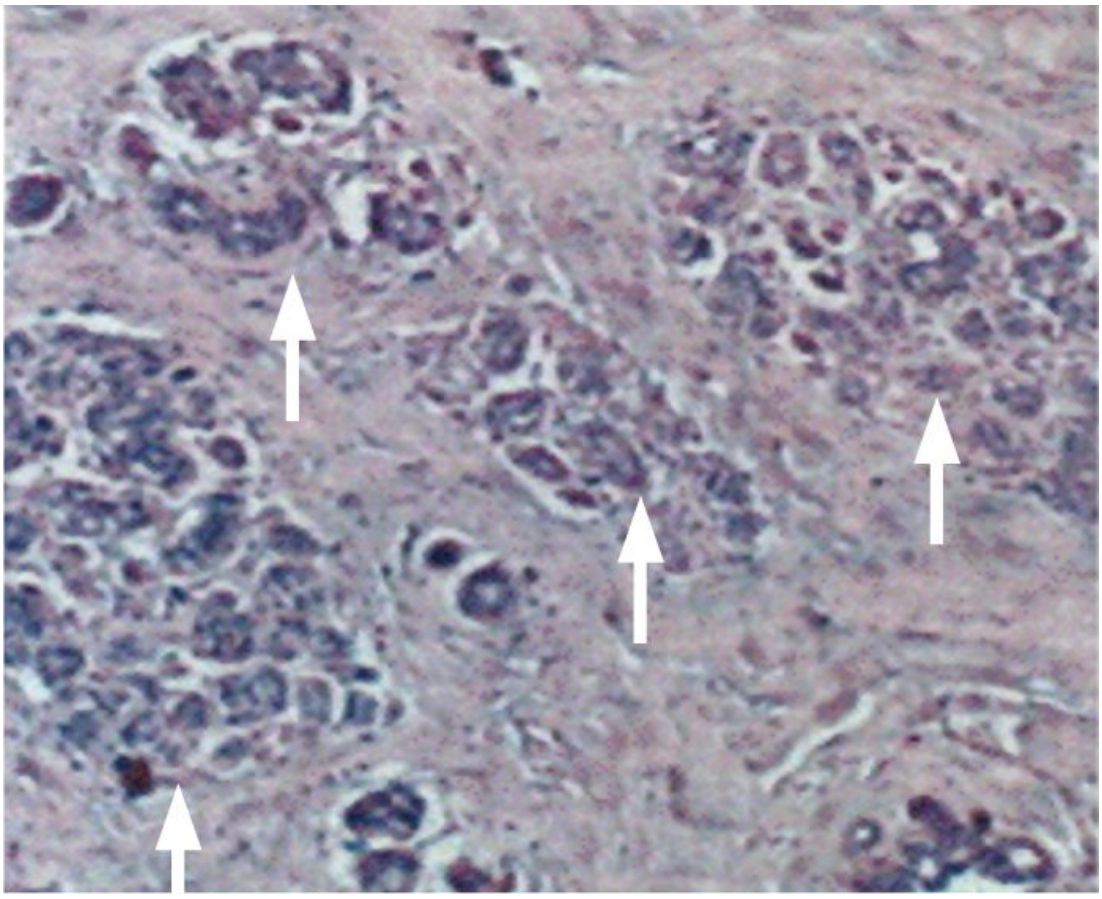
A tissue sample in which all the cells are dark blue.

(B)



A tissue sample that is generally pale.

(C)



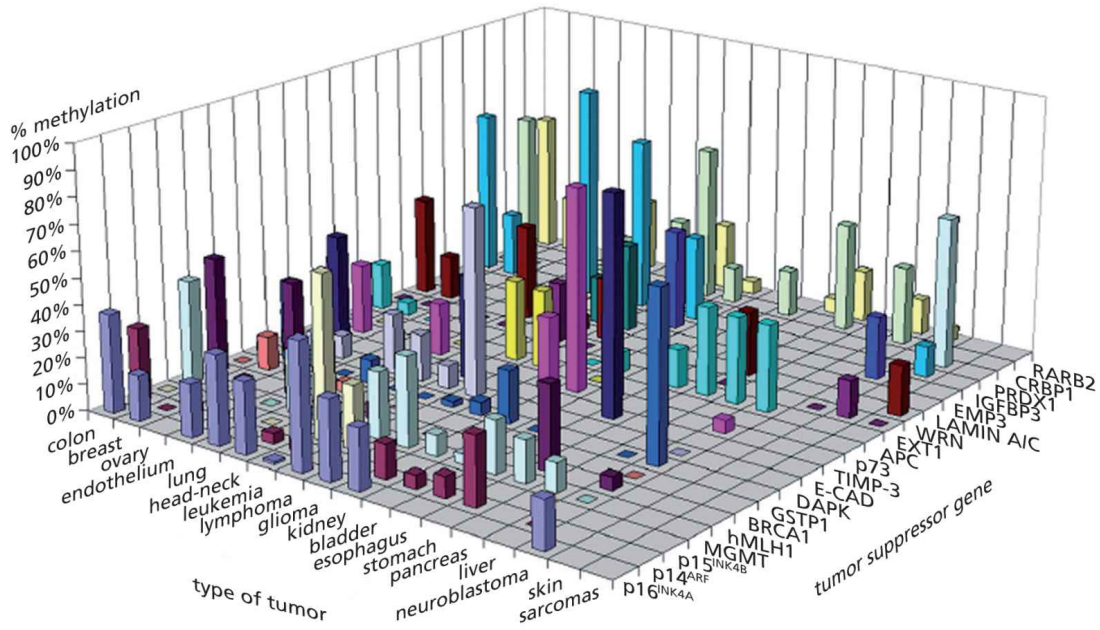
A tissue sample with nodules of darker tissue indicated by arrows surrounded by lighter colored cells.

(D)

Figure 7.13 *In situ* measurements of DNA methylation The presence or absence of methylation at specific sites in the genomes of cells can be determined in tissue sections that are fixed to a microscope slide using *in situ* hybridization. In these images, the methylation status of the promoter of the TSG $p16^{INK4A}$ is analyzed with a methylation-specific probe, which yields dark staining in areas where this gene promoter is methylated. (A) In a low-grade squamous intraepithelial lesion of the cervix (*left*), nuclei of cells located some distance from the uterine surface show promoter methylation, whereas those near the surface (*arrow*) do not. (B) However, in an adjacent high-grade lesion, which is poised to progress to a cervical carcinoma (*right*), all the cells show promoter methylation. (C, D) In these micrographs of normal breast tissue, some histologically normal lobules show no promoter methylation (C), whereas others (*arrows*) show uniform promoter methylation (D). This suggests that the mammary epithelial cells in such outwardly normal lobules have already undergone a critical initiating step in

cancer progression. (A and B, from G.J. Nuovo et al., *Proc. Natl. Acad. Sci. USA* 96:12754–12759, 1999. With permission from National Academy of Sciences, U.S.A. C and D, from C.R. Holst et al., *Cancer Res.* 63:1596–1601, 2003. With permission from American Association for Cancer Research.)

Genome-wide methylation analysis (**Supplementary Sidebar 7.4**) has allowed for comprehensive characterization of the methylation status of nearly all known TSGs. As illustrated in **Figure 7.14**, the frequency of methylation of a specific TSG varies dramatically from one type of human tumor to the next. However, the data clearly reinforce the pervasiveness of promoter methylation during the development of a wide variety of human cancers.



A 3 D bar graph with type of tumor on one horizontal axis, tumor suppressor gene on the other horizontal axis, and percent methylation on the vertical axis. The 18 tumor types range from colon, breast and ovary through glima, kidney and bladder to liver, neuroblastoma, and skin sarcomas and have a wide range of methylation. Most genes are rarely if ever methylated in skin sarcomas.

Figure 7.14 Methylation of multiple genes within tumor cell genomes This three-dimensional bar graph summarizes measurements of the methylation state of the CpG islands associated with 20 different genes that are known or presumed to play an important role in suppressing the development of human tumors. Methylation status of each was determined for 18 different tumor types. The height of each bar indicates the proportion of tumors of a given type in which a specific promoter has undergone methylation. All of these promoters are

unmethylated (or methylated to an insignificant extent) in normal tissues. The data indicate that the hypermethylation profiles vary by tumor type: several genes are hypermethylated in cancers of the colon, for example, whereas less methylation of these genes takes place in sarcomas. (Adapted from M. Esteller, *Hum. Mol. Genet.* 16:R50–R59, 2001. With permission from Oxford University Press.)

Beyond the biological significance of hypermethylation as a mechanism for the silencing of cancer-related genes, the overall state of DNA methylation in neoplastic tissue compared to normal tissue can have implications for disease diagnosis, prognosis, and therapy. For several cancer types, the overall changes in DNA methylation patterns correlate with the severity of the disease and the response to therapy, both of which affect patient survival after diagnosis. In addition, there is a growing list of cancer therapies that are directed at the enzymes that are responsible for DNA methylation and histone modifications.

7.8 TSGs and their encoded proteins function in diverse ways

Even a cursory examination of Table 7.1 makes it clear that TSGs specify a diverse array of proteins that operate in many different intracellular sites to reduce the risk of cancer. Indeed, an anti-cancer function is the only property that is shared in common by these otherwise unrelated genes.

Some function to directly suppress the proliferation of cells in response to a variety of signals that inhibit growth and induce differentiation. Others are components of the cellular control circuitry that inhibits proliferation in response to metabolic imbalances and genomic damage.

The first two TSGs that were studied intensively—the *Rb* gene discussed earlier and another called *p53* (or sometimes *Trp53* or *TP53*)—also happen to be two of the more frequently altered TSGs in human cancers. The protein encoded by the *Rb* gene, pRb, governs progress through the growth-and-division cycles of a wide variety of cells, and the growth control imposed by the *Rb* circuit appears to be disrupted in most and perhaps all human tumors. Because of its central importance, we will devote an entire chapter to *Rb* and its function (Chapter 8). The TSG *p53* and its product, p53, play an equally central role in the development of cancers and, consequently, we devote an additional chapter to an extended description of p53 and its cellular functions (Chapter 9). Several of the proteins encoded by the TSGs listed in Table 7.1 happen to be components of the *Rb* and *p53* pathways; included in these circuits are the $p16^{INK4A}$, $p15^{INK4B}$, and $p19^{ARF}$ genes, and so discussion of these will be postponed until Chapters 8 and 9 as well. Of note, several tumor viruses encode proteins that disrupt the function of pRB and p53. This explains the observations discussed earlier in this chapter showing that cancer cells transformed by infection with certain tumor viruses, unlike cancer cells lacking viral genomes, exhibit a dominant phenotype when fused with normal cells (see Figure 7.1B).

The remaining TSGs that have been discovered to date encode gene products that operate in diverse ways to suppress cell proliferation or tumor progression. These proteins interact with virtually all of the control circuits that are responsible for governing cell proliferation and survival. Some of their functions are well understood, but the actions of others remain to be fully elucidated. In the remainder of this chapter, we will focus on three TSGs that reflect the diversity of the mechanisms that cells deploy to control proliferation—and reveal how disruption of their function enhances the fitness of cancer cells. Although these mechanisms do not encompass all the ways that TSGs function, each represents an approach to regulating cell growth that is shared by many other TSGs—from those that constrain proliferation and are thus lost early in tumor initiation to those that allow malignant cells to adapt to cellular stresses and detoxify chemicals, thereby promoting their continued survival and acquired resistance to treatment.

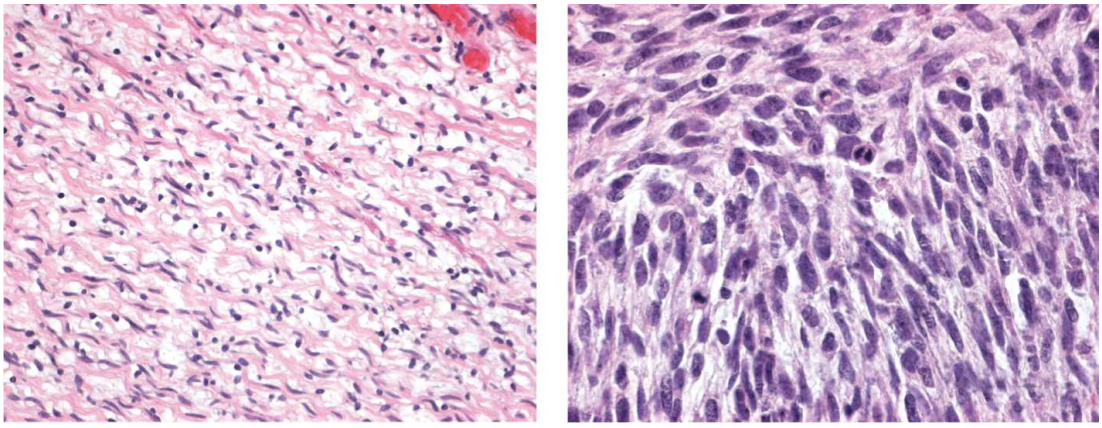
7.9 The NF1 protein acts as a negative regulator of Ras signaling

The disease neurofibromatosis was first described by Friedrich von Recklinghausen in 1862. We now know that neurofibromatosis type 1 (NF1)—sometimes called von Recklinghausen's neurofibromatosis—is a relatively common familial cancer syndrome, with 1 in 3500 individuals affected on average worldwide. The primary feature of this disease is the development of benign tumors, called neurofibromas, in the sheaths surrounding nerves of the peripheral nervous system. On occasion, a subclass of these tumors, termed *plexiform neurofibromas*, progress to malignant tumors called neurofibrosarcomas or malignant peripheral nerve sheath tumors (MPNSTs) (**Figure 7.15A**). Patients suffering from NF1 also have greatly increased risk of gliomas (tumors of the astrocyte lineage in the brain; see Figure 2.8A), pheochromocytomas (arising from the adrenal glands), and myelogenous leukemias (see Figure 2.7B). This collection of tumors involves cell types arising from diverse embryonic lineages. Neurofibromatosis type 2, which we do not discuss in detail, has distinct clinical features and arises from mutations in a completely unrelated TSG (see Table 7.1).



Two histology images. In the first image, cells and their nuclei appear small and spaced apart. In the second image, they appear large and crowded together.

(A)

A photo of a patient’s back, showing many nodules that look like acne bumps, and also two large, pale tan patches.

(B)

A portion of a human iris, with small nodules visible. They look like brown skin tags.

(C)

Figure 7.15 Neurofibromatosis Neurofibromatosis type 1 is considered a *syndrome* because a number of distinct conditions and phenotypes are associated with a single genetic state. (A) Histological observation of afflicted tissues indicates the benign neurofibromas (*left*), which occasionally progress to malignant peripheral nerve sheath tumors (MPNSTs, *right*). Whereas benign neurofibromas contain multiple distinct cell types and abundant extracellular matrix material—giving them a more diffuse appearance—malignant MPNSTs consist of a more uniform collection of densely packed cancer cells. The

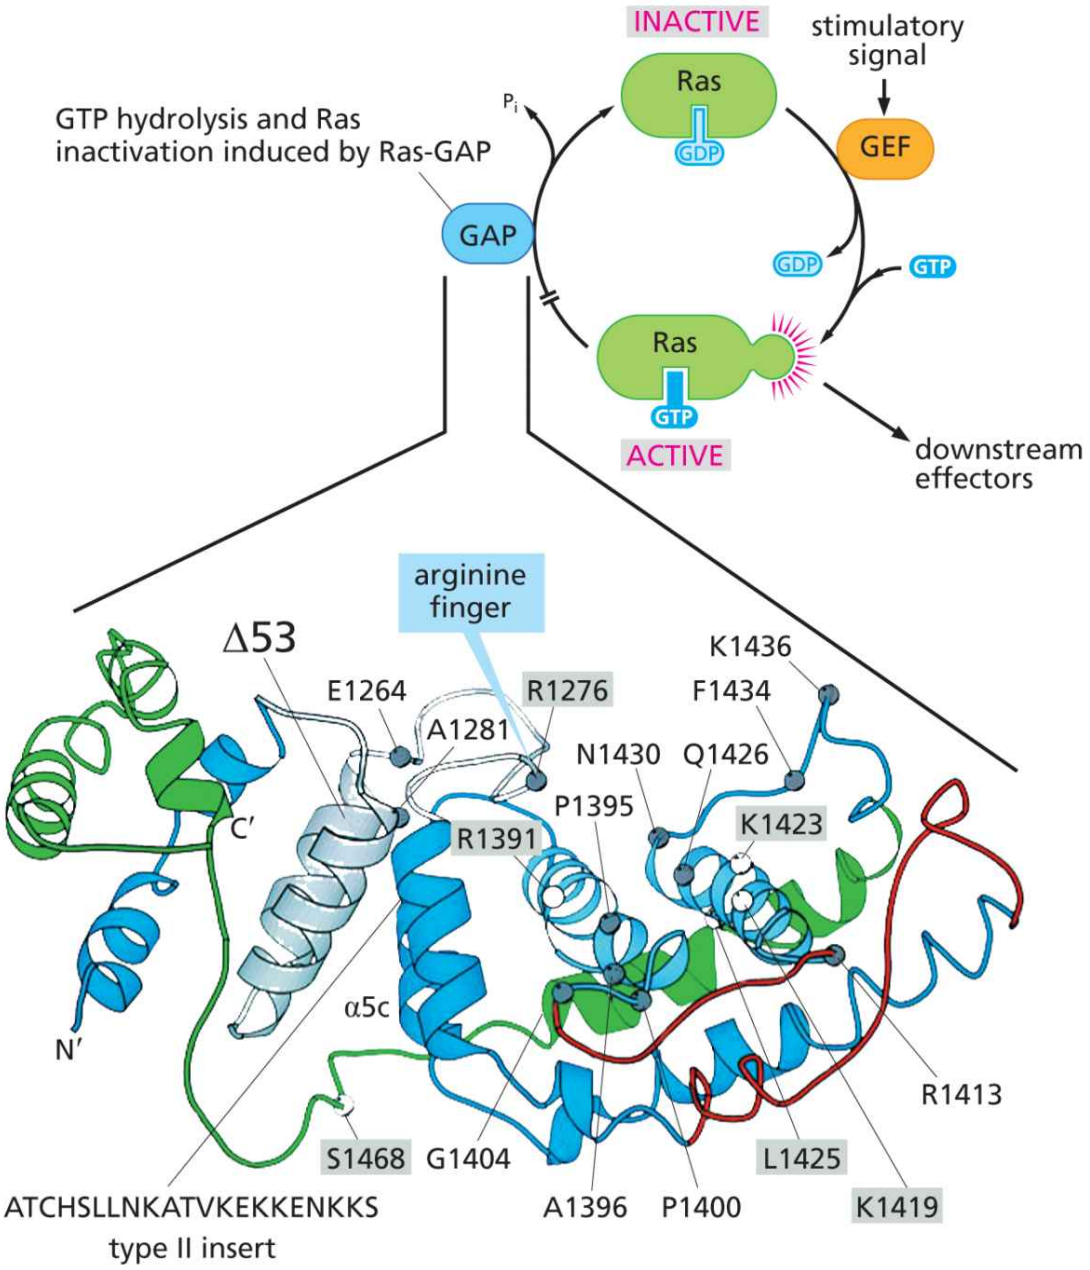
histological complexity of the neurofibromas greatly complicated the identification of the progenitors of these growths, which are now thought to be the precursors of the Schwann cells that wrap around peripheral axons. (B) Notable among the conditions associated with this syndrome are the numerous small, subcutaneous nodules (that is, neurofibromas) and the light brown *café au lait spots* (*arrows*) seen here on the back of a patient. (C) In addition, Lisch nodules are often observed in the iris of the eyes. (A, courtesy of S. Carroll. B, courtesy of B.R. Korf. C, from B.R. Korf, *Postgrad. Res.* 61:3225–3229, 1988 and courtesy of J. Kivlin.)

Patients with NF1 often suffer from additional abnormalities that involve still other cell types. Among these are café au lait spots (Figure 7.15B), which are areas of hyperpigmentation in the skin; subtle alterations in the morphology of the cells in the skin and long bones; cognitive deficits; and benign lesions of the iris called "Lisch nodules" (Figure 7.15C). The risk of developing these additional manifestations is strongly influenced by the patient's genetic background (that is, the array of all other genetic alleles in an individual's genome), because siblings inheriting the same mutant allele of the responsible TSG, called *Nf1*, often exhibit dramatically different disease phenotypes. Such variation in the clinical presentation of a genetic disease is referred to as variable expressivity.

The *Nf1* gene was cloned in 1990. The genetics of the *Nf1* gene parallels closely that of the *Rb* gene. Thus, mutant, inactivated alleles of the *Nf1* gene transmitted through the germ line act in a dominant fashion to create disease phenotypes. At the cellular level, the originally heterozygous configuration of the gene ($Nf1^{+/-}$) is converted to a homozygous state ($Nf1^{-/-}$) in tumor cells through LOH. Finally, as many as half of the patients with NF1 lack a family history of the disease, indicating that the mutant allele that they carry is the consequence of a *de novo* mutation in the germ line. More than 80% of such *de novo* mutations usually occur during spermatogenesis in the fathers of afflicted patients, a pattern also seen with *de novo* germ-line mutations of the *Rb* gene (see Sidebar 7.2).

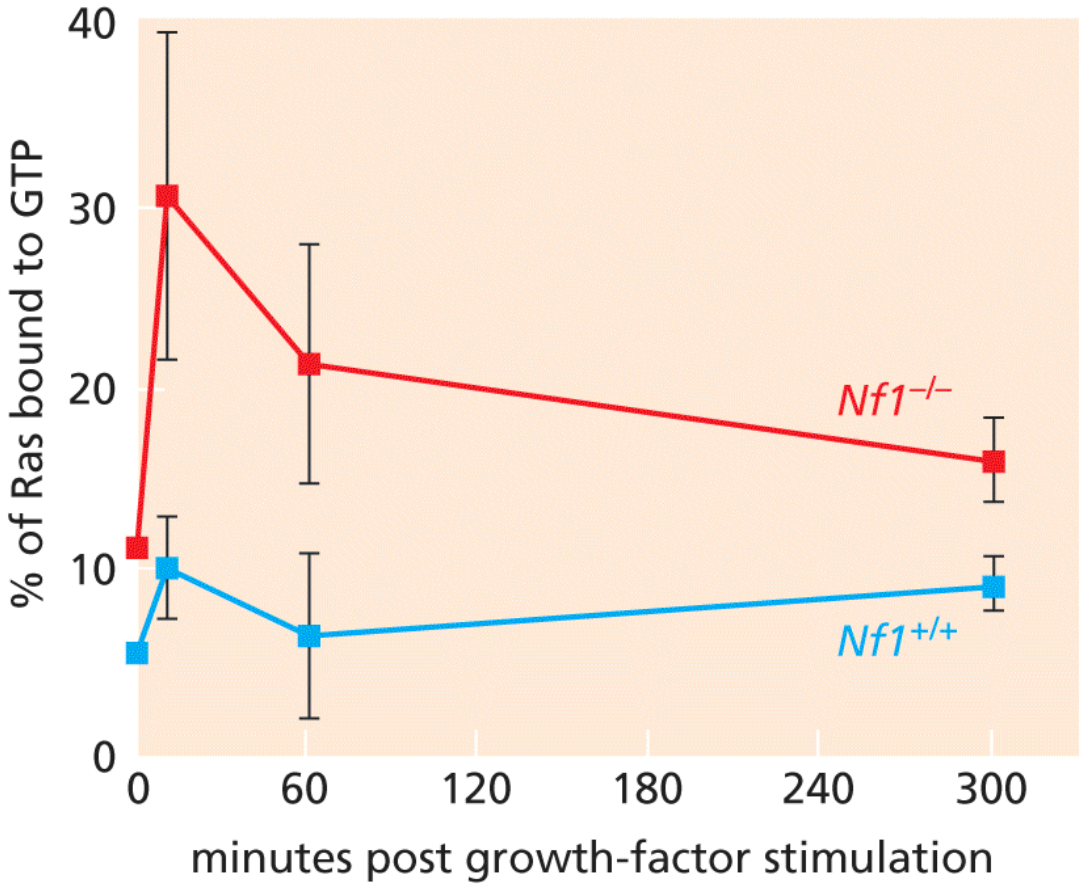
Once the cloned *Nf1* gene was sequenced, researchers were able to assign a function to its encoded protein neurofibromin: the amino acid sequence of neurofibromin shows extensive relatedness to that of proteins that function as GTPase-activating proteins for Ras (Ras-GAPs; see Figure 5.24). Eukaryotic cells use Ras proteins to regulate important aspects of their metabolism and proliferation, and Ras-GAPs negatively control the state of Ras activation. These regulatory proteins do so by inducing Ras to activate its intrinsic GTPase activity, thereby forcing Ras to convert itself from its activated GTP-bound form to its inactive, GDP-bound form (**Figure 7.16A**). Indeed, a

Ras-GAP may even ambush activated Ras before the latter has had a chance to stimulate its coterie of downstream effectors (see Section 5.10).



The cycle the R a s protein passes through. Inactive R a s G D P is activated by a G E F that promotes the release of G D P and binding of G T P. The activated R a s signals to downstream effectors. The R a s is inactivated by an R a s-G A P that induces G T P hydrolysis. A detail of the image shows the structure of the G A P as a ribbon diagram. A point near the center is labeled R1276 and is the arginine finger.

(A)



A line graph with minutes post growth-factor stimulation, 0 to 300, on the horizontal axis and percent of R a s bound to G T P on the vertical axis. The line for wild-type N f 1 plus plus mice stays below 10 percent, whereas the line for N f 1 minus minus mice jumps to 30 percent within 10 minutes before settling between 10 and 20 percent after 300 minutes.

(B)

Figure 7.16 Neurofibromin and the Ras signaling cycle (A) As shown at the top, the Ras protein passes through a cycle in which it is activated by a guanine nucleotide exchange factor (GEF), promoting the release of GDP and binding of GTP, and inactivated by a GTPase-activating protein (Ras-GAP). One of the main Ras-GAPs is neurofibromin, which can stimulate the GTPase activity of Ras more than 1000-fold. The structure of the neurofibromin domain that interacts with Ras is illustrated here. A subdomain of neurofibromin, termed the “arginine finger” (*blue box*), carries a critical arginine (R1276) that is inserted into the GTPase cleft of Ras and actively contributes to the hydrolysis of GTP to GDP by Ras.

Mutations that cause replacement of this critical arginine residue with another amino acid decrease the GTPase-stimulating activity of neurofibromin by 1000-fold. In this diagram, mutant forms of neurofibromin, which carry amino acid substitutions observed in neurofibromatosis patients, are indicated by *white spheres* that are labeled by *gray boxes*; experimentally generated mutations that produce amino acid substitutions (*gray spheres without boxed labels*) also compromise neurofibromin's GTPase activity. The *white sphere with boxed label* (R1391) indicates a mutation that arose through both routes. In addition, a large-scale deletion (Δ53) and an insertion ("type II insert") found in patients are shown; both are also disease-associated. (B) When myeloid cells of wild-type $Nf1^{+/+}$ mice are stimulated with the growth factor GM-CSF, the ligand-activated receptor causes GTP-bound Ras levels to rise rapidly and then decrease slightly over the next five hours (*blue line*). In contrast, in $Nf1^{-/-}$ myeloid cells, the basal level of GTP-bound Ras is already elevated, and in response to GM-CSF stimulation, levels of this active form of Ras rise threefold further and remain elevated over this time period (*red line*). (A, from K. Scheffzek et al., *EMBO J.* 17:4313–4327, 1998. With permission from John Wiley and Sons. B, from D. Largaespada et al., *Nat. Genet.* 12:137–143, 1996. With permission from Nature.)

This initial insight into *Nf1* function inspired a simple scheme of how defective forms of neurofibromin create disease phenotypes. *Nf1* is expressed widely throughout the body, with especially high concentrations of neurofibromin found in the adult peripheral and central nervous systems. In normal cells, stimulation by growth factors would initially trigger a degradation of neurofibromin, enabling Ras signaling to continue without interference by this negative regulator. However, after 60 to 90 minutes, neurofibromin levels would return to normal, allowing the accumulation of this inhibitory protein to help shut down further Ras signaling—a form of negative-feedback control (see Figure 6.25). In cells that lack *Nf1* function, Ras proteins are predicted to persist in their activated, GTP-bound state for longer-than-normal periods of time. In fact, in myeloid cells (a class of cells in bone marrow) that have been genetically engineered to be $Nf1^{-/-}$, the basal (that is, unstimulated) levels of GTP-bound activated Ras are higher than normal and respond to growth factor stimulation by increasing rapidly to far higher levels before declining gradually (Figure 7.16B). Consequently, the loss of *Nf1* function in a cell can mimic functionally the hyperactivation of Ras proteins created by mutant *Ras* oncogenes (see Section 5.10).

The histological complexity of neurofibromas has made it very difficult to identify the normal cell type that yields the bulk of the cells in these growths. Microscopic analyses (see Figure 7.15A) reveal that these tumors are composed of a mixture of cell types, including Schwann cells (which wrap around and insulate nerve axons), neurons, perineurial cells (which seem to surround and protect the axon–Schwann cell

complexes), fibroblasts, and mast cells, the latter being a type of granulocyte and originating in the bone marrow. In some of these benign tumors, Schwann cells are clearly the prevailing cell type, whereas in others it seems that fibroblasts or perineurial cells may dominate.

The weight of evidence indicates that (1) primitive, undifferentiated neural crest-derived cells related to Schwann cell precursors are the primary targets of *Nf1* LOH leading to neurofibromas, and (2) once these cells have lost all *Nf1* function, they initiate the development of these histologically complex growths by inducing the co-proliferation of a variety of other cell types via paracrine signaling (see Section 5.5). This co-proliferation raises an interesting and still-unanswered question, however: Because these other cell types, including those in neighboring tissues and in the bone marrow are heterozygous for *Nf1*—and carry only half the normal dose of functional neurofibromin—might they be hyper-responsive to any growth-stimulatory, paracrine signals released by the neoplastic $Nf1^{-/-}$ cells? This hypothesis is borne out by detailed studies of neurofibromatosis formation in a genetically engineered mouse model of the disease. This approach to producing mouse models of cancer via targeted gene deletion is outlined in **Sidebar 7.2** and in **Figure 7.17**.

Sidebar 7.2 Targeted gene deletion can produce mouse models of cancer

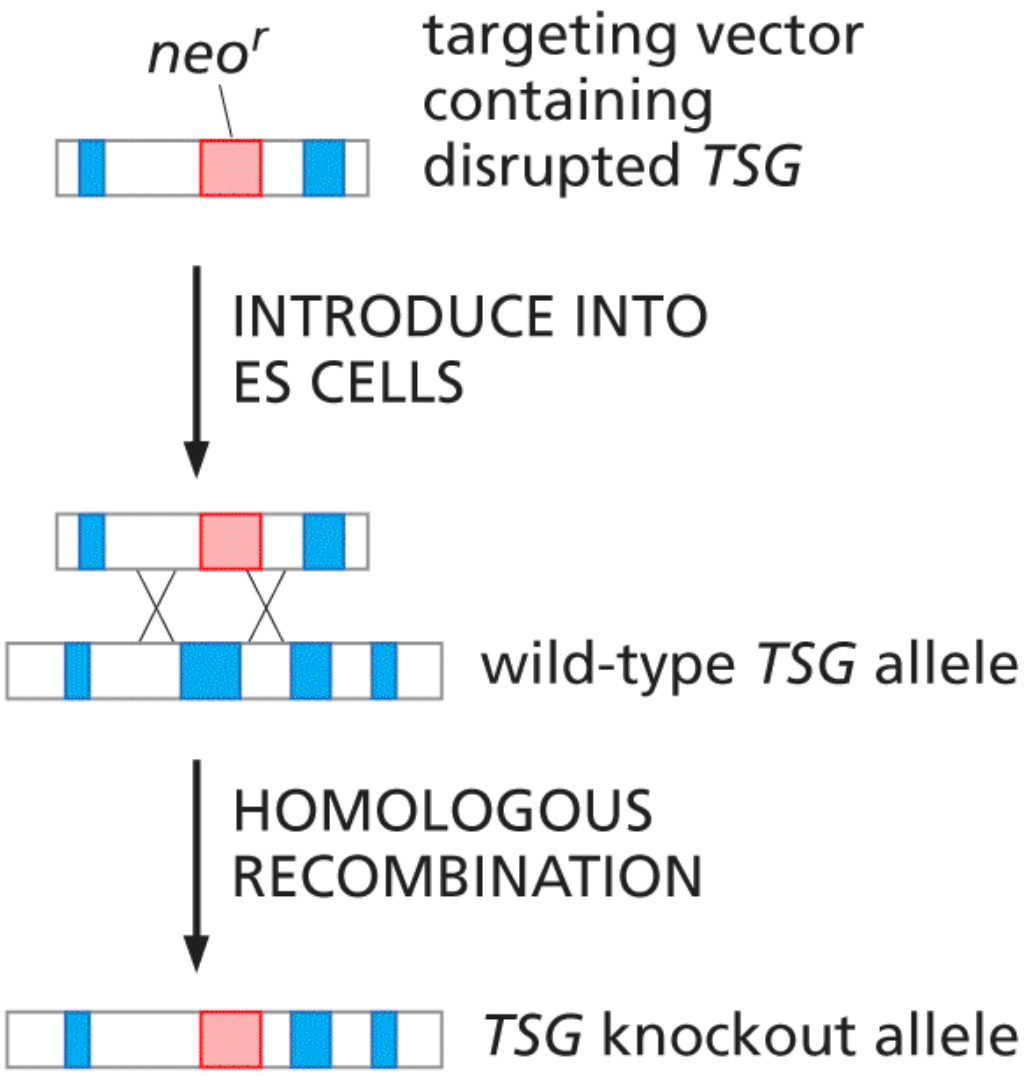
The natural process of homologous recombination can be exploited to introduce well-defined genetic changes into the mouse germ line in order to mutate an endogenous gene. This technology has been instrumental in the study of TSG function in the whole organism and for the development of mouse models of human cancer involving this class of genes. The process begins by manipulating the genome of a mouse embryonic stem (ES) cell. A cloned gene fragment that is introduced by electroporation into an ES cell is able to recombine, with a low but significant frequency, with homologous DNA sequences residing in the chromosomal DNA of this cell. Selectable markers—for example, neo^r (a gene that confers resistance to neomycin)—can be exploited to identify those cells that have integrated the exogenous DNA into the ES cell genome. Additional screening methods can then be used to identify the rare cells in which the cloned gene fragment, with its selectable marker, has disrupted one copy of the endogenous TSG by homologous recombination, thus creating an inactivating (or "knockout") mutation. These ES cells are thus heterozygous for the mutation in the targeted TSG (or $TSG^{+/-}$) (Figure 7.17A). A similar approach can be used to replace endogenous sequences with a gene whose activity has been altered more subtly, thereby creating a "knock-in" mutation.

$TSG^{+/-}$ ES cells can then be introduced via micro-injection into the blastocoel cavity of a mouse blastocyst (an early embryo), and the embryo transferred into a

pseudopregnant female for further development (Figure 7.17C). Because ES cells are pluripotent (able to differentiate into all cell types in the body), the descendants of the injected cells can insert themselves (chimerize) into any tissues within the developing embryo, including the germ line. Such germ-line chimeras can be bred with wild-type animals to transmit the inactivated TSG allele to their offspring, creating mice that are constitutionally $TSG^{+/-}$ in all of their cells. These animals are genetic analogs of humans with a familial cancer syndrome caused by an inherited mutation in the TSG, and they can be studied for tumor predisposition and other aspects of tumor biology. In addition, two animals that are $TSG^{+/-}$ can be bred and their $TSG^{-/-}$ offspring can be used to assess the effects of homozygosity for a given TSG mutation (Figure 7.17D). For most TSGs, this condition results in embryonic lethality, indicating the requirement for the TSG in one or more aspects of normal development. Genes required for embryonic development are often referred to as essential genes.

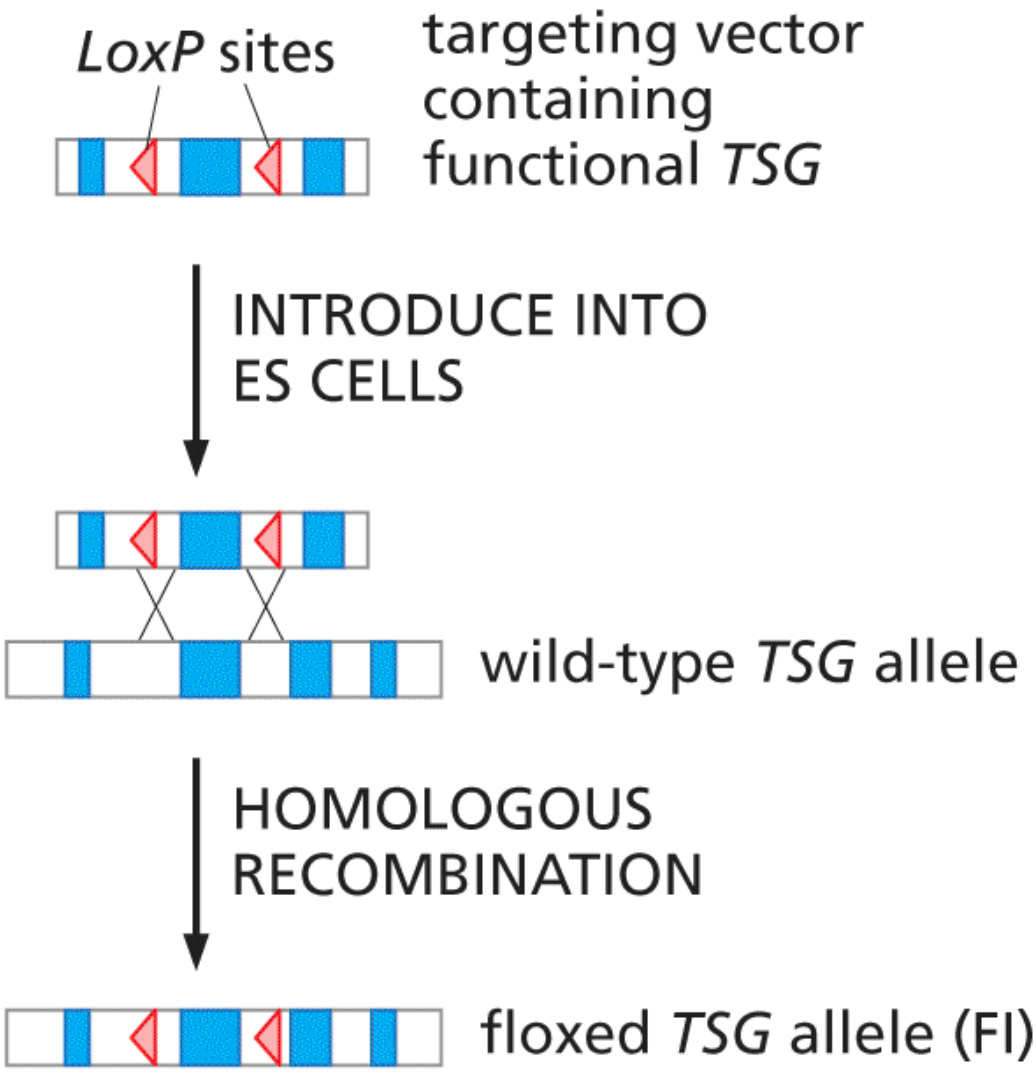
To examine the effects of inactivating an essential TSG in adult tissues, researchers have developed strategies to knockout the gene *conditionally*—in a subset of tissues or at a particular time. In this approach, homologous recombination is used in ES cells to flank a functionally important region of the target gene with a pair of short DNA sequences that serve as the recognition sequences for a site-specific recombinase (Figure 7.17B). The most frequently used system involves the use of *LoxP* sites and the recombinase Cre, which were initially derived from bacteriophage P1. Because the *LoxP* sites are inserted in such a way that they do not disrupt the function of the target gene, the alleles carrying flanking *LoxP* sites (or “floxed” alleles) remain functional and can be carried in a homozygous configuration. However, in cells in which Cre is expressed—for example, through the use of a cell type- or tissue-specific transcriptional promoter—the recombinase can catalyze the deletion of the sequences between the *LoxP* sites in both floxed alleles, leading to complete disruption of gene function (see Figure 7.17B).

These approaches can greatly facilitate the development of mouse models involving loss-of-function mutations in TSGs in different tissues in the body. The system can be further engineered so that the elimination of TSG activity can be induced by treating the animal with a drug. For example, the Cre recombinase molecule can be fused to a mutant form of estrogen receptor (ER) that can be activated by the drug tamoxifen, a ligand of this receptor (Figure 7.17E). When this hybrid Cre-ER is initially synthesized, it will be confined to the cytoplasm and will only gain access to the nucleus—where the floxed TSG alleles reside—when tamoxifen is provided. This allows for temporal control of gene deletion.



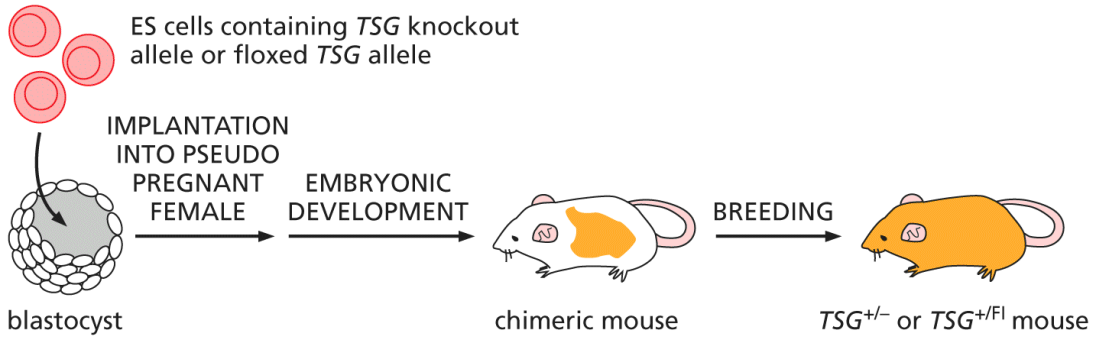
A targeting vector contains T S G disrupted by a neo-r gene. This targeting vector is then introduced into E S cells, where it encounters the wild-type T S G allele. Homologous recombination then produces a T S G knockout allele.

(A)



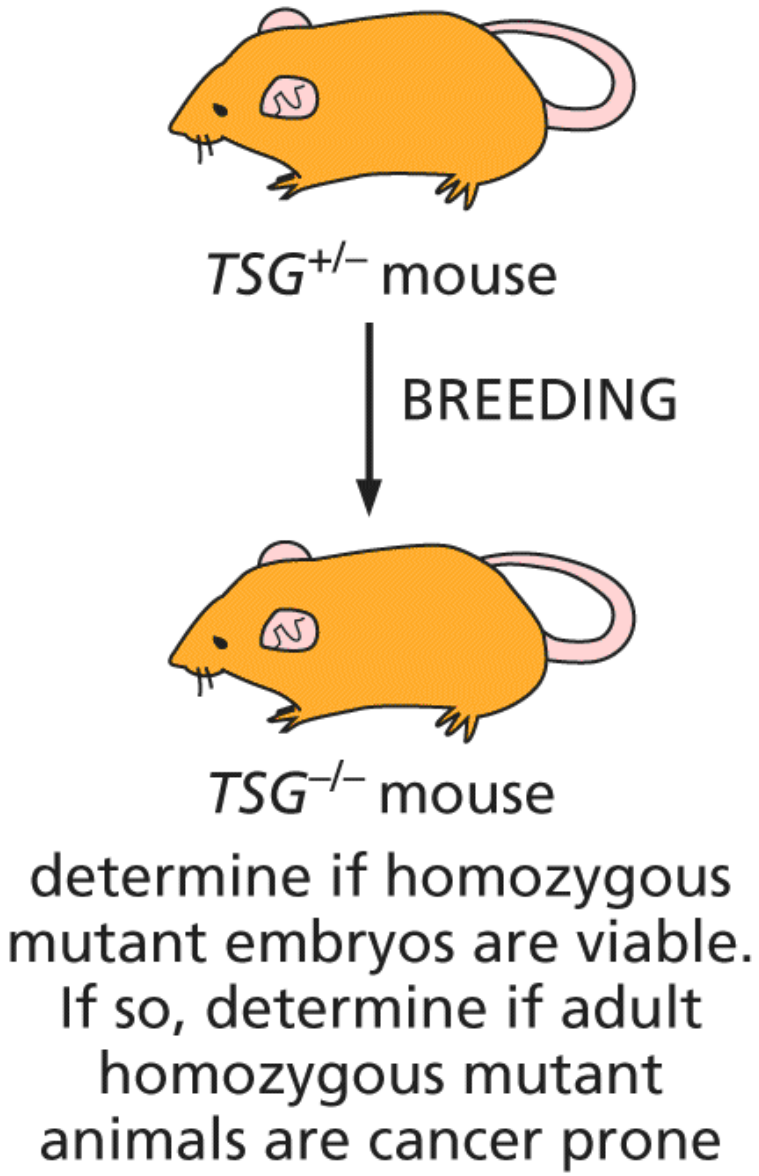
A targeting vector has two Lox-p sites. This targeting vector is introduced into E S cells, where it encounters the wild-type T S G allele. Homologous recombination then produces a floxed T S G allele.

(B)



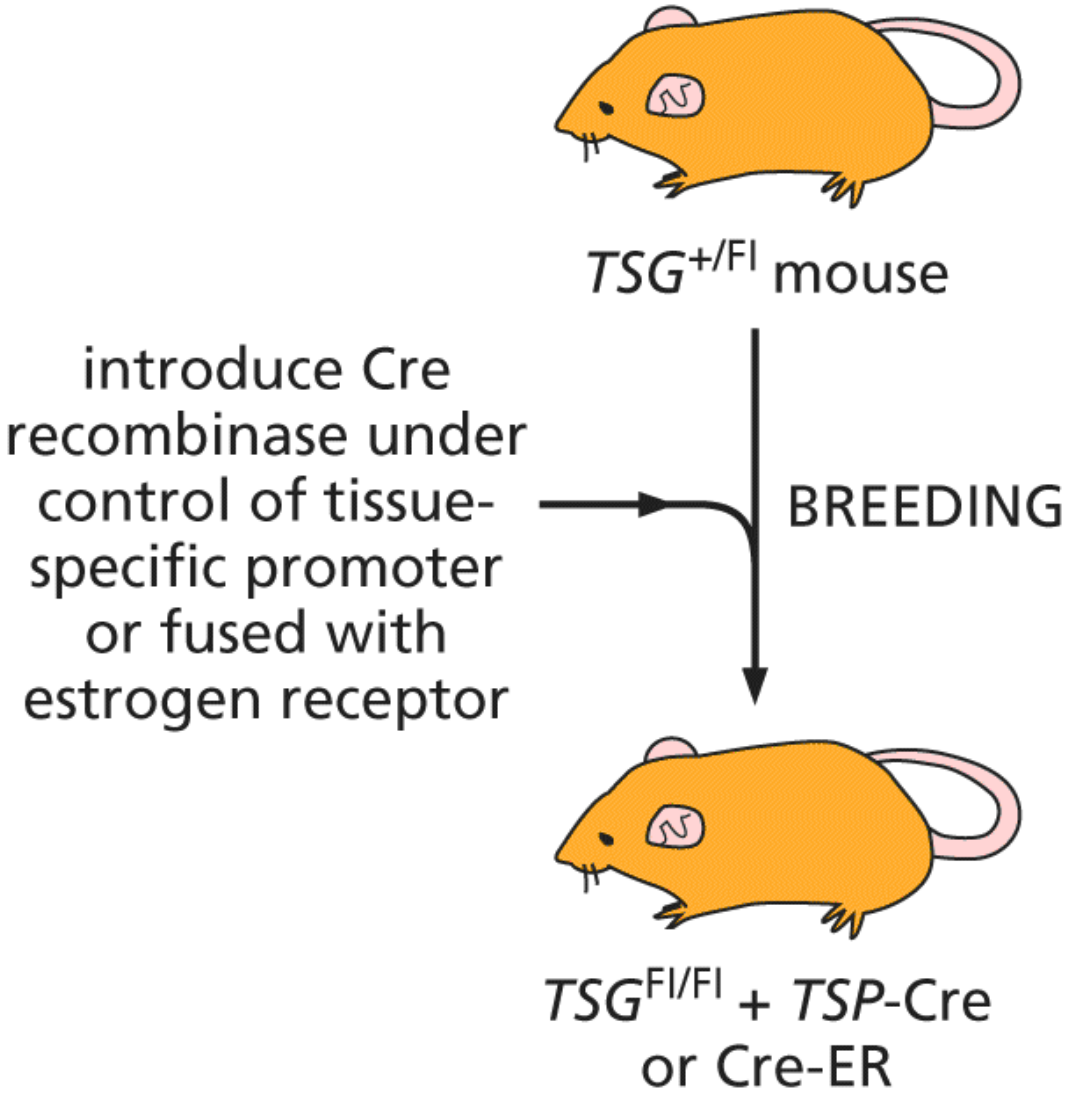
E S cells containing T S G knockout allele or floxed T S G allele are injected into a blastocyst. When this is implanted in a pseudopregnant female, the embryo develops into a chimeric mouse. If it is bred, its offspring may be heterozygous knockout or floxed mice.

(C)



Heterozygous knockout mice are bred, resulting in some offspring that are homozygous knockout. If the homozygous mutant embryos are viable, the adult homozygous mutants can be examined for cancer proneness.

(D)



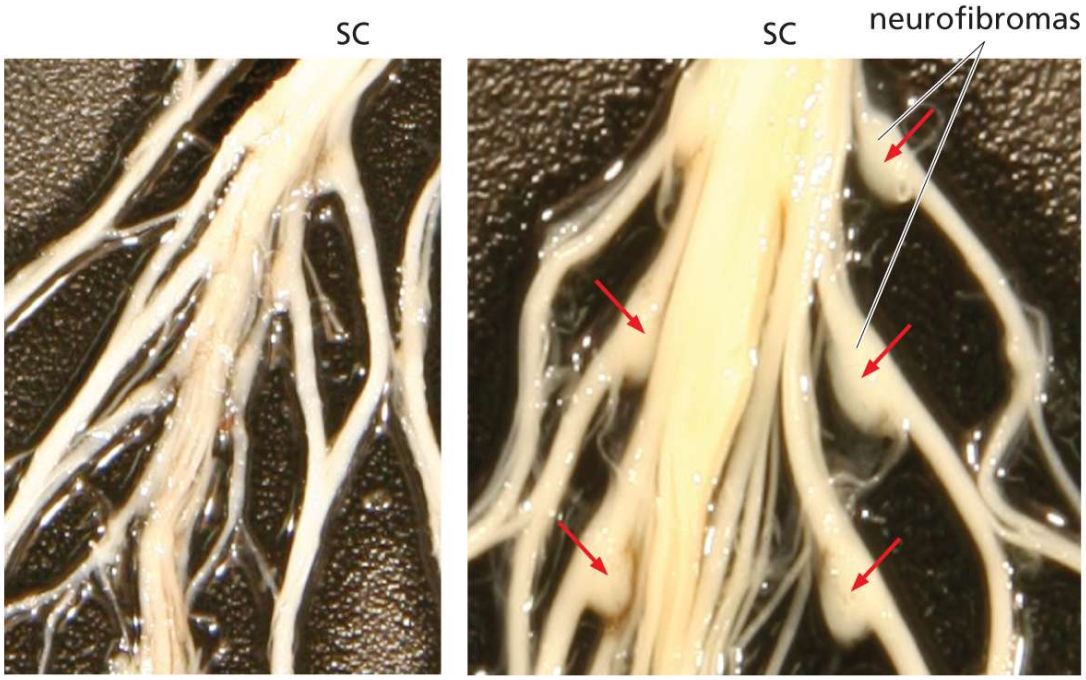
Heterozygous floxed mice are bred, with the introduction of C r e recombinase under control of tissue specific promoter or fused with estrogen receptor. The result may be homozygous floxed offspring with T S P C r e or with C r e E R.

(E)

Figure 7.17 Homologous recombination can be used to produce TSG knockout or conditional knockout mice (A) Using recombinant DNA techniques, a targeting vector is constructed that contains a cloned mouse TSG in which the *neo*^{r} gene disrupts or replaces a functionally important segment of the gene. This targeting vector is then introduced via *electroporation* into mouse embryonic stem (ES) cells, and drug selection and genetic screening are performed to identify those ES cells that have undergone homologous

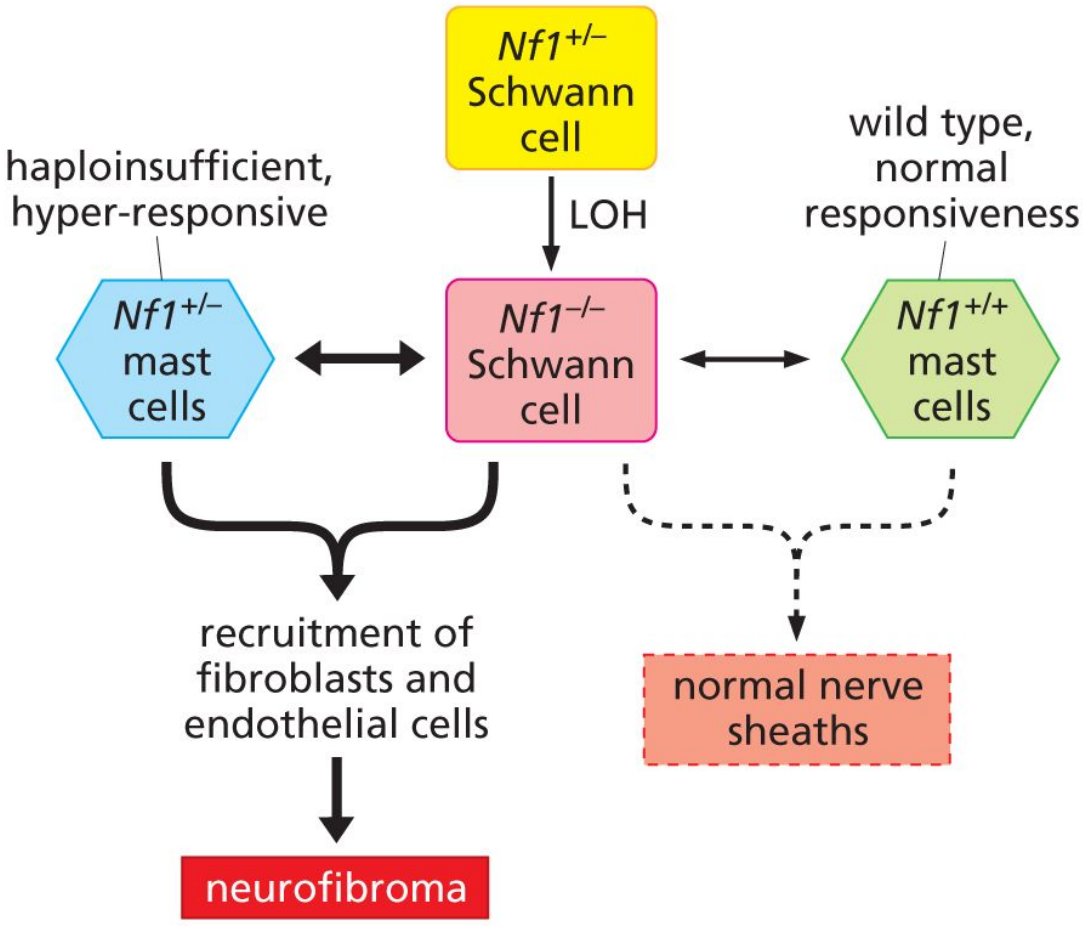
recombination between the targeting vector and one allele of the TSG; this recombination creates a “knockout” allele. (B) It is also possible to conditionally knock out a TSG. This begins with a targeting vector carries *LoxP* sites, which function as target sequences for the site-specific recombinase Cre; pairs of *LoxP* sites are used to create a “floxed” allele of the TSG following their insertion into the genome via homologous recombination. Here, the *LoxP* sites do not, on their own, disrupt TSG function and will only do so following Cre-driven recombination (see E below). (C) ES cells carrying properly integrated knockout or floxed alleles (either $TSG^{+/-}$ or $TSG^{+/Fl}$) are injected into wild-type mouse blastocysts, whereupon their progeny may become incorporated into the tissues of the resulting embryo. The embryos are implanted into pseudo-pregnant females and, following their development, some of the newborn chimeric mice may carry the altered allele in their germ cells, that is, sperm or eggs; these germ-line chimeras, when bred, enable the germ-line transmission of this DNA fragment to their descendants. (D) $TSG^{+/-}$ mice can be studied for tumor predisposition. They can also be bred with one another to determine if homozygosity for the TSG mutation leads to embryonic lethality. If $TSG^{-/-}$ animals survive to adulthood, they too can be studied for tumor predisposition. (E) Mice that are bred to be homozygous for a floxed allele of a TSG ($TSG^{Fl/Fl}$) can be made to carry an allele of *Cre* expressed from a tissue-specific promoter (TSP); these mice are used to determine the effects of conditional deletion of the TSG in a given tissue or cell type. Alternatively, a mutant estrogen-receptor fusion of *Cre* (*CreER*) that is activatable by a ligand of the ER can be used to control the timing of Cre activation through the addition of the drug tamoxifen (an estrogen analog and thus ER ligand). Adapted from H. Lodish et al., Molecular Cell Biology, 5th ed. New York: Freeman, 2004 and from B. Alberts et al., Molecular Biology of the Cell, 7th ed. New York: W.W. Norton & Company, 2022.

Studies of such mice reveal that recruitment of mast cells into incipient neurofibromas is critical to the formation of these histopathologically complex tumors. In mouse models of NF1 in which Schwann cells are engineered to become $Nf^{-/-}$ and the remaining cells—including the cells of the hematopoietic system—are $Nf1^{+/-}$, tumors termed *plexiform* neurofibromas form with high frequency at the roots of nerves emerging from the spinal cord. However, if the hematopoietic system (including the mast cells) of such mice is replaced with cells that are wild type (that is, $Nf1^{+/+}$), these cells are not as responsive to signals released by the $Nf1^{-/-}$ Schwann cells and are no longer recruited in large numbers to developing neurofibromas. The result is a drastic decrease in the numbers of these tumors (**Figure 7.18**). Such collaborations between multiple cell types in forming a tumor will be discussed in greater detail in Chapter 13.



Two images of dissected spinal cords from mice with N f 1 minus minus Schwann cells. The spinal cord on the left is from a mouse with N f 1 plus plus mast cells. The cord appears normal. The spinal cord on the right is from a mouse with N f 1 plus minus mast cells. The central column of the spinal cord is thickened, and five branching nerves have lumpy grows, neurofibromas, at the base.

(A)



A flowchart that begins with an N f 1 plus minus Schwann cell that undergoes loss of heterozygosity to become an N f 1 minus minus. If this is paired with wild type N f 1 plus plus mast cells that have normal responsiveness, the result is normal nerve sheaths. On the other hand, if the N f 1 minus minus Schwann cell is paired with haploinsufficient, hyper-responsive N f 1 plus minus mast cells, the result is recruitment of fibroblasts and endothelial cells, leading to formation of neurofibromas.

(B)

Figure 7.18 Contribution of genotype of surrounding tissue to neurofibroma development (A) In *Nf1*$^{+/+}$ mice in which the Schwann cells have specifically been rendered *Nf1*$^{-/-}$, the nerve roots emerging from the spinal cord (SC) exhibit a relatively normal morphology (*left*); hence, loss of all *Nf1* function in the target cells—the Schwann cells—does not suffice to allow abnormal neurofibromas to form. However, if, in addition, mast cells originating in the bone marrow are rendered *Nf1*$^{+/-}$, both a thickened spinal cord and plexiform neurofibromas (*arrows*) are readily apparent (*right*). Hence, a partial loss of *Nf1* function in mast

cells must cooperate with total loss of *Nf1* function in the Schwann cells to generate these growths. (B) The observations in panel A suggest that mast cells originating in the bone marrow are normally recruited to the developing spinal cord, where they contribute to normal morphogenesis. However, when these mast cells are $Nf1^{+/-}$—and thus are deprived of half of their neurofibromin protein—they and their progeny that are recruited to the developing spinal cord behave abnormally and become hyper-responsive to certain signals released by homozygous mutant $Nf1^{-/-}$ Schwann cells. This in turn causes the mast cells to trigger aberrant morphogenesis by collaborating with the Schwann cells to recruit yet other cell types, such as fibroblasts and endothelial cells, thereby generating the histopathologically complex neurofibromas. In patients who are born with an $Nf1^{+/-}$ genotype, some $Nf1^{+/-}$ Schwann cells may undergo LOH, generating $Nf1^{-/-}$ derivatives that recruit heterozygous ($Nf1^{+/-}$) mast cells from the bone marrow and resulting in the formation of neurofibromas. In fact, other work suggests that the $Nf1^{-/-}$ Schwann cells release elevated levels of stem cell factor (SCF), to which the $Nf1^{+/-}$ mast cells are hyper-responsive because the intracellular signaling pathway downstream of their SCF receptor is hyperactive as a consequence of hyperactive Ras protein. (A, from F.C. Yang et al., *Cell* 135:437–448, 2008. With permission from Elsevier.)

The observation that a half-normal dose of neurofibromin in the mast cells (or their immediate precursors) results in a clear and aberrant cellular phenotype raises a more general point about TSGs: although the full phenotypic changes associated with inactivation of these genes may only be felt when both gene copies are lost, a half-dosage of their encoded proteins (which is often observed in cells having a $TSG^{+/-}$ genotype) can in some instances yield subtle but functionally important changes in cell phenotype. Such behavior is a manifestation of haploinsufficiency, a state in which the presence of only a single functional copy of a gene yields a mutant or partially mutant phenotype (**Sidebar 7.3**).

Sidebar 7.3 Haploinsufficiency: when half a loaf is not much better than none

The Knudson paradigm of TSG inactivation postulates that mutant alleles are recessive at the cellular level. Hence, cells that are heterozygous for a TSG (that is, $TSG^{+/-}$) should be phenotypically normal. This is the case for individuals who inherit a mutant, inactive *Rb* gene, who only develop pathologies in cell populations that have lost the remaining wild-type *Rb* gene copy, usually by LOH, rendering these cells $Rb^{-/-}$; the remaining $Rb^{+/-}$ tissues throughout the body seem to develop normally and exhibit normal function.

However, there are perfectly good biochemical reasons to predict that cells expressing half the normal amount of a TSG protein might have a phenotype that deviates significantly from the wild type, and several clear examples of such haploinsufficiency have been observed. Mice carrying only one copy of the gene encoding the Smad4 transcription factor, which is used by TGF-β to inhibit cell proliferation (as we will see in Section 8.10), are predisposed to developing polyps in the stomach and small intestine, and the cells in these tumors continue to carry single copies of the wild-type allele of this gene. Mice that are heterozygous for the TSG $p27^{Kip1}$ are similarly prone to forming tumors, without indication of LOH in tumor cells; this gene encodes an important inhibitor of cell cycle progression (see Section 8.4). A third example is provided by mice that are heterozygous for the gene encoding the tumor suppressor protein PTEN (see Section 6.6), where a clear acceleration of prostate cancer tumorigenesis is created by the presence of only a single copy of this TSG. Finally, deletion of one copy of the *Dmp1* gene, which encodes a transcription factor that induces expression of the $p19^{ARF}$ TSG (see Section 9.7), leads once again to increased tumor susceptibility without loss of the wild-type gene copy in tumor cells. Analysis of cancer genomes has suggested there are many genes that could contribute to tumor formation through haploinsufficiency.

Given their role in regulating signaling through the Ras pathway, inactivation of neurofibromin or other Ras-GAPs might also be expected to occur sporadically in human cancers. Indeed, large-scale genome sequence analyses of human cancer specimens (as discussed in Section 12.12) have revealed somatic mutations in *Nf1* in a wide variety of human cancers, most notably in glioblastoma (a malignant tumor of the brain), lung cancer, and melanoma. Moreover, several other of the 13 documented Ras-GAPs encoded in the human genome have been shown to undergo mutation or epigenetic silencing in cancers (**Table 7.3**).

Table 7.3 Examples of Ras-GAPs mutated or silenced in human cancers

Gene	Ras-GAP protein	Cancers	Mechanism of inactivation
NF1	neurofibromin	neurofibromas, neurofibrosarcomas, glioblastomas, pheochromocytomas, lung cancer, melanoma, myelogenous leukemias	mutation

Gene	Ras-GAP protein	Cancers	Mechanism of inactivation
RASA1	p120 Ras-GAP	lung cancer, melanoma	mutation
RASA2	Ras p21 protein activator 2	range of cancers	mutation
DAB2IP	Disabled homolog 2-interacting protein	malignant progression in breast and prostate cancers	epigenetic silencing
RASAL2	Ras protein activator like 2	breast cancer	mutation and epigenetic silencing

OceanofPDF.com

Glossary

neurofibroma
: Benign tumor of cells forming the sheath around nerve axons.

neurofibrosarcoma
: Malignant tumor of cells forming the sheath around nerve axons.

malignant peripheral nerve sheath tumor
: A tumor, usually displaying mesenchymal traits, that often arises from a neurofibroma and derives from cells that form the cellular sheaths protecting peripheral nerves.

pheochromocytoma
: Tumor of the neural crest-derived cells of the adrenal glands that secrete elevated levels of certain hormones through which they may instigate a number of abnormal clinical symptoms.

café au lait spots
: Coffee-with-milk–colored spots on the skin that are seen characteristically in patients suffering the neurofibromatosis type 1 syndrome.

genetic background
: The entire array of alleles carried in a cell or organismic genome with the exception of a gene or a small number of genes that are the subject of study.

expressivity
: The quantitative extent to which a measurable or observable phenotype is expressed by an individual or cell carrying a specific allele or gene. *See also* **penetrance**.

myeloid
: (1) Referring to the lineages of hematopoietic cells that yield cells that are not lymphocytes and includes erythrocytes, platelets, granulocytes, monocytes, mast cells, and their derivatives. (2) Pertaining to or resembling bone marrow; often used as a synonym for myelogenous. *Compare* **lymphoid**.

neural crest
: Dorsal region of the early chordate embryo that contains cells serving as precursors of various specialized tissue and cell types, including

certain cells of the peripheral nervous system, bones of the face, melanocytes, and several types of neurosecretory cells.

blastocoel

Inner cavity present in a blastocyst.

blastocyst

An early stage of vertebrate embryogenesis in which the embryo consists largely of an outer layer of cells enclosing an inner cavity that contains a cell mass destined to form the embryo.

pseudopregnant

Referring to a female that has been placed in a physiological state that closely resembles that of pregnancy, achieved through exposure to certain hormones.

pluripotent

Referring to the ability of a stem cell to generate progeny that can participate in the formation of all of the tissues of an embryo except the extraembryonic membranes. *See also* **multipotent**, **totipotent**.

germ-line chimera

An organism in which the germ cells derive from more than one genetic background.

essential genes

The collection of genes that is required for normal organismic development and viability or for normal cellular viability or behavior. *See also* **essentialome**.

haploinsufficiency

Genetic condition in which the presence of only a single functional copy of a gene yields a mutant or partially mutant phenotype.

chimerized

(1) Referring to the protein product of a re-engineered gene in which two portions of the protein derive from two distinct sources, such as two distinct species. (2) Describing an antibody molecule whose constant (C) region amino acid sequences have been replaced by the homologous sequences from another species, e.g., one in which a mouse C region is replaced by a human C region.

7.10 APC facilitates egress of cells from colonic crypts

Although the great majority (>95%) of colon cancers appear to be sporadic, a small group arises as a consequence of inherited alleles that create substantial lifelong risk for this disease. One form of familial colon cancer, referred to as hereditary nonpolyposis colon cancer (HNPCC) or Lynch syndrome, is caused by inherited mutations in a class of DNA repair genes. We will discuss HNPCC further in Chapter 12. Here we focus on the other major familial colon cancer syndrome, termed adenomatous polyposis coli (APC) or, more commonly, familial adenomatous polyposis (FAP). At relatively young ages, patients with FAP develop hundreds or thousands of growths or polyps in the colon (**Figure 7.19**). Although these polyps are themselves nonmalignant, they are prone to develop into carcinomas at a low but predictable frequency. FAP is responsible for a bit less than 1% of all colon cancers in the West.

Two images of a colon wall. The one on the left is pink and has the normal folded texture. The one on the right is more orange and is covered with tiny polyps.

Figure 7.19 Familial adenomatous polyposis The wall of a normal colon is convoluted but smooth (*left*); in an individual afflicted with familial adenomatous polyposis (FAP), the colon wall is often carpeted with hundreds of small polyps (*right*). The structure of one type of colonic polyp is shown in Figure 2.14A. (Courtesy of A. Wyllie and M. Arends.)

The *Apc* gene, which is inherited in mutant form in FAP patients, was cloned in 1991 following a series of genetic mapping studies that pinpointed its location on Chromosome 5 (**Sidebar 7.4**). As in the case of the *Rb* gene, *Apc* follows a classic

TSG cancer-associated mutation pattern. In FAP, patients inherit one mutant allele of the gene and accumulate mutations or LOH to inactivate the remaining wild-type allele. In sporadic colon cancer, in which *Apc* gene mutation occurs in ~90% of cases, the complete loss of *Apc* function occurs through two sequential steps, another example of the Knudson “two hit” mechanism (see Figure 7.4). Characterization of the wild-type *Apc* gene product (also called APC) has led to new insights into the control of intestinal stem cells and the normal maintenance of epithelial tissues. As we discuss in greater detail in later chapters, the epithelia in the colon and duodenum are organized in a fashion that is typical of a number of epithelia throughout the body. In these tissues, groups of relatively undifferentiated stem cells yield two distinct daughter cells when they divide: one daughter remains a stem cell, thereby ensuring that the number of stem cells in the tissue remains constant; however, the other daughter cell and its descendants become committed to differentiate.

Sidebar 7.4 Special human populations facilitate the detection of heritable cancer syndromes and the isolation of responsible genes

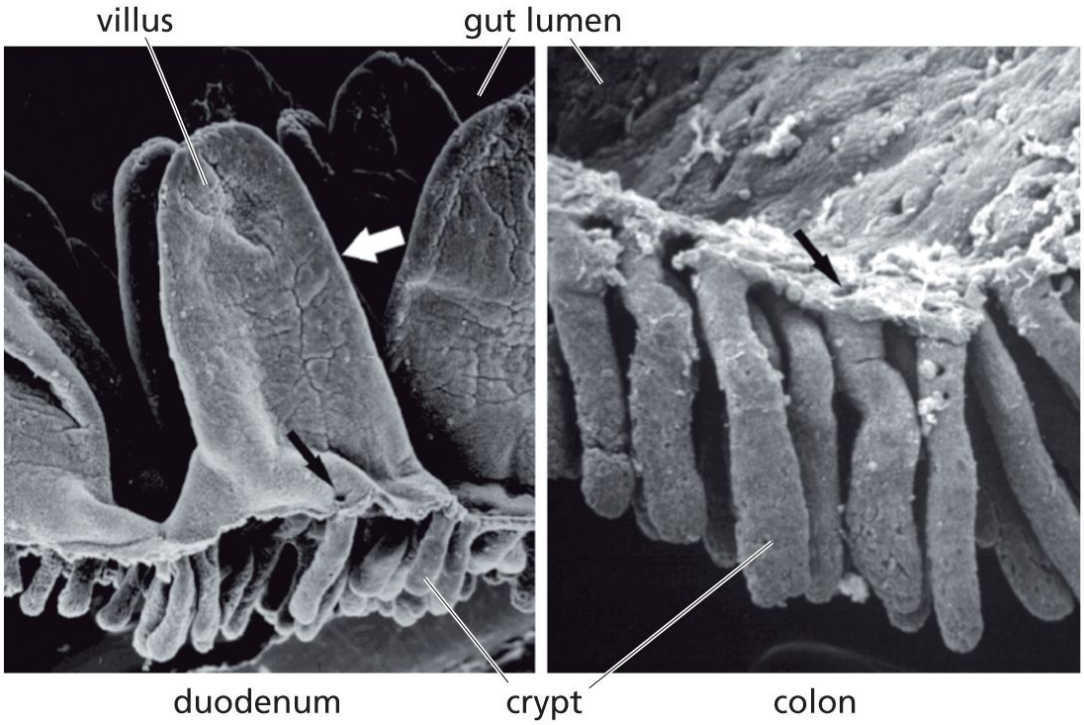
The Mormons in the state of Utah represent a population that provides a golden opportunity to understand the genetics of various types of heritable human diseases. A substantial proportion of these individuals can trace their ancestry back to a relatively small group of founding settlers who arrived in Utah in the mid-nineteenth century. Mormon couples have traditionally had large numbers of children and have reproduced relatively early in life, leading to large, multigenerational families—ideal subjects of genetic research.

In addition, the Mormon church maintains the world’s largest genealogical archive in Salt Lake City, which facilitates the assembly of multigenerational pedigrees. Such extensive pedigrees enabled geneticists to trace with precision how the mutant allele of a gene predisposing a person to familial adenomatous polyposis is transmitted through multiple generations of a single large family and how this allele operates in a dominant fashion to increase the susceptibility to colonic polyps and risk of colon cancer.

The use of linkage analysis, in which the genetic transmission of this predisposing allele was connected to anonymous genetic markers on various human chromosomes, revealed that this allele was repeatedly co-transmitted from one generation to the next together with genetic markers on the long arm of human Chromosome 5. This localization, together with more detailed LOH analyses, eventually made possible the molecular cloning of the *Apc* gene in 1991.

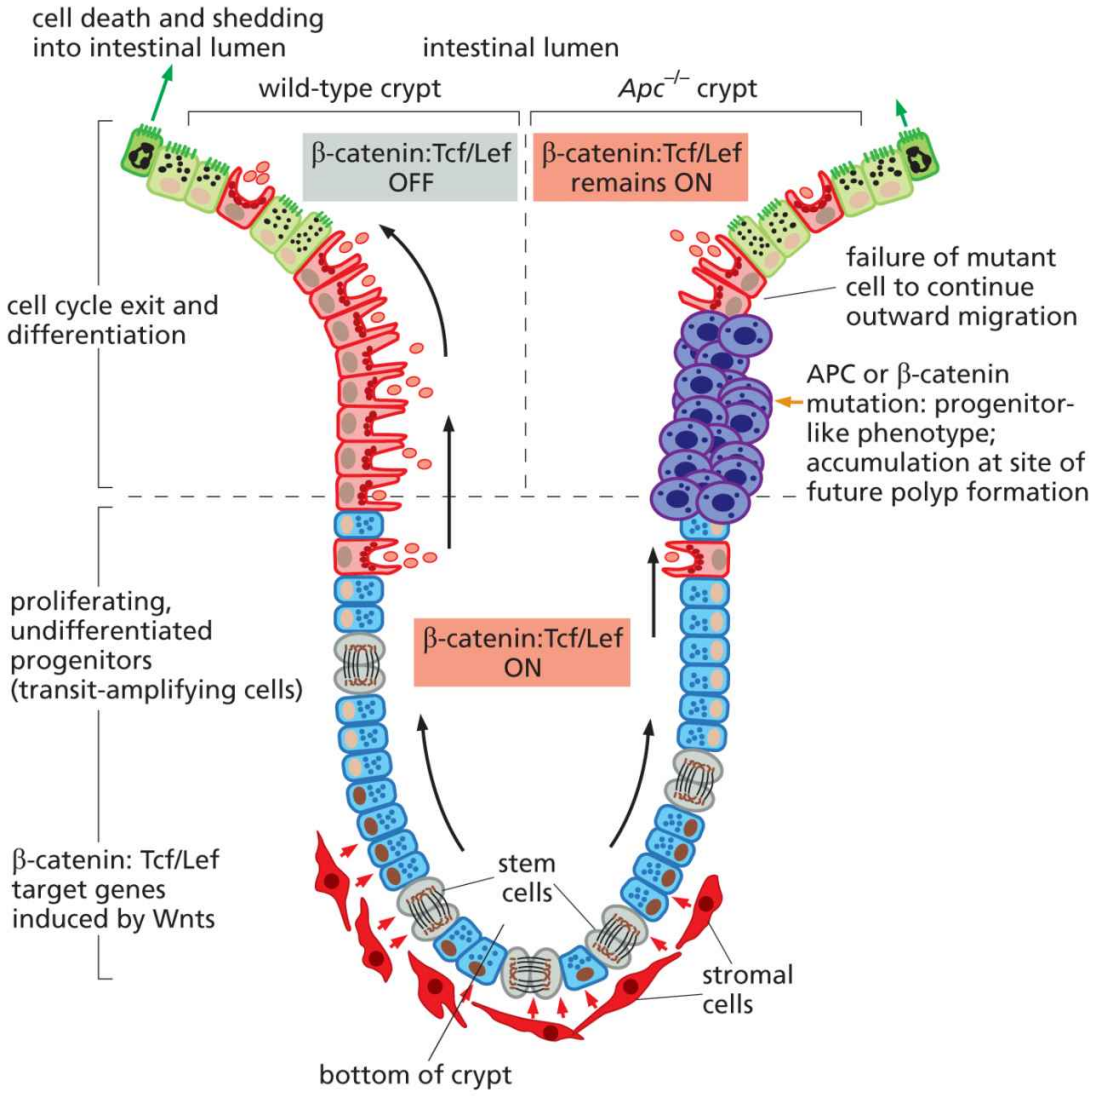
In the small intestine, some of these differentiated epithelial cells participate in absorbing nutrients from the lumen and transferring these nutrients into the circulation;

in the colon, many of them absorb water from the lumen. Yet other specialized epithelial cells secrete mucin (a mucus-like material) that helps to protect the colonic epithelium from the contents of the lumen. In the gastrointestinal tract, these various epithelial cells are termed enterocytes. In both parts of the intestine, enterocytes are born in deep, mucin-filled cavities termed crypts, which initially shield them from the contents of the intestine (**Figure 7.20A**).



Two scanning electron micrographs. The left image shows large villi rising up in the duodenum, each surrounded by many small crypts hanging down. The right image shows a relatively flat intestinal wall with many many small crypts hanging down.

(A)



A diagram of the structure of a single colonic crypt. At the bottom of the crypt, stem cells replicate under the influence of W n tees from stromal cells that surround the crypt. Proliferating, undifferentiated offspring cells migrate up the sides of the crypt, toward the lumen above. In this lower part of the crypt, beta catenin T c f L e f is on and targets certain genes. Higher up, with normal, wild-type development beta catenin T c f L e f switches off. This is the part of the crypt where cell cycle exit and differentiation occurs. At the top of the crypt, cell death and shedding into the intestinal lumen occurs. On the other hand, when the A P C protein is defective, beta-catenin T c f L e f remains on. APC or beta-catenin mutation leads to cells with a progenitor-like phenotype. These still-undifferentiated cells fail to continue outward migration, accumulate within crypts, and may ultimately generate an adenomatous polyp.

(B)

Figure 7.20 β-Catenin and the biology of colonic crypts (A) As seen in these scanning electron micrographs, the linings of the small (*left*) and large (*right*) intestines are organized similarly, with deep crypts in which stem cells reside; new enterocytes produced in these crypts migrate up toward the lumen of the gut, differentiate, and emerge, via small openings (*narrow black arrows*). In the duodenum, however, these newly born cells continue their upward migration along the sides of the fingerlike villi that protrude into the lumen (*broad white arrow*). (B) At the bottom of the colonic crypt, replicating stem cells (*gray*) receive paracrine Wnt signals (*red arrows*) from neighboring stromal cells (*red*), which keeps their levels of β-catenin high. Within individual enterocytes at the bottoms of the crypts, the β-catenin molecules migrate to the nucleus and associate with Tcf/Lef transcription factors; this complex activates genes that enhance proliferation of these cells and prevents their differentiation. In the normal intestine (*left side of crypt*), many of the progeny of these stem cells migrate upward toward the lumen (*above*). As they do so, stimulation by Wnts decreases and intracellular levels of APC increase; these two changes together lead to increased degradation of β-catenin, which results in cessation of proliferation and increased differentiation as these cells approach the lumen; ultimately, the cells undergo apoptosis and are shed into the lumen (*small green arrow*). In contrast, when the APC protein is defective (*right side of crypt*), β-catenin levels remain high, even in the absence of intense Wnt signaling, and proliferating, still-undifferentiated cells (*purple*) fail to migrate upward, accumulate within crypts, and may ultimately generate an adenomatous polyp. (A, from M. Bjerknes and H. Cheng, *Methods Enzymol.* 419:337–383, 2006. B, from M. van de Wetering et al., *Cell* 111:251–263, 2002. Both with permission from Elsevier.)

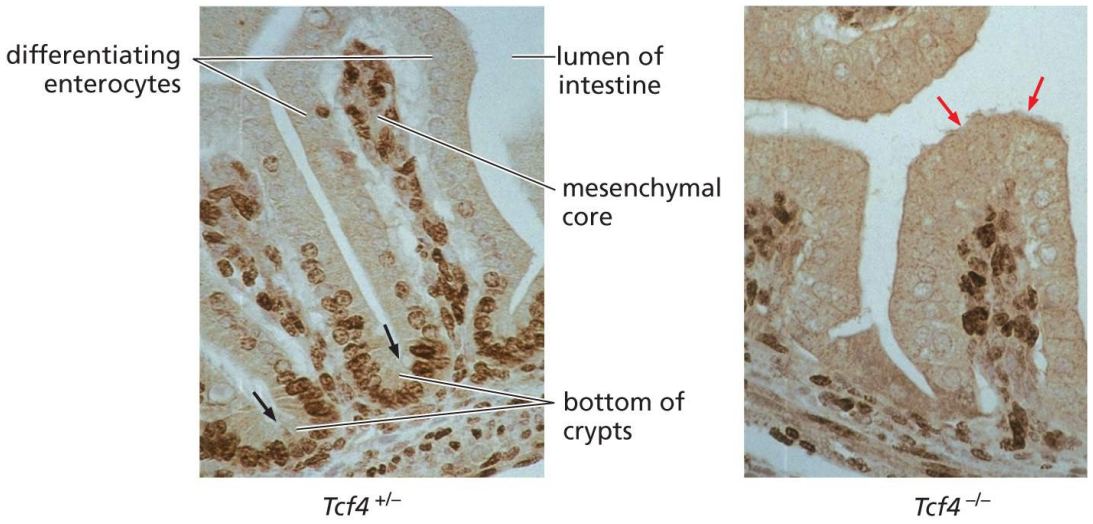
The locations of the stem cells and more differentiated cells in a colon crypt are illustrated in (Figure 7.20B). Although some of the progeny of these stem cells stay behind to maintain a constant number of stem cells, others are dispatched upward and out of the crypts toward the luminal surface of the epithelium, where they will function briefly to form the epithelial lining of the gut; they subsequently die by apoptosis and are shed into the colonic lumen. In the human colon, this entire process of out-migration and death takes only 3 to 4 days.

The scheme depicted in Figure 7.20B represents a highly effective defense mechanism against the development of colon cancer, because almost all cells that may have sustained mutations while on duty protecting the colonic wall are doomed to die within days after they have been formed. By this logic, the only type of mutations that could lead to the development of a cancer would be those mutations (and resulting mutant alleles) that block both the out-migration of colonic epithelial cells from the crypts and

the cell death that follows soon thereafter. Should a colonic enterocyte acquire such a mutation, this cell and its descendants could accumulate in the crypt, and any additional mutant alleles acquired subsequently by their progeny would be similarly retained in the crypt, rather than being rapidly lost through out-migration and apoptosis. Such additional mutations might include, for example, genes that push the progeny toward a neoplastic growth state.

The protein called β-catenin governs much of this out-migration behavior. As described in Section 6.10, levels of soluble β-catenin in the cytoplasm are controlled by the Wnt family of growth factors and other accessory proteins. When Wnts bind cell surface receptors, β-catenin is saved from destruction; the protein then accumulates and migrates to the nucleus, where it associates with a group of DNA-binding proteins termed Tcf/Lef (see Figure 6.19B). The resulting heterodimeric transcription factor complexes ultimately activate expression of a series of target genes that program (in the case of enterocytes) the stem cell phenotype.

In the context of the intestinal crypts, enterocyte stem cells encounter Wnt factors that are released by neighboring Paneth cells in the small intestine and mesechymal stromal cells in the colon, located near the bottom of the crypt, leading to high β-catenin levels in the stem cells (see Figure 7.20B). Indeed, the β-catenin:Tcf4/Lef transcription factor complex is required for the formation of these stem cells (**Figure 7.21**). However, as the progeny of these stem cells begin their upward migration, they leave the Wnt signaling zone and their intracellular β-catenin levels fall precipitously. As a consequence, these cells lose their stem cell phenotype, exit the cell cycle, and differentiate into functional enterocytes.



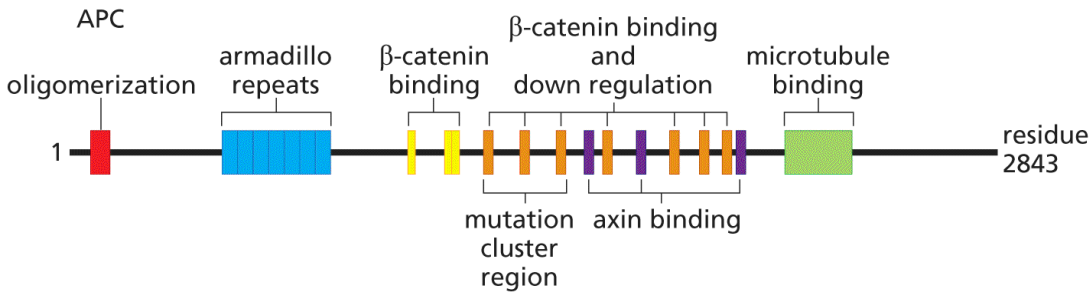
Two histology images. In the one on the left, crypts in the intestinal tissue of T c f 4 plus minus mice are dense with large nuclei. So, unrelatedly, are cells in the mesenchymal cores of nearby villi. Differentiating enterocytes, on the other hand,

have few visible nuclei. In the right image, crypts in the intestinal tissue of T c f 4 minus minus mice, the curved pockets of proliferating stem cells at the bottoms of crypts are absent.

Figure 7.21 The Tcf4 transcription factor and crypt development The formation of the stem cell compartment near the bottoms of small intestinal crypts depends critically on high levels of β-catenin and on its ability to associate with the TCF4 protein in the nucleus to form an active transcription factor complex. As seen in this figure, epithelial cells in the bottoms of the crypts of the small intestine of *Tcf4*$^{+/-}$ mice (*black arrows, left panel*) are highly proliferative, as evidenced by the staining for Ki67, a marker of cell proliferation (*dark brown nuclei*). As they move out of the crypt up the sides of the villi, they lose proliferative potential. (Although the mesenchymal cells in the core of each villus are also highly proliferative, their behavior is unrelated to that of the epithelial enterocytes.) In *Tcf4*$^{-/-}$ mice (*right panel*), in contrast, a layer of enterocytes is initially formed (*red arrows*), but there are no proliferating stem cells at the bottom of the crypts; therefore, new enterocytes are not continually formed to replace those lost by apoptosis and sloughing into the intestinal lumen. (From V. Korinek et al., *Nat. Genet.* 19:379–383, 1998. With permission from Nature.)

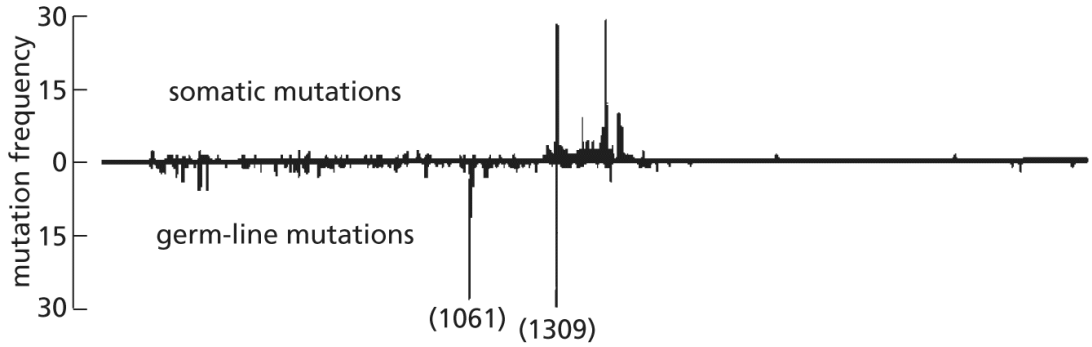
The APC protein is normally responsible for negatively controlling the levels of β-catenin in the cytosol. In stem cells, the action of APC is inhibited through the effects of Wnt signaling, allowing β-catenin to accumulate. However, as cells begin to move out of the crypts, the declining concentration of Wnts and other factors, plus the increased levels of *Apc* expression in these cells, leads to a significant decline in intracellular levels of β-catenin cited above and thus the levels of nuclear β-catenin:Tcf/Lef transcription factor complexes.

The molecular mechanism of action of APC helps to explain these declining levels of intracellular β-catenin: APC is a large protein of 2843 amino acid residues that can associate with β-catenin (**Figure 7.22A**). Together with scaffolding proteins, APC forms a multiprotein complex that brings together glycogen synthase kinase-3β (GSK-3β) and β-catenin (see Figure 6.19B). This association enables GSK-3β to phosphorylate four amino-terminal residues of β-catenin, an event that leads to the degradation of β-catenin via the ubiquitin–proteasome pathway (**Supplementary Sidebar 7.5**). APC is thus essential for triggering the degradation of β-catenin; in its absence, β-catenin levels accumulate to high levels within cells.



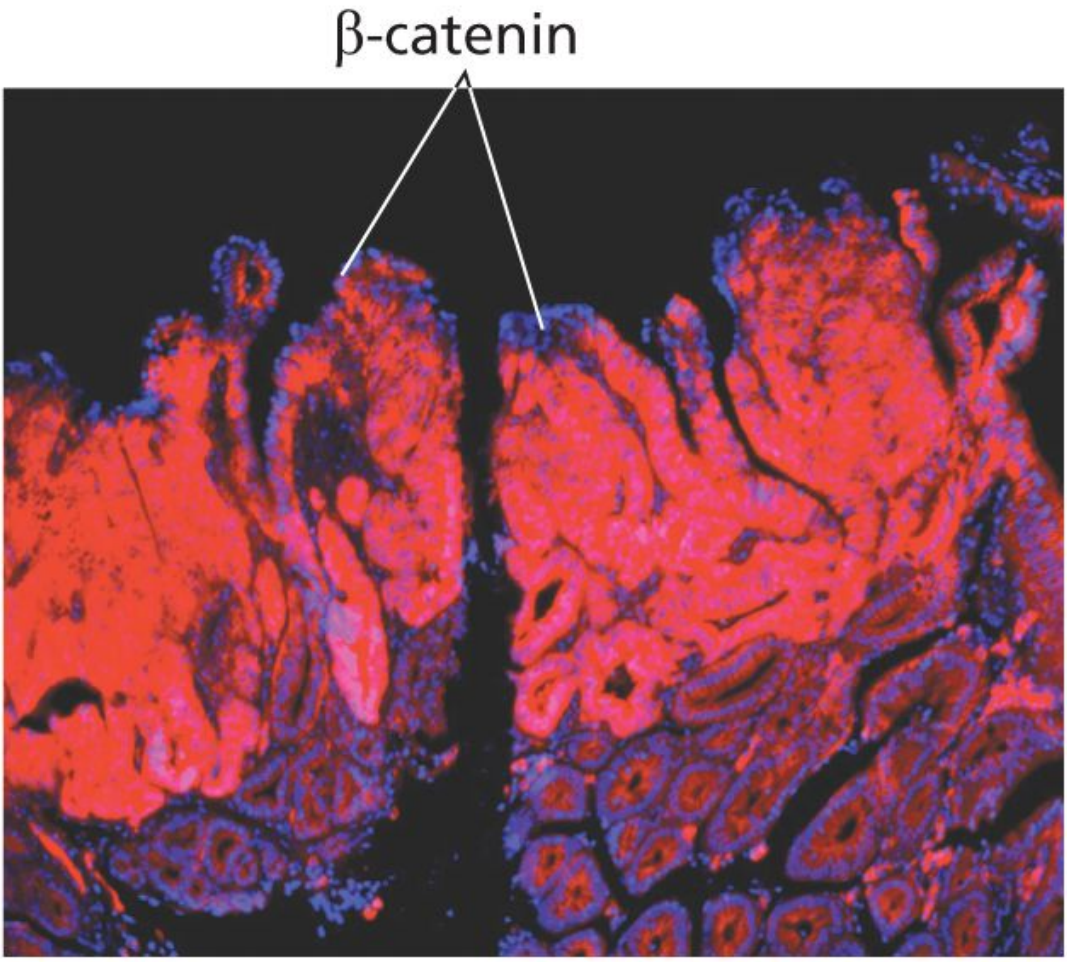
The multidomain structure of the protein A P C. The left end is labeled 1, the right end is labeled residue 2 8 4 3. In between, from left to right, are segments labeled oligomerization, armadillo repeats, beta catenin binding, beta catenin binding and down regulation with sub-parts labeled mutation cluster region and axin binding, and microtubule binding.

(A)



The frequencies of somatic and germ-line mutations along the A P C protein. The vast majority of Germ-line mutations occur either in the beta catenin binding region or the mutation cluster region. The vast majority of somatic mutations occur in the mutation cluster region.

(B)



A fluorescence microscopy image of adenoma cells, stained bright pink, overlying normal cells in which blue nuclei are visible.

(C)

Figure 7.22 *Apc* mutations andβ-catenin (A) This diagram outlines the multidomain structure of APC. The interactions of the microtubule-binding domain (*light green*) are important for proper regulation of cell motility and mitosis (see **Supplementary Sidebar 7.6**). (B) This plot shows the spectrum of *Apc* mutations and where they occur with relation to the domains outlined in (A). As can be seen, the mutations that occur with high frequency tend to affect APC's ability to bind to β-catenin. (C) In the Min mouse model of familial polyposis, an inactivating point mutation was introduced into the *Apc* gene by the actions of a mutagenic chemical. The chromosomal region carrying this mutant allele undergoes LOH in some cells within intestinal crypts. In these cells, which lack all APC activity, β-catenin is no longer degraded, accumulates to high levels, and enters the cell nuclei, where it collaborates with Tcf/Lef transcription factors to

drive expression of growth-promoting genes and prevent the usual exit of cells from the crypt. The result is a clonal outgrowth within the crypt, such as the adenoma seen here, in which the β-catenin is visualized by immunostaining (*pink*, *above*). The nuclei in all cells, including those of the normal crypts (*below*), are seen in *blue*. (A and B, from P. Polakis, *Biochim. Biophys. Acta* 1332:F127–F147, 1997, and adapted from R. Fodde et al., *Nat. Rev. Cancer* 1:55–67, 2001. With permission from Elsevier. C, courtesy of K.M. Haigis and T. Jacks.)

With this mechanism in mind, we can see a clear role for the mutation of *Apc* in colon cancer, whether it is inherited, as in FAP patients, or occurs via two independent mutational events, as in the high percentage of cases of the sporadic form of the disease. Cataloging the spectrum of *Apc* mutations found in human colon cancers reveals many mutations that cause premature termination of translation of the APC protein, thereby removing domains that are important for its ability to associate with β-catenin and the scaffolding protein axin and for the resulting degradation of β-catenin (Figure 7.22B).

The accumulation of β-catenin (Figure 7.22C) is clearly the most important consequence of *Apc* inactivation. One can draw this conclusion from studying the minority of sporadic colon carcinomas (approximately 10%) that carry wild-type *Apc* alleles. In some of these, the *Apc* gene promoter is hypermethylated and rendered inactive. In others, the gene encoding β-catenin carries point mutations, and the resulting mutant β-catenin molecules lose the amino acid residues that are normally phosphorylated by GSK-3β. Because they cannot be properly phosphorylated, these mutant β-catenin molecules escape proteasomal degradation and accumulate—precisely the outcome that is seen when APC is missing.

When β-catenin accumulates in enterocyte precursors—as a result of APC inactivation or alternative mechanisms—the affected cells retain a progenitor cell-like phenotype, which prevents them from migrating out of the crypts. This retention leads, in turn, to the accumulation of large numbers of relatively undifferentiated cells in the colonic crypt (see Figure 7.20B), which eventually form adenomatous polyps. Equally important, these accumulating cells can later sustain additional mutations that enable them to form more advanced polyps and, following even more mutations, carcinomas.

This model explains the sequence of mutations that, over time, leads to the formation of human colon carcinoma cells. The first of these mutations invariably involves inactivation of *Apc* function (or the functionally equivalent changes mentioned above). The resulting cells, now trapped in the crypts, may then suffer mutations in a number of other genes—such as K-*ras* (see Chapter 4) and *p53* (see Chapter 9)—which cause the cells to proliferate more aggressively. Importantly, alterations of the APC–β-

catenin pathway nearly always come first, whereas the order of the subsequent genetic changes is more variable.

Many important insights into the function of this pathway in cancer came from the study of mouse models of colorectal cancer. In the early days, such models were generated by random, chemically induced mutagenesis followed by selection for the phenotype of interest—in this case, the appearance of intestinal adenomas in the mutant animals. One of the earliest models of colon cancer, dubbed the *Min* mouse (for its multiple intestinal neoplasias), was developed in this manner. These animals, which can develop 100 polyps in the small intestine in addition to colon tumors, were later found to contain heterozygous point mutations in the *Apc* gene. Tumor cells in these mice were shown to undergo LOH to eliminate the remaining wild-type *Apc* allele.

As discussed above, today biologists have access to more sophisticated genetic tools for inactivating or "knocking out" specific genes in a more targeted fashion—including genes suspected of being TSGs (see Sidebar 7.2 and Figure 7.17). Like *Min* mice, mice engineered to have one inactive *Apc* allele ($Apc^{+/-}$) are predisposed to develop intestinal tumors. Using a conditional knockout strategy (see Figure 7.17) to mutate the *Apc* gene specifically in intestinal stem cells, researchers discovered that this targeted inactivation fueled the growth of microscopic tumors at the base of the crypts. These microadenomas then expanded unimpeded, forming adenomas within a matter of weeks. In contrast, elimination of *Apc* function in the short-lived transit-amplifying cells triggered the formation of microadenomas whose growth rapidly fizzled out; full-blown adenomas were rarely found in these mutant mice. These observations reinforce the notion that loss of *Apc* in stem cells is the event that drives colon cancer.

Another form of conditional inhibition of *Apc* function relies on the use of inducible expression of short hairpin RNAs (shRNAs), which target the gene for inactivation through the RNA interference (RNAi) pathway, as will be discussed in Chapter 12. In these experiments, suppressing *Apc* function with an *Apc*-targeted shRNA generates tumors in mice, as would be expected. What is surprising, however, is that shutting off the shRNA—which restores the expression of *Apc*—leads to rapid tumor regression, even in highly advanced tumors. Hence, as discussed later in Chapter 11, the mutant allele that initiated the multi-step development of a tumor continues to be critical to its ongoing growth long after additional mutant alleles have been acquired by the cancer cells. Conditional knockouts and conditional RNAi approaches are now being used widely to interrogate TSG function.

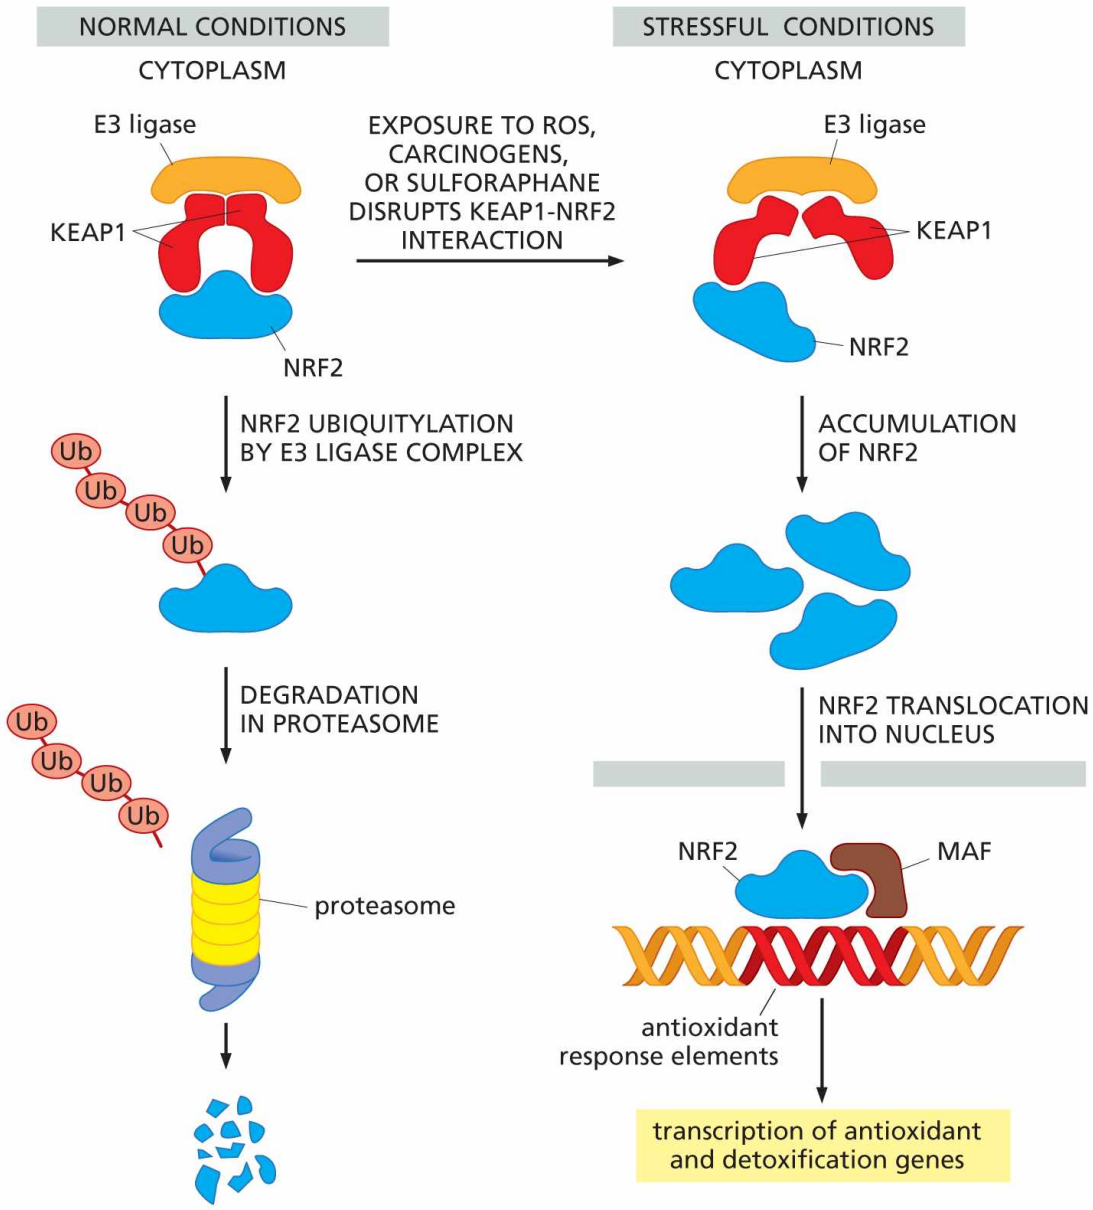
7.11 KEAP1 regulates cellular response to oxidative stress

Thus far, we have focused mainly on TSGs whose primary function is related to constraining cell proliferation. Mutation of these genes would be expected to liberate a developing cancer cell from a variety of growth-inhibitory mechanisms and allow increased, inappropriate proliferation. Consistent with this role in proliferation control, mutations in such genes typically occur in the early stages of tumorigenesis and can serve as the initiating events for certain cancer types. However, TSGs can also control processes linked to disease progression—that is, the acquisition of more aggressive phenotypes that occurs later in the multi-step process of tumorigenesis. Mutant alleles of these types of genes would be selected for only at later stages of tumorigenesis. One prominent example of such a TSG is *Keap1*, a gene that encodes the protein KEAP1 (Kelch-like ECH-associated protein 1), which is mutated in a significant percentage of lung and other cancers.

In normal cells, KEAP1 acts as a sensor for a variety of chemical and environmental stresses—from the carcinogens in cigarette smoke and the phytochemicals produced by the plants we eat to the reactive oxygen species (ROS) generated by cells as a by-product of oxidative metabolism and intracellular signaling pathways. When detected by KEAP1, such chemically reactive, toxic compounds activate a cellular response program that directs the expression of a suite of genes encoding various cellular antioxidants and detoxification enzymes. This defensive response relies on the interaction of KEAP1 and the transcription factor called NRF2.

In the absence of oxidative stress, KEAP1 sequesters NRF2 in the cytoplasm and targets this protein for ubiquitylation and degradation; as a result, this protein has a lifetime of only 20 minutes (see **Supplementary Sidebar 7.5**). This ongoing targeted destruction of NRF2 minimizes the activity of the antioxidant response pathway under normal conditions (**Figure 7.23**). However, when cells are exposed to ROS or other toxic molecules, these chemicals react with key cysteine residues in KEAP1, which causes KEAP1 to release NRF2. Once liberated from KEAP1, NRF2 is free to translocate to the nucleus, where it joins with members of the MAF transcription factor family as well as other transcription factors and binds to genes whose promoters include antioxidant responsive element (ARE) sequences. In this way, NRF2 orchestrates the activation of a series of genes involved in cellular detoxification (see Figure 7.23). Once the reactive compounds have been cleared, the chemical modifications to the KEAP1 cysteines are reversed, allowing the protein to again sequester NRF2 and trigger its degradation in the cytoplasm.



Two diagrams show K E A P 1-N R F 2 interaction under normal conditions and stressful conditions. Under normal conditions, two copies of K E A P 1 bind to one copy of N R F 2 and one copy of E3 ligase. N R F 2 undergoes ubiquitylation by the E3 ligase complex, resulting in it being released with a chain of you bees attached. It then undergoes degradation in a proteasome. Under stressful conditions, such as exposure to R O S, carcinogens, or sulforaphane, the binding between K E A P 1, N R F 2, and E3 ligase is not completed. Instead of undergoing ubiquitylation and degradation, N R F 2 accumulates in the cytoplasm, translocates into the nucleus, and together with M A F binds to the antioxidant response elements in a gene. This prompts transcription of antioxidant and detoxification genes.

Figure 7.23 KEAP1, NRF2, and the cellular antioxidant response In normal cells, the KEAP1–NRF2 pathway monitors the cellular environment and, upon exposure to ROS, carcinogens, or other chemically reactive compounds, activates an elaborate transcriptional program that boosts the production of cellular antioxidants and detoxifying enzymes. Under normal conditions, in the absence of these reactive chemicals, KEAP1 sequesters NRF2 in the cytoplasm (*left*). This interaction brings NRF2 in contact with a protein complex containing an E3 ligase—an enzyme that recognizes NRF2 and tags it with a polyubiquitin (Ub) chain. Polyubiquitylated NRF2 is then degraded in a proteasome (as described in Supplementary Sidebar 7.5). This destruction of NRF2 keeps the activity of the antioxidant response pathway low. Exposure to chemically reactive compounds disrupts the binding of KEAP1 and NRF2 (*right*). Once released from KEAP1, NRF2 accumulates and enters the nucleus, where it couples with a MAF transcription factor and activates expression of genes containing an antioxidant-reactive element (ARE) in their promoters. These genes encode a variety of proteins that act as antioxidants and detoxifying enzymes.

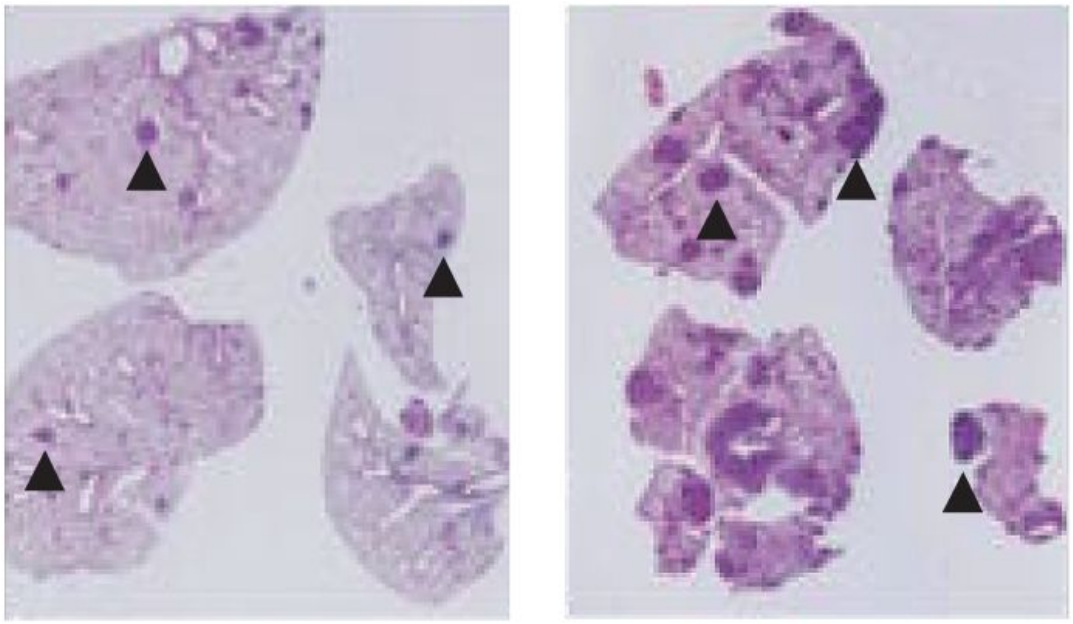
By eliminating carcinogens and disarming ROS that could otherwise damage DNA and other cellular constituents, this cellular detoxification program can prevent cancer initiation and progression. However, in cells that are already malignant, activation of this pathway can provide a selective advantage, both by thwarting chemotherapies and allowing cells to survive and grow under conditions of higher levels of oxidative stress. Indeed, changes in their metabolism often cause cancer cells to produce high concentrations of ROS. Under these conditions, cancer cells that boost their detoxification ability may have a marked selective advantage.

Some cancers achieve this detoxification boost by mutating *Keap1*. Loss-of-function mutations in *Keap1* can chronically upregulate the NRF2-dependent detoxification pathway. In one study, inactivating mutations in *Keap1* were found in the genomes of half of the lung cancer cell lines examined. These mutations included missense mutations (which cause an amino acid substitution in the protein), deletions, frameshift mutations, and nonsense mutations (which cause premature truncation of the protein)—all of which are characteristic of the types of loss-of-function mutations associated with other TSGs. Subsequent large-scale cancer genome sequencing studies (as described in Chapter 12) extended these findings to large numbers of primary cancer specimens. Among the numerous human cancers profiled, adenocarcinomas and squamous cell cancers of the lung were found to have the highest frequency of *Keap1* mutations (17 and 12%, respectively), although *Keap1* mutations were also observed in other cancer types at significant frequency. The same studies also found that the chromosomal region around *Keap1* is a frequent target of LOH in lung cancers and other cancer types. In addition, many cancers—particularly those of lung and prostate

—show hypermethylation of the *Keap1* promoter, another common means of functionally inactivating TSGs, as discussed earlier in this chapter.

As an alternative to inactivating mutations in *Keap1*, the KEAP1–NRF2 pathway can also be made constitutively active by mutations in the *Nrf2* gene. In contrast to those seen in *Keap1*—which affect a variety of amino acids throughout the KEAP1 sequence—the cancer-associated mutations in *Nrf2* are narrowly targeted to the sequences encoding the amino acid residues that mediate NRF2 binding to KEAP1. These gain-of-function mutations prevent KEAP1-mediated degradation of NRF2 while preserving its ability to activate antioxidant-responsive genes. Hence, both the inactivating *Keap1* mutations and the gain-of-function *Nrf2* mutations lead to constitutive activation of the pathway. Analogous to the cancer-causing mutations that affect either the APC or the β-catenin genes within a given colorectal carcinoma genome (see Section 7.10), those cancers that carry mutations activating the antioxidant response pathway affect either *Keap1* or *Nrf2* but not both genes.

Functional studies in mice have confirmed the importance of the KEAP1–NRF2 pathway in tumor progression. For example, targeted inactivation of *Keap1* in a mouse model of lung adenocarcinoma using CRISPR-Cas9—a powerful gene editing technique described in Sidebar 12.11—led to accelerated growth and a significant expansion in the volume of primary tumors (**Figure 7.24A**). These tumors exhibited increased levels of nuclear NRF2 as well as increased expression of NRF2 target genes. Interestingly, *Keap1*-deficient tumors and cell lines also show altered metabolic requirements, which may suggest novel targets for cancer therapy. In other mouse models of lung and pancreatic cancer, inactivation of *Nrf2* significantly inhibited tumor development (Figure 7.24B). These animal studies provide strong evidence for the pro-tumorigenic effect of constitutive activation of the antioxidant pathway, as driven by inactivation of KEAP1. The loss of KEAP1 thus creates an intracellular environment that enables evolving neoplastic cells to tolerate a variety of tumor-promoting alterations.



Two histology images, comparing K e a p plus plus to K e a p minus minus. Dark lumps within the tissue samples are larger and darker in the K e a p minus minus image.

(A)

(B)

Figure 7.24 Effects of inactivating mutations in the *Keap1* and *Nrf2* genes on lung tumor development (A) Inactivation of the *Keap1* gene in a mouse model of lung adenocarcinoma leads to larger and more advanced tumors. The left panel shows hematoxylin plus eosin (H&E) staining of lungs containing adenomas (*black arrowheads*) formed in a genetically engineered mouse model of lung cancer in which *Keap1* is wild type. CRISPR-Cas9–mediated deletion of *Keap1* in this model (*right panel*) results in larger, more advanced tumors (*black arrowheads*). (B) In a related model of lung cancer, germ-line deletion of *Nrf2* (*right panel*) causes a reduction in the size of hyperplasias (*black arrows*) and adenomas (*black arrowheads*) compared to those seen in mice with wild-type *Nrf2* (left panel). Note that images in (B) are taken at higher magnification than those in (A). A, from R. Romero et al. *Nature Medicine* 23(11):1362-1368, 2017. Reprinted with permission from Springer Nature. B, from G. DeNicola et al., *Nature* 475:106-109, 2011. Reprinted with permission from Springer Nature.)

Finally, because the KEAP1–NRF2 pathway is important for detoxifying mutagenic carcinogens, mutations in *Keap1* and *Nrf2* can affect the potency of certain chemical carcinogens, at least in animal studies. Mutations in *Keap1* that lead to pathway activation in the mouse can inhibit tumorigenesis induced experimentally by mutagenic carcinogens, presumably because these chemicals are more effectively detoxified. Interestingly, mutations that inactivate *Nrf2* can *enhance* cancer initiation in response to such mutagenic agents but *reduce* the subsequent progression of these cancers to full-fledged malignancy (because they are less capable of coping with the oxidative stress conditions found in highly malignant cells). This observation reflects the differing roles that can be played by the antioxidant response at different stages of multi-step tumor progression.

7.12 Not all familial cancers can be explained by inheritance of mutant TSGs

Many of the cloned TSGs listed in Table 7.1—and indeed, many of the TSGs we have discussed in this chapter—are involved in both familial and sporadic cancers. Generally speaking, this means that inheritance of defective copies of these genes creates a greatly increased risk of developing one or another specific type of cancer, often a type of tumor that is otherwise relatively rare in the human population.

However, not all familial cancer syndromes can be traced back to an inherited TSG allele. As we will discuss in Chapter 12, mutant germ-line alleles of a second class of genes also cause cancer predisposition. These other genes are normally responsible for maintaining the cellular genome and thus act to reduce the likelihood of mutations and chromosomal abnormalities will accumulate. Because cancer pathogenesis depends on the accumulation by individual cells of multiple somatic mutations, genes that reduce the mutation rate, such as these genome maintenance genes, are highly effective in suppressing cancer onset. Conversely, defects in genome maintenance often lead to a significant increase in cancer risk because they increase the overall mutation rate of a cell.

Thus, there are really two distinct classes of familial cancer genes: the TSGs described in this chapter and the genome maintenance genes described in Chapter 12. We can rationalize the distinction between the two classes of genes as follows. The TSGs function to directly control the biology of cells by affecting how they proliferate, differentiate, or die; genes functioning in this way are sometimes called gatekeepers to indicate their role in allowing or disallowing cells to progress through cycles of growth and division. The DNA maintenance genes affect cancer cell biology only indirectly by controlling the rate at which cells accumulate mutant genes; these genes have been termed caretakers to reflect their role

in the maintenance of cellular genomes. Unlike mutant gatekeeper and caretaker alleles, mutant, functionally activated versions of proto-oncogenes are rarely transmitted through the germ line and are thus not commonly associated with familial cancer syndromes (**Sidebar 7.5**).

Sidebar 7.5 Why are mutant tumor suppressor genes transmitted through the germ line, whereas mutant proto-oncogenes are usually not?

A number of familial cancer syndromes have been associated with the inheritance of mutant alleles of TSGs (see Table 7.1). Very few cancer syndromes, however, are associated with inherited mutant alleles of proto-oncogenes (that is, activated oncogenes). These include Costello syndrome (H-*ras*); familial gastrointestinal stromal tumors (*Kit* and *PDGFR-A*); hereditary papillary renal cell cancer (*Met*); multiple endocrine neoplasia (*Ret*); Noonan syndrome (*PTPN11*, K-*ras*, and *SOS*); and familial neuroblastoma (*ALK*). How can we explain this dramatic difference in the heritability of mutant TSGs and mutant proto-oncogenes?

Mutations that yield activated oncogenes, like those that eliminate the activity of TSGs, are likely to arise with some frequency during gametogenesis—the processes that form sperm and egg. Thus, they are likely to be transmitted to fertilized eggs. However, because oncogenes act at the cellular level as dominant alleles, these mutant alleles are likely to perturb the behavior of individual cells in the developing embryo and therefore to disrupt normal tissue development. Consequently, embryos carrying these mutant oncogenic alleles are unlikely to develop to term, and these mutant alleles will disappear from the germ line of a family and thus from the gene pool of the species. (For example, experiments reported in 2004 indicate that mouse embryos arising from sperm carrying a mutant, activated K-*ras* oncogene develop only to mid-gestation; the mutant germ-line alleles of the H-*ras* and K-*ras* genes that cause Costello and Noonan syndromes in humans carry mutations that are much weaker in their transforming powers than those somatically mutated alleles responsible for creating the *Ras* oncogenes that underlie many types of cancer.)

Mutant germ-line alleles of TSGs behave much differently, however. Because these alleles are generally recessive at the cellular level, their presence in most cells of an embryo will not be apparent. For this reason, the presence of inherited mutant TSGs will often be compatible with normal embryonic development, and the cancer phenotypes that they create will become apparent only in a small number of cells and after great delay, allowing an individual carrying these alleles to develop normally and, as is often the case, to survive through much of adulthood.

Still, if mutant TSGs undergo LOH in 1 out of 10^4 or 10^5 cells, and if an adult human has many more than 10^{13} cells, why doesn't a person who inherits a mutant TSG develop tens of thousands, even millions of tumors? The answer stems from the fact that, for most types of cancer, tumorigenesis is a multi-step process (as we discuss in Chapter 11). This means that a mutant gene (whether it be an oncogene or a TSG) may be necessary for tumor formation but will not, on its own, be sufficient. Hence, many cells in an individual heterozygous for a mutant TSG may well undergo LOH of this gene, but only a tiny minority of these cells will ever acquire the additional genetic changes needed to make a clinically detectable tumor. For other, rare cancers—including retinoblastoma—the inactivation of a single gene (*Rb*) may be sufficient to initiate tumor formation, at least in fetal retinal cells. This explains why individuals with the Rb^+/Rb^- genotype are predisposed to this tumor type.

OceanofPDF.com

Glossary

gatekeeper

(1) An oligopeptide domain that controls access by small molecules to the catalytic cleft of an enzyme such as a kinase. (2) A gene that operates to regulate cell proliferation or to regulate cell number by controlling cell differentiation or cell death. Loss of a gatekeeper gene removes an impediment to cell proliferation and thus to the appearance of populations of neoplastic cells. *Compare* **caretaker**, **tumor suppressor gene**.

caretaker

A gene that encodes a protein that maintains the integrity of the genome and thereby prevents the accumulation of mutations and, in turn, the formation of neoplastic cells. *See also* **gatekeeper**.

gametogenesis

Processes that yield gametes, i.e., sperm or eggs.

OceanofPDF.com

7.13 Synopsis and prospects

TSGs constitute a large group of genes having only one shared attribute: in one way or another, each of these genes normally functions to reduce the likelihood that a clinically detectable tumor will appear in one of the body's tissues. Some TSGs function to decrease the likelihood that early steps of multi-step tumor progression will occur, whereas others operate specifically to suppress completion of the later steps of tumor progression. The dynamics governing these complex processes are the subject of Chapter 11. We therefore should expand the definition of TSGs to include genes that operate to suppress initial benign tumor formation, as well as those that constrain subsequent malignant progression. A further refinement of definitions has come from the demonstration that some TSGs encode microRNAs rather than proteins; the pleiotropic powers of many microRNAs makes them potent regulators of complex cellular phenotypes, including neoplastic transformation (see Table 7.1). Hence, proteins are not the only macromolecules that can control runaway cell growth.

The discovery of TSGs helped to explain one of the major mysteries of human cancer biology—that of familial cancer syndromes. As we discussed in this chapter, inheritance of a defective allele of one of these genes is often compatible with normal embryonic development. The phenotypic effects of this genetic defect may only become apparent with great delay, sometimes in midlife, when its presence is revealed by the loss of the surviving wild-type allele and the outgrowth of a particular type of tumor. Elimination of these wild-type alleles often involves LOH events, and the repeatedly observed LOH in a certain chromosomal region among a group of tumors can serve, on its own, as a clear indication of the presence of a still-unidentified TSG lurking in this region.

The diverse behaviors of these genes highlight an ongoing difficulty in this area of cancer research: What criteria can be used to define a TSG? For our purposes, we have included in the family of TSGs only those genes whose products operate in some dynamic fashion to constrain cell proliferation, survival, or malignant progression. Other genes that function indirectly to

prevent cancer through their abilities to maintain the genome and suppress mutations are described in Chapter 12. From the perspective of a geneticist, this division—the dichotomy between the "gatekeepers" and the "caretakers"—is an artificial one, because the wild-type versions of both classes of genes are often found to be eliminated or inactivated in the genomes of cancer cells. Moreover, the patterns of inheritance of the cancer syndromes associated with defective caretaker genes are formally identical to the mechanisms described in this chapter. Still, for those who would like to understand the biological mechanisms of cancer formation, the distinction between TSGs (the gatekeepers) and genome maintenance genes (the caretakers) is a highly useful one and is therefore widely embraced.

In the years since the first TSGs (*p53* and *Rb*) were cloned, numerous other genes have been touted as "candidate" TSGs because their expression was depressed or absent in cancer cells, while being readily detectable in corresponding normal cells. This criterion for membership in the TSG family was soon realized to be flawed, in no small part because it is often impossible to identify the normal precursor of a cancer cell under study. Certain kinds of tumor cells may not express a particular gene because of a gene expression program that is played out during normal differentiation of the tissue in which these tumor cells have arisen. Hence, the absence of expression of this gene in a cancer cell may reflect only the actions of a normal differentiation program rather than a pathological loss. So, this criterion—absence of gene expression—is not definitive.

In certain instances, expression of a candidate TSG may be present in the clearly identified normal precursors of a group of tumor cells and absent in the tumor cells themselves. This would appear to provide slightly stronger support for the candidacy of this gene. But even this type of evidence is not conclusive, because the absence of gene expression in a cancer cell may often be one of the myriad *consequences* of the transformation process rather than one of its root *causes*. Thus, inactivation of this gene may have played no role whatsoever in the formation of the tumorigenic cell.

Responding to these criticisms, researchers have undertaken to functionally test candidate TSGs. The process involves introducing cloned wild-type versions of candidate genes into cancer cells that lack any detectable

expression of these genes. The goal here has been to show that once the wild-type TSG function is restored in these cancer cells, they revert partially or completely to a normal growth phenotype, or they may even enter into apoptosis (as discussed in Chapter 9). However, the results of such experiments are often difficult to interpret, because the expression of genes at unnaturally elevated levels—and in cells or locations where they do not normally belong (termed ectopic expression)—often makes cells quite unhappy and causes them to stop growing or even to die. Such responses are often observed following introduction of a variety of genes that would never be considered TSGs.

The ambiguities of these functional tests have necessitated the introduction of genetic criteria to validate the candidacy of many putative TSGs. If a gene repeatedly undergoes LOH in tumor cell genomes, for example, then surely its candidacy becomes far more credible. But here too ambiguity reigns. After all, genes that repeatedly suffer LOH may only be closely linked on a chromosome to a bona fide TSG that is the true target of elimination during tumor development.

These various considerations have led to an even stricter genetic definition of a TSG: a gene can be safely called a TSG only if it undergoes LOH in many tumor cell genomes *and* if the resulting homozygous alleles bear clear and obvious inactivating mutations. (This latter criterion should allow an investigator to discount any bystander genes that happen to be closely linked to bona fide TSGs on human chromosomes.) Recent advances in large-scale genomic sequencing, which we will discuss in Chapter 12, have now revealed more than 200 human genes that meet these criteria.

Not surprisingly, even these quite rigid genetic and molecular criteria have proven to be flawed, because they exclude from consideration certain genes that are likely to be genuine TSGs. The activity of many TSGs can be eliminated by promoter methylation (see Section 7.7), which explains why mutant alleles of a bona fide TSG might rarely be encountered in tumor cell genomes, even though effective silencing of the gene has occurred and contributed, in turn, to tumor outgrowth.

The ability to knock out or otherwise modify the functions of candidate TSGs through manipulation of the mouse genome line (see Sidebar 7.5)

provides yet another powerful tool for validating their role in tumorigenesis. Although the biology of mice and humans differs in many respects, the shared, fundamental features of mammalian biology make these genetically altered mice extraordinarily useful for accurately modeling many aspects of human tumor biology.

Many of the genes that are listed in Table 7.1 have been knocked out in the germ line of mice. For the most part, resulting heterozygotes have been found to exhibit increased susceptibility to one or another type of cancer. In many instances, the particular tissue that is affected differs from that observed in humans. For example, *Rb*-heterozygous mice (that is, $Rb^{+/-}$) tend to develop pituitary and thyroid tumors rather than the retinoblastomas observed in humans. Still, the development of any type of tumor at an elevated frequency in such genetically altered mice adds persuasive evidence to support the candidacy of a gene as a TSG.

All this explains why multiple criteria are now brought to bear when evaluating nominees for membership in this exclusive gene club. For us, perhaps the most compelling criterion is a functional one: Can the tumor-suppressing ability of a candidate TSG be rationalized in terms of the biochemical activities of its encoded protein and the known position of this protein in a cell's regulatory circuitry?

In the end, these many complications in validating candidate TSGs have one attribute in common: the very existence of a TSG becomes apparent only when it is absent. This fact sets the stage for all the difficulties that have bedeviled TSG research, and it underscores the difficulties that will continue to impede the validation of new TSGs in the future.

With all these reservations in mind, we can nevertheless distill some generalizations about TSGs that will likely stand the test of time. To begin, the name that we apply to these genes is, in one sense, a misnomer. The normal roles of many are to suppress inappropriate increases in cell number, either by suppressing proliferation or by triggering apoptosis in normal tissues. The participation of these genes in cancer formation only becomes apparent in their absence. Thus, in the absence of these genes, cells survive and proliferate at times and in places where their survival and proliferation

are inappropriate. Beyond the resulting effects on cell number are the important roles of some of these genes, as highlighted here, in constraining malignant progression of already-initiated tumors.

Another generalization is also obvious, even without knowing the identities of all TSGs: their protein products do not form any single, integrated signaling network. Instead, these proteins crop up here and there in the wiring diagrams of various regulatory subcircuits operating in different parts of the cell. This diversity is explained by the simple and obvious rationale with which we began this chapter: all well-designed control systems have both positive and negative regulatory components that counterbalance one another. Thus, for every type of positive signal, such as those signals that flow through mitogenic signaling pathways, there must be negative controllers ensuring that these signaling fluxes are kept within proper limits. Perhaps cancer biologists should have deduced this from first principles, long before they launched their studies of TSGs.

Even after the full repertoire of TSGs are cataloged and characterized, the pRb and p53 proteins will continue to be recognized as the products of TSGs that are of preeminent importance in human tumor pathogenesis. The reasons for this will become apparent in the next two chapters. Although all the pieces of evidence are not yet in hand, it seems increasingly likely that the two signaling pathways controlled by pRb and p53 are deregulated in the great majority of human cancers. Almost all of the remaining TSGs (see Table 7.1) are involved in the development of more circumscribed sets of human tumors.

The fact that certain TSGs are missing from the expressed genes within cancer cells has prompted many to propose the obvious: if only we could replace or repair the missing TSGs in cancer cells, these cells would revert partially or totally to a normal cell phenotype and the problem of cancer would be largely solved. Such “gene therapy” strategies have the additional attraction that the occasional, inadvertent introduction of a TSG into a normal cell should have little if any negative effect if the gene is expressed at an appropriate, physiological level; this reduces the risk of undesired side-effect toxicity to normal tissues.

As attractive as such gene therapy strategies are in concept, they have been extremely difficult to implement in practice. The viral vectors that form the core of most of these procedures are inefficient in delivering intact, wild-type copies of TSGs to the neoplastic cells within tumor masses. Unfortunately, efficient transfer is essential for curative anti-tumor therapies: if significant numbers of cancer cells within a tumor under treatment fail to acquire a vector-borne wild-type TSG, these cells will serve as the progenitors of a reborn tumor mass. Similar concerns about the efficiency of gene delivery lessen enthusiasm for using CRISPR-based genome editing techniques to repair defective TSGs in cancer cell genomes. For these reasons, although TSGs are profoundly important to our understanding of cancer formation, in most cases, transformation of this knowledge into therapeutic practice is still largely beyond our reach.

Given the challenges associated with restoring TSG function as a therapeutic strategy, an alternative approach is to target signaling pathways that are activated following TSG loss. For example, loss of the *PTEN* TSG leads to hyperactivity of the kinase Akt/PKB, on which some types of cancer cells come to depend for their continued viability. This dependence explains why drugs that shut down an essential upstream co-activator of Akt/PKB, termed mTOR, hold promise as therapeutic agents against tumors, such as glioblastomas and prostate carcinomas, in which PTEN activity has been lost.

The loss of a TSG may render a cell more susceptible to other types of intervention. For example, using CRISPR-based methods (see Sidebar 12.11), it is now possible to perform genetic screens to systematically identify genes and pathways that cancer cells lacking the function of a TSG have come to depend on for their continued growth or survival. This strategy is often termed a "synthetic lethal screen," simply because elimination of a gene identified in such a screen is only injurious to a cell when accompanied by the presence of a mutant TSG allele located elsewhere in the genome of a cancer cell. This approach holds the promise of identifying drug targets for the treatment of cancers with particular TSG mutations. At present, we confront a rapidly expanding roster of TSGs and a rudimentary understanding of how most of them work to forestall cancer,

which explains why we cannot begin to forecast the clinical ramifications of this work that will be realized only over the coming decades.

OceanofPDF.com

Glossary

ectopic

(1) Referring to the expression of a gene or protein in a location or physiological situation where it normally would not be expressed. (2) Referring to the presence of cells or tissues in an anatomical site where they would not naturally be found in the body. *See also* **orthotopic**.

synthetic lethal screen

A screen of a large number of genes, often those present in an entire genome, in which the cells introduced into the screen bear one or another mutation; the subsequent screen is designed to detect, in an unbiased fashion, other genes that, when disrupted, lead to lethality in these cells but not in wild-type cells lacking the mutation.

OceanofPDF.com

Key concepts

- At the cellular level, the neoplastic phenotype of human cancer cells is usually recessive, because expression of this phenotype depends, in part, on the inactivation of tumor suppressor genes (TSGs). This indicates that the loss of genetic information is critical for the development of most if not all human tumors.
- Much of the loss of functionally important genetic information during the formation of tumors is demonstrated by TSGs, which are often present in the genomes of cancer cells as inactive, null alleles.
- TSG loss usually affects cell phenotype only when both copies of such a gene are lost in a cell. This means that null alleles of TSGs may be present in a heterozygous state in many cells throughout the body without affecting cell and tissue phenotype.
- The loss of TSG function can occur either through genetic mutation or the epigenetic silencing of genes via promoter methylation.
- Inactivation (by mutation or methylation) of one copy of a TSG may be followed by other mechanisms that facilitate loss of the other gene copy; these mechanisms often depend on loss of heterozygosity (LOH) at the TSG locus and may involve mitotic recombination, loss of a chromosomal region that harbors the gene, inappropriate chromosomal segregation (nondisjunction), or gene conversion stemming from a switch in template strand during DNA replication.
- LOH events usually occur more frequently per cell generation than mutations or promoter methylation, and they occur with different frequencies in different genes.
- Repeated LOH occurring in a given chromosomal region in a number of independently arising tumors often indicates the presence of a TSG in that region.
- In certain instances, the absence of a single functional copy of a TSG leads to changes in cell or tissue behavior—the state of haploinsufficiency.
- When mutant, defective copies of a TSG are inherited in the germ line, the result is often greatly increased susceptibility to one or another specific type of cancer.

- The loss of TSGs occurs far more frequently during the development of a tumor than the activation of proto-oncogenes into oncogenes, and individual tumor cell genomes usually harbor multiple inactivated TSGs.
- TSGs regulate cell proliferation through many biochemical mechanisms. The only theme that unites them is that the loss of any one of them increases the likelihood that a cell will undergo neoplastic transformation or progression to a highly malignant state.
- TSGs are often called “gatekeepers” to signify their involvement in governing the dynamics of cell proliferation and to distinguish them from a second class of genes, the “caretakers,” which also increase cancer risk when inherited in defective form but function entirely differently, working to maintain the integrity of the cell genome.
- Replacing or repairing a TSG as a therapeutic strategy for cancer is challenging because of limitations in the efficiency of gene delivery technologies; targeting pathways that become activated upon TSG loss is a promising alternative strategy.

Thought questions

1. Why is the inheritance of mutant, activated oncogenes responsible for only a small proportion of familial cancer syndromes, whereas the inheritance of defective tumor suppressor genes (TSGs) is responsible for the lion's share of these diseases?
2. What factors may determine whether the inactivation of a TSG occurs at a frequency per cell generation higher than the activation of an oncogene?
3. How might the loss of TSG function yield an outcome that is, at the cell-biological level, indistinguishable from the acquisition of an active oncogene?
4. Some TSGs undergo LOH in fewer than 20% of tumors of a given type. Why and how do such low rates of LOH complicate the identification and molecular isolation of such genes?
5. What criteria need to be satisfied before you would be comfortable in categorizing a gene as a TSG?
6. What factors might influence the identities of the tissues affected by an inherited, defective allele of a TSG?
7. What methods could be used to identify genes or pathways that cancer cells harboring a particular TSG mutation become dependent on for growth or survival?
8. What evidence might be produced to demonstrate that a group of candidate TSGs function in the same regulatory pathway within normal cells?

Supplementary Sidebars

Supplementary Sidebar 7.1 Heterozygosity in the human gene pool

The human gene pool carries millions of small variations in DNA sequence, which ensure that at many genetic loci, the gene copy we receive from one parent is subtly different from the gene copy we inherit from the other. This heterogeneity is often called *genetic polymorphism* (see Section 1.2, Figure 1.5). Recall that this term refers to a genetic variability in DNA sequence that may have no effect on the functioning of a gene or its encoded protein product and therefore no effect on cell or organismic phenotype.

In the case of two nonidentical gene copies, these sequence polymorphisms will create, in a molecular-biological sense, two distinct allelic variants of a gene. (For a molecular biologist, a gene cannot be considered homozygous unless its two copies have nucleotide sequences that are 100% identical.) Because such sequence polymorphisms may not affect phenotype, their behavior cannot be faithfully tracked by the classical procedures of Mendelian genetics.

In the intergenic regions on a chromosome, there are often polymorphisms that distinguish the paternal from the maternal copy of a sequence. Though these DNA sequence segments cannot be considered to be alleles of a gene (because they are far removed from any gene on the chromosome), they nonetheless behave just like Mendelian alleles; that is, they are transmitted in a Mendelian fashion from parent to offspring. Hence, the sequence AAGCC in one chromosome and its counterpart AAGGC in the homologous chromosome will be transmitted like Mendelian alleles from generation to generation. Because these sequence variants are not expected to affect phenotype, their existence and patterns of transmission must be gauged through biochemical analyses of DNA, such as DNA sequencing. These sequences, because they have no affiliation with known genes, are sometimes termed “anonymous” sequence markers.

We humans descend from a small population (fewer than several thousand) of founding ancestors who lived 100,000 to 150,000 years ago. We might imagine that during the 6000 to 10,000 generations that have intervened between then and now, a variety of additional mutations, often deriving from DNA copying errors, have accumulated in human genomes, resulting in a progressive increase in the amount of polymorphism that can be detected in the now-large human gene pool. In truth, on an evolutionary time scale, this time period has been too short for large numbers of

additional polymorphisms to accumulate in human genomes, and so we basically own the same genes and DNA sequences that our early ancestors carried during the founding of our species. Hence, the great bulk of polymorphisms in the contemporary human population were already present in the gene pool of this founder population.

Supplementary Sidebar 7.2 Which is more likely: LOH or secondary, independent mutations?

The logic of LOH would seem to indicate that this mechanism, rather than an independent mutational event striking the second, still-intact copy of a TSG, is invariably responsible for the loss of the surviving wild-type allele during tumor development. In truth, it is very difficult to predict the relative probabilities of these two alternative mechanisms, which vary from one gene to another. For example, the probability of a TSG suffering LOH through mitotic recombination (see Figure 7.6) is roughly proportional to the distance of this TSG from the centromere of a chromosome. Hence, TSGs that map close to centromeres lose heterozygosity only infrequently through mitotic recombination. Moreover, the likelihood that this recombination will occur is affected by the nuclear environment, which varies from one cell type to another and seems to influence whether the two homologous chromosomes will be in constant, close proximity to one another within the nucleus and therefore poised to recombine.

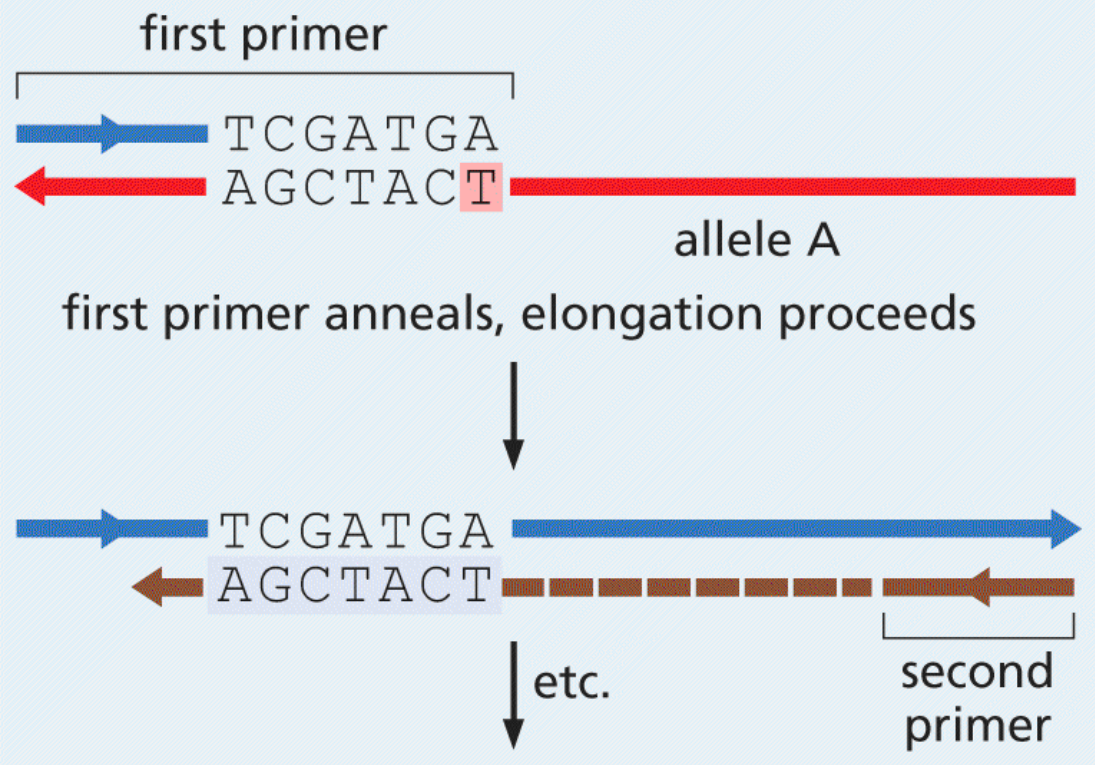
The chances of losing the second, wild-type gene copy through independent mutation are also affected by other variables. Large genes encompassing many tens of kilobases of DNA are more vulnerable to being struck and inactivated by a mutation than are small, compact genes. Genes that have large numbers of CpG sequences (in which the cytosine can be subjected to methylation) are also more vulnerable, because the methyl-CpG is susceptible to a spontaneous chemical conversion into thymine, resulting in the replacement of a CpG sequence by a TpG (see Section 12.4). Yet other factors—including whether or not a gene is being actively transcribed in a particular cell type (notably germ cells)—may also affect the likelihood of its accumulating mutations that can be transmitted through the germline.

Together, these factors make it very difficult to predict precisely how much LOH is favored over genetic mutation as the mechanism for eliminating the second, still-intact copies of TSGs. To cite a specific example, in one study of 158 retinoblastomas, 101 (64%) were found to have undergone LOH at the *Rb* locus; the remaining 57 tumors presumably suffered independent mutations that struck the second *Rb* gene copy or else underwent promoter methylation to silence the wild-type allele (see Section 7.7). Of those that underwent LOH, 94 showed true homozygosity in the chromosomal region surrounding the *Rb* gene, and 7 showed hemizygosity due to total deletion of the chromosomal region that included the second *Rb* gene copy. Consequently, these 7

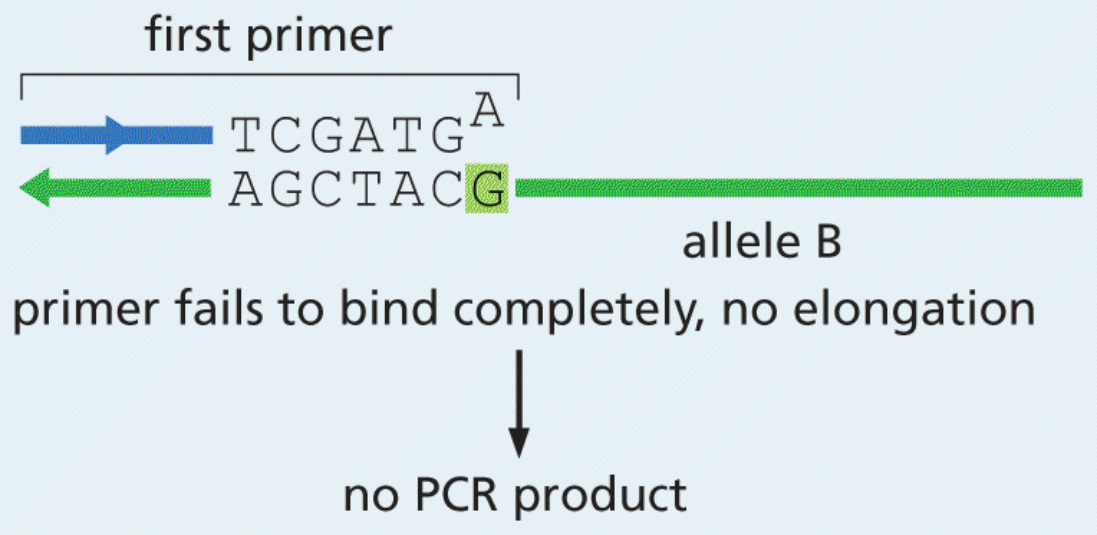
tumors also suffered independent, secondary mutations—in these cases massive deletions of an entire chromosomal region.

Supplementary Sidebar 7.3 The polymerase chain reaction makes it possible to genetically map tumor suppressor genes rapidly

In recent years, the use of RFLPs (see Figure 7.11A) has been replaced by markers that can be detected using the polymerase chain reaction (PCR) to amplify specific chromosomal segments. In a simple form of this LOH analysis, one of the two DNA primers in a PCR reaction may be complementary to one allelic version of a DNA sequence that is polymorphic in the human gene pool; the other primer binds to a sequence on the complementary strand that is invariant in the human gene pool. The ability of the first primer to bind to one allelic version of the sequence and not to another can be used to determine whether or not the particular allele is present in a DNA preparation (**Figure S7.1**). The ability to perform multiple PCRs simultaneously enables geneticists to survey the configuration of many polymorphic markers at the same time; this application of PCR analysis has facilitated the discovery of thousands of these markers scattered throughout the genome. The vastly increased density of markers along each chromosomal arm has made it possible to localize tumor suppressor genes far more precisely than the use of the very rough mapping strategy illustrated in Figure 7.11A and B.



(A)



(B)

Figure S7.1 Use of the polymerase chain reaction to determine sequence polymorphisms The polymerase chain reaction (PCR) can be used to determine the presence or absence of a single-nucleotide polymorphism (SNP)—a polymorphism in which the two alleles differ by only a single nucleotide. (A) In one version of this procedure, the first primer (*blue*) is perfectly complementary to the nucleotide sequence of allele A (*red strand*), and therefore the rightward-moving primer extension reaction (*blue line*) proceeds normally, thereby generating a template for the leftward-moving elongation from the second primer (*brown dashed line*). (B) However, if the first primer is not perfectly complementary to the sequence present in allele B, which contains a SNP that changes a T to a G (*light green*), the rightward-moving primer extension reaction will fail and no PCR product will be made. Hence, the presence or absence of a SNP can be ascertained by the presence or absence of the resulting PCR products, which will accumulate to millions of copies in one set of reactions and will be absent in the other. The arrowheads indicate the 5′ to 3′ polarity of the DNA strands.

Supplementary Sidebar 7.4 Bisulfite sequencing makes it possible to gauge methylation status of promoters

Treatment of genomic DNA with sodium bisulfite under alkaline conditions converts unmethylated cytosines (C's) to uracils (U's), while leaving methylated cytosines untouched. Amplification of this treated DNA—or of a specific segment of interest—

by PCR will produce DNA copies in which the U's have been replaced by T's and the methylated cytosines will remain as C's (**Figure S7.2**). When this amplified DNA is sequenced, the C's that appear in the sequence represent sites at which the cytosine in the original sample had been methylated, whereas the C's that are replaced by T's are presumed to have been unmethylated in the original sample.

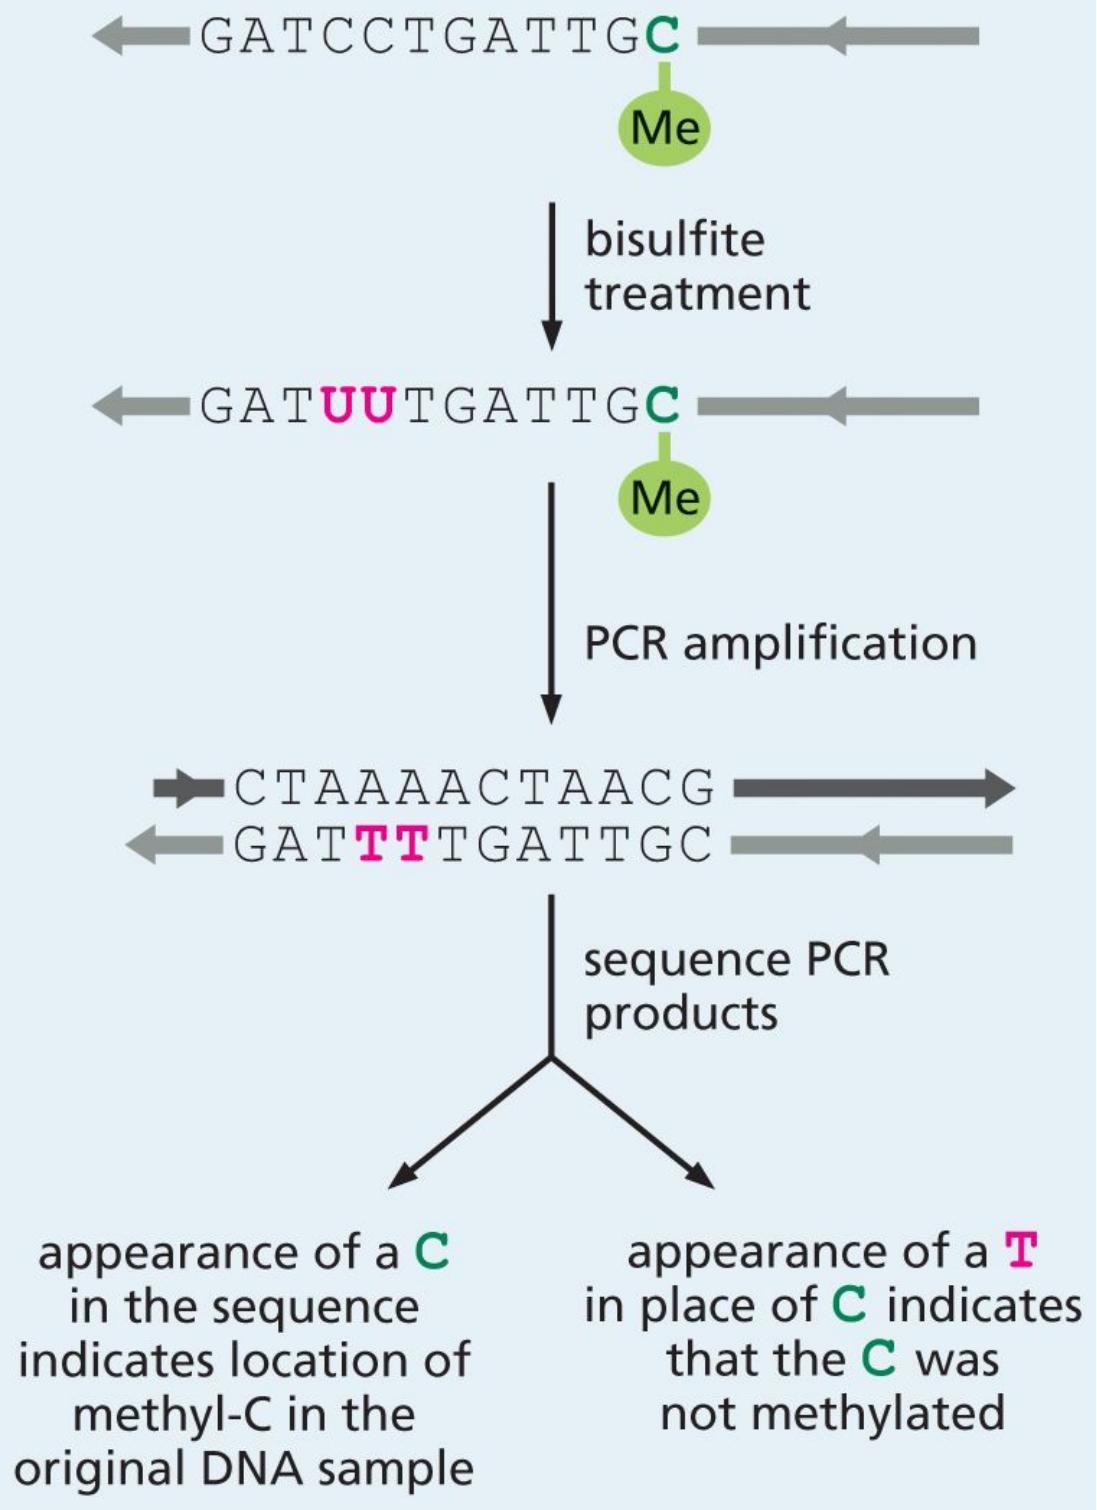


Figure S7.2 Bisulfite sequencing This method for the detection of methylcytosines depends on the fact that the treatment of cellular DNA with sodium bisulfite causes the conversion of all existing cytosine residues to uracil residues; methylcytosines, in contrast, remain unchanged. Hence, DNA can be

treated with bisulfite and then amplified by PCR—which will replace the uracils with thymines and the methylcytosines with (unmodified) cytosines. When this amplified PCR product is then sequenced, the appearance of a C in the sequence readout indicates the location of a methylcytosine in the original DNA sample.

Supplementary Sidebar 7.5 Ubiquitylation tags cellular proteins for destruction in proteasomes

The concentrations of many cellular proteins must be tightly controlled in response to a variety of physiological signals. Much of this control is achieved through the selective degradation of these proteins by the ubiquitin–proteasome system (**Table S7.1**).

Table S7.1 Advantages of ubiquitin-regulated proteolysis

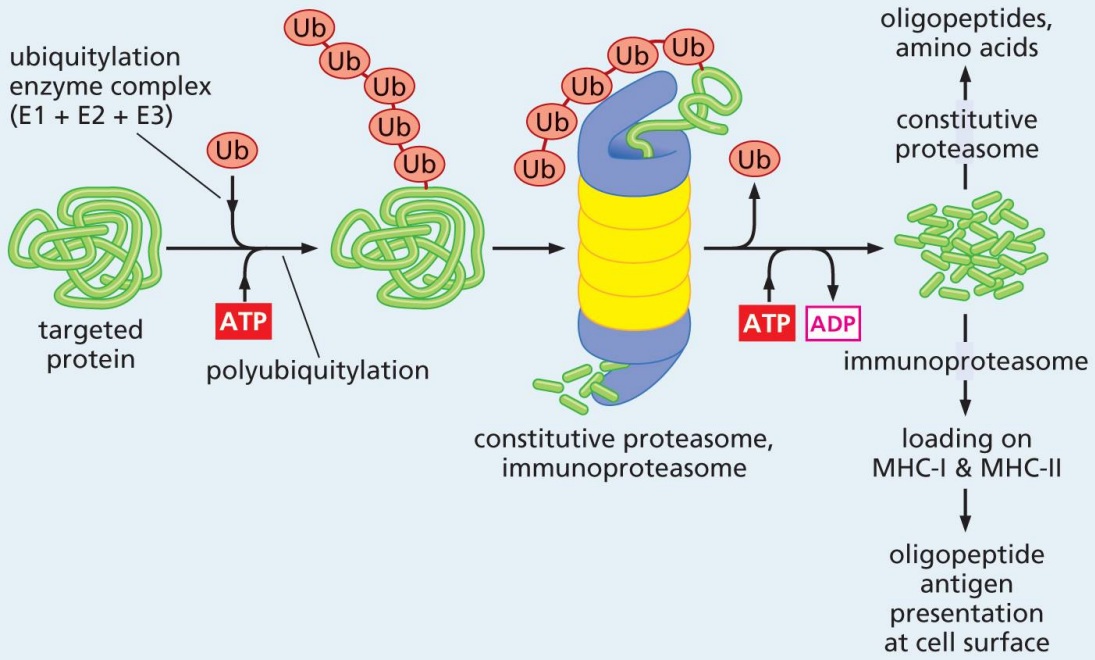
A. Unidirectional—unlike phosphorylation and other post-translational modifications of proteins, degradation cannot be rapidly reversed
B. Rapid—a large number of protein molecules can be eliminated in a regulated fashion in a matter of minutes
C. Fine-tuning—provides another way to finely adjust the levels of critical regulatory proteins
D. Localized—can be confined to specific subcellular compartments
E. Specific—a small set of proteins can be degraded without any effect on all other proteins

Courtesy of M. Pagano.

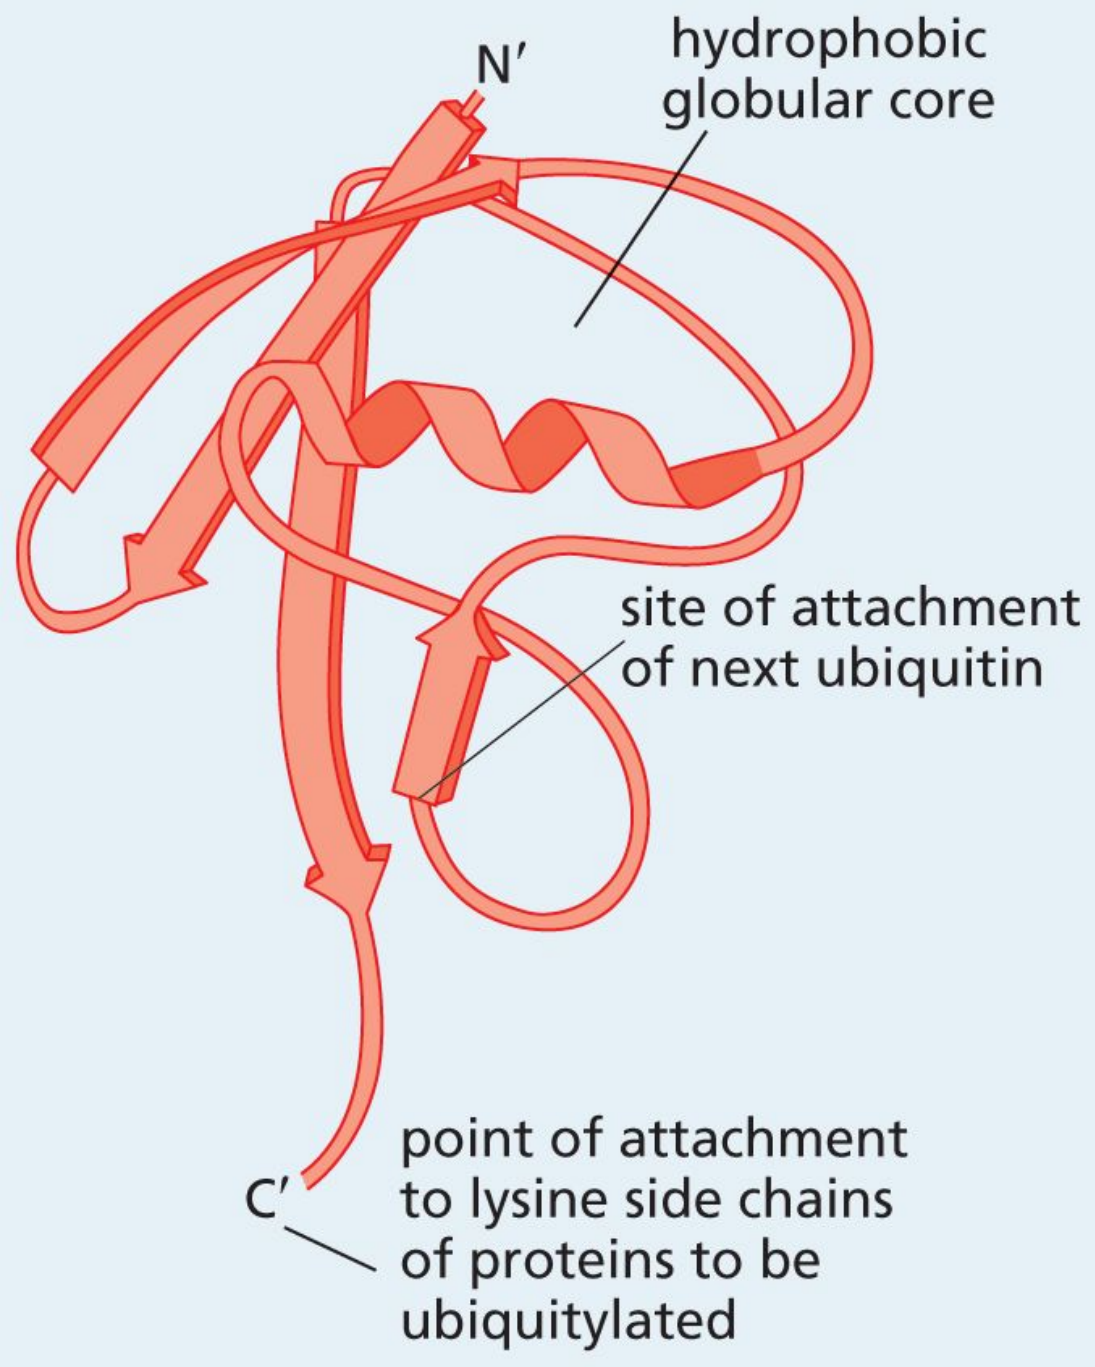
For many proteins, phosphorylation of specific amino acids by a cellular kinase marks them for degradation. The resulting phosphoamino acid, in the context of neighboring amino acid residues, attracts a complex of enzymes that covalently attaches a ubiquitin molecule to the protein—a process called ubiquitylation (or sometimes ubiquitination). In other cases, the exposure of a normally hidden subdomain—as a result of protein

misfolding or damage—attracts the attention of a ubiquitylation enzyme complex. Alternatively, the ubiquitin enzyme complexes that act on specific protein targets are only active under certain states or conditions.

Ubiquitin is a small (76-residue) protein whose sequence is highly conserved between single-cell eukaryotes and mammalian cells; only 3 of 76 amino acid residues differ between the yeast and human versions of this protein. (Its ubiquitous presence in the biosphere inspired its name.) During the ubiquitylation reaction, the first ubiquitin molecule is attached, via its C-terminal glycine, to the side chain of a lysine present in the target protein; a second ubiquitin molecule may then be linked to a lysine within the first ubiquitin; this process can be repeated a number of times, yielding a polyubiquitin chain. This tagging and polyubiquitylation are carried out by a complex of proteins dubbed E1, E2, and E3 (**Figure S7.3**). A protein molecule tagged in this fashion is eventually recognized by a proteasome in the nucleus or cytoplasm. There, the marked protein is digested into oligopeptides that are released for further degradation. A specialized proteasome, termed the immunoproteasome, is employed to degrade cellular proteins into oligopeptides that are loaded in the endoplasmic reticulum (ER) onto MHC-I or MHC-II molecules for subsequent presentation as potential antigens at the cell surface. The levels of immunoproteasomes are increased in a cell following viral infection or in response to inflammation.



(A)



(B)

Figure S7.3 Ubiquitylation and proteasomes Much of protein degradation in the mammalian cell is carried out by the ubiquitin–proteasome pathway. (A) A complex of three proteins (E1, E2, and E3) recognizes a protein destined for degradation and tags this target protein with a chain of ubiquitins (Ub). Following polyubiquitylation, the target protein is conveyed to a proteasome (see Figure

S7.4), sometimes termed a constitutive proteasome, where it is de-ubiquitylated and digested into oligopeptides that can be further degraded into amino acids. A specialized proteasome, termed the immunoproteasome, is induced under conditions of viral infection and inflammation and employed for oligopeptide antigen presentation at the cell surface following oligopeptide binding to nascent MHC-I and MHC-II molecules in the lumen of the endoplasmic reticulum; see Section 15.7. (B) Ubiquitin itself is a relatively short protein of 76 amino acid residues, whose amino acid sequence and structure are almost totally conserved among all eukaryotic cells. Its structure is indicated here in this ribbon diagram determined by X-ray crystallography.

Proteasomes are cellular factories dedicated to the degradation of proteins that are presented to them. The proteasome is a large, hollow, cylindrical complex of multiple protein subunits, which uses ATP to unfold a protein prior to degrading this protein in the cylinder's interior (**Figure S7.4**). Polyubiquitylated proteins that are introduced into the proteasome are first de-ubiquitylated and then digested into short peptide fragments ranging in size from 3 to 25 amino acid residues. The latter are then degraded by cytosolic proteases. An immunoproteasome is a slightly altered version of the regularly present proteasome, sometimes termed the constitutive proteasome, and is used to generate the oligopeptides that are presented at the cell surface by MHC-I molecules, a topic that is discussed at length in Section 15.7.

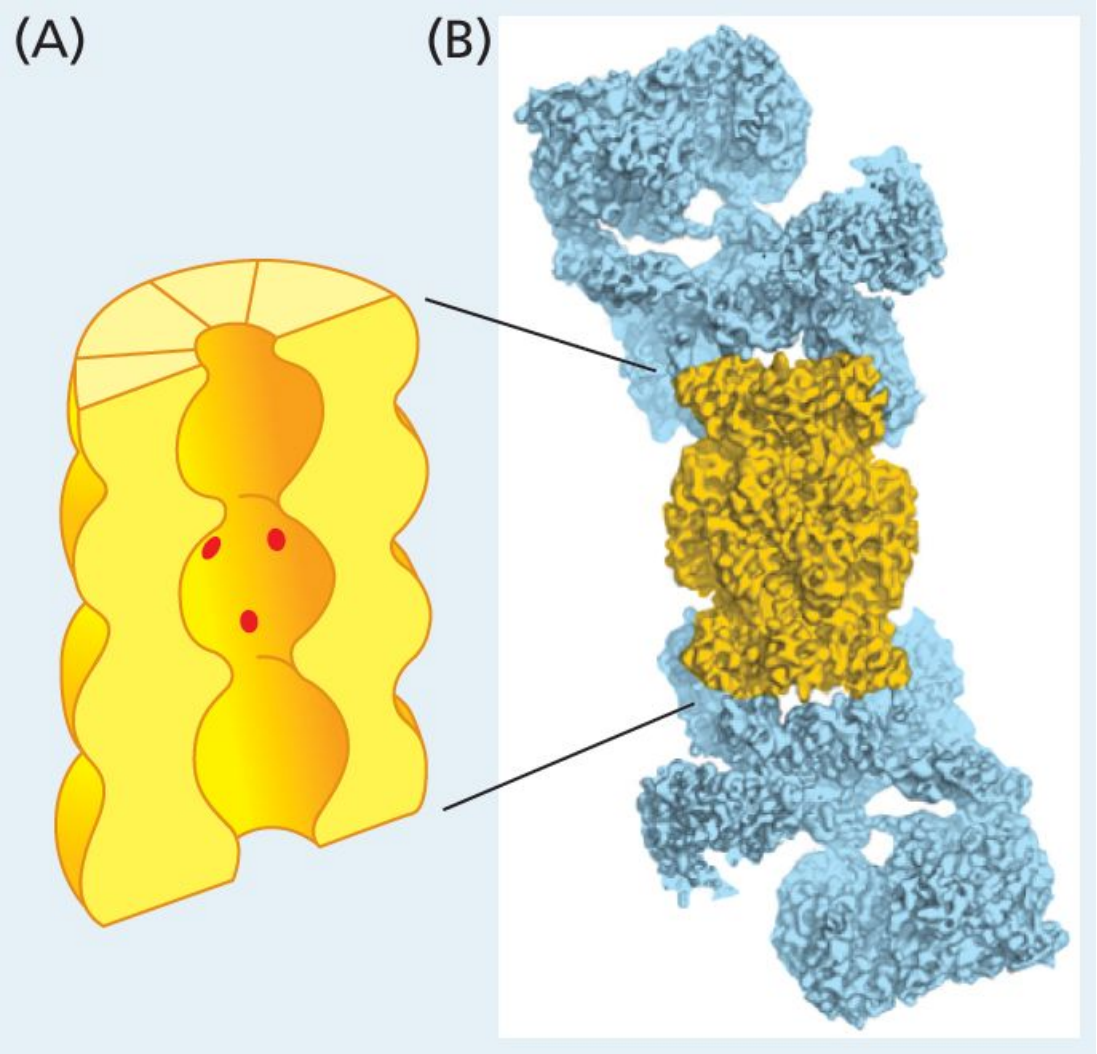


Figure S7.4 The proteasome The proteasome is a complex of about 2.5 megadaltons assembled from more than 30 distinct protein species. (A) A schematic diagram of a cross section of the central barrel of the proteasome indicates the region (*red dots*) where the actual proteolysis takes place. (B) The structure of the entire proteasome, which was determined by X-ray crystallography, includes two "cap" regions (*blue*), where ubiquitylated proteins are bound, de-ubiquitylated, and then introduced into the centrally located barrel region (*yellow*), in which they are processed by proteolytic degradation into oligopeptides or amino acid residues. (B, from P.C.A. da Fonseca et al., *Mol. Cell* 46:54–66, 2012. With permission from Elsevier.)

Polyubiquitylation is known to be responsible for the degradation of many short-lived growth-regulating proteins such as Myc, p53, Jun, and certain cyclins (described in Chapter 8). Altogether, more than 80% of the proteins in mammalian cells, some far

more long-lived, are degraded in proteasomes. Polyubiquitylation marks proteins for destruction, whereas the function of mono-ubiquitylation (in which only a single ubiquitin is attached) is complex and less well understood. There are clear indications that mono-ubiquitylation is used in certain cellular contexts for regulating endocytosis, protein sorting, trafficking of proteins within the nucleus, and even regulating gene expression. For example, mono-ubiquitylation of the p53 tumor suppressor protein tags it for export from the nucleus; subsequent polyubiquitylation can then mark p53 for destruction in proteasomes. Mono-ubiquitylated growth factor receptors are marked for endocytosis.

There are several additional dimensions of complexity in this form of post-translational modification of proteins. To begin, ubiquitin contains seven internal lysines. Of these, linkage via Lys48 is used to generate the polyubiquitin chains that are described above, which tag proteins for destruction in proteasomes. An alternative linkage can be forged via Lys63 residues of ubiquitin, and these polyubiquitin chains confer certain positive effects on the modified protein rather than marking them for destruction. End-to-end linkage of ubiquitin molecules also occurs with yet other consequences for the modified protein. Another dimension of complexity derives from the fact that ubiquitin is only one of a group of as many as 10 distinct marker proteins (for example, the ubiquitin-like Sumo and NEDD8 proteins) that are used to tag various proteins, marking them for a variety of metabolic fates other than proteolysis.

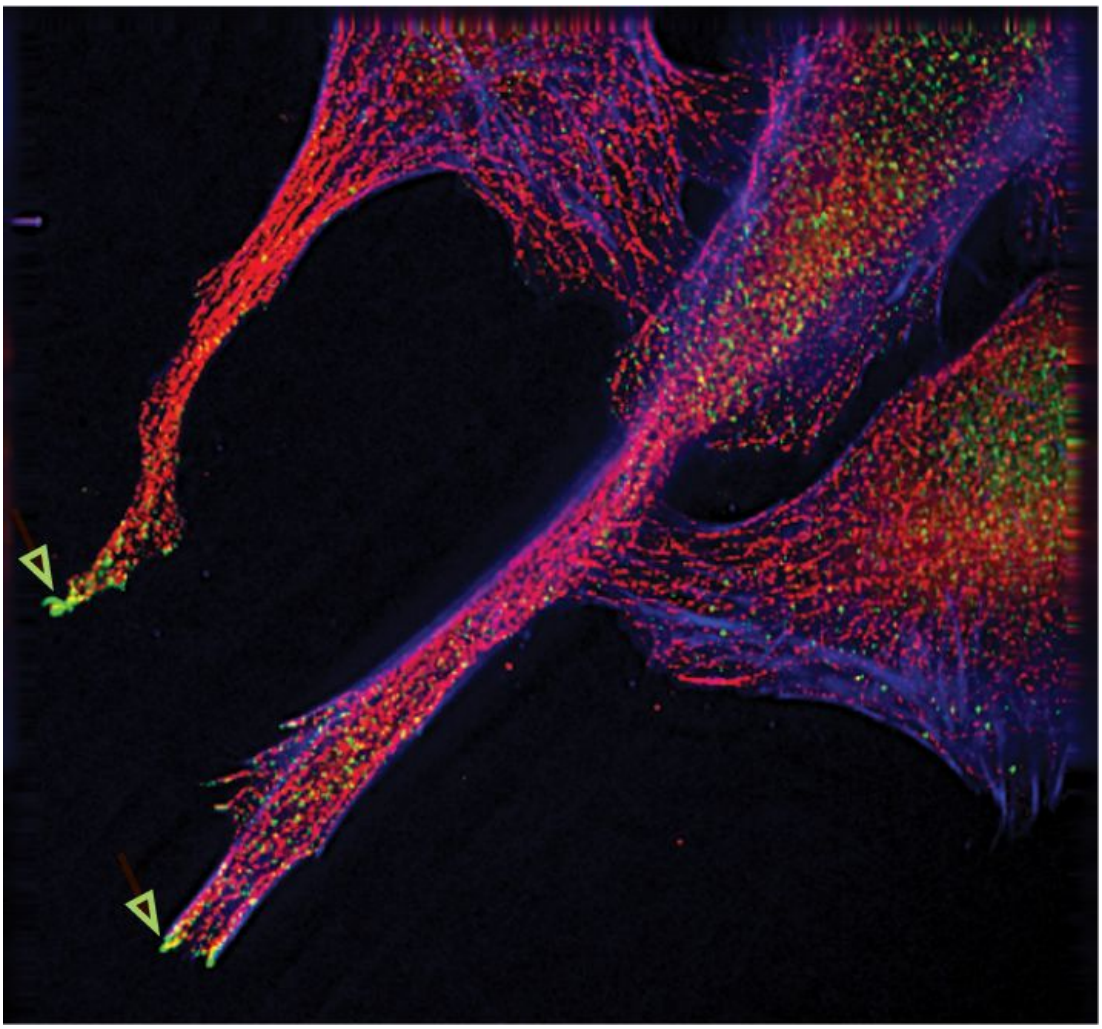
The widespread importance of ubiquitylation is evident from sequence analysis indicating that at least 630 of the approximately 20,000 genes in the human genome appear to encode E3 ubiquitin ligases—the proteins responsible for initially recognizing substrate proteins that are to be targeted for ubiquitylation and destruction.

Supplementary Sidebar 7.6 APC and microtubules

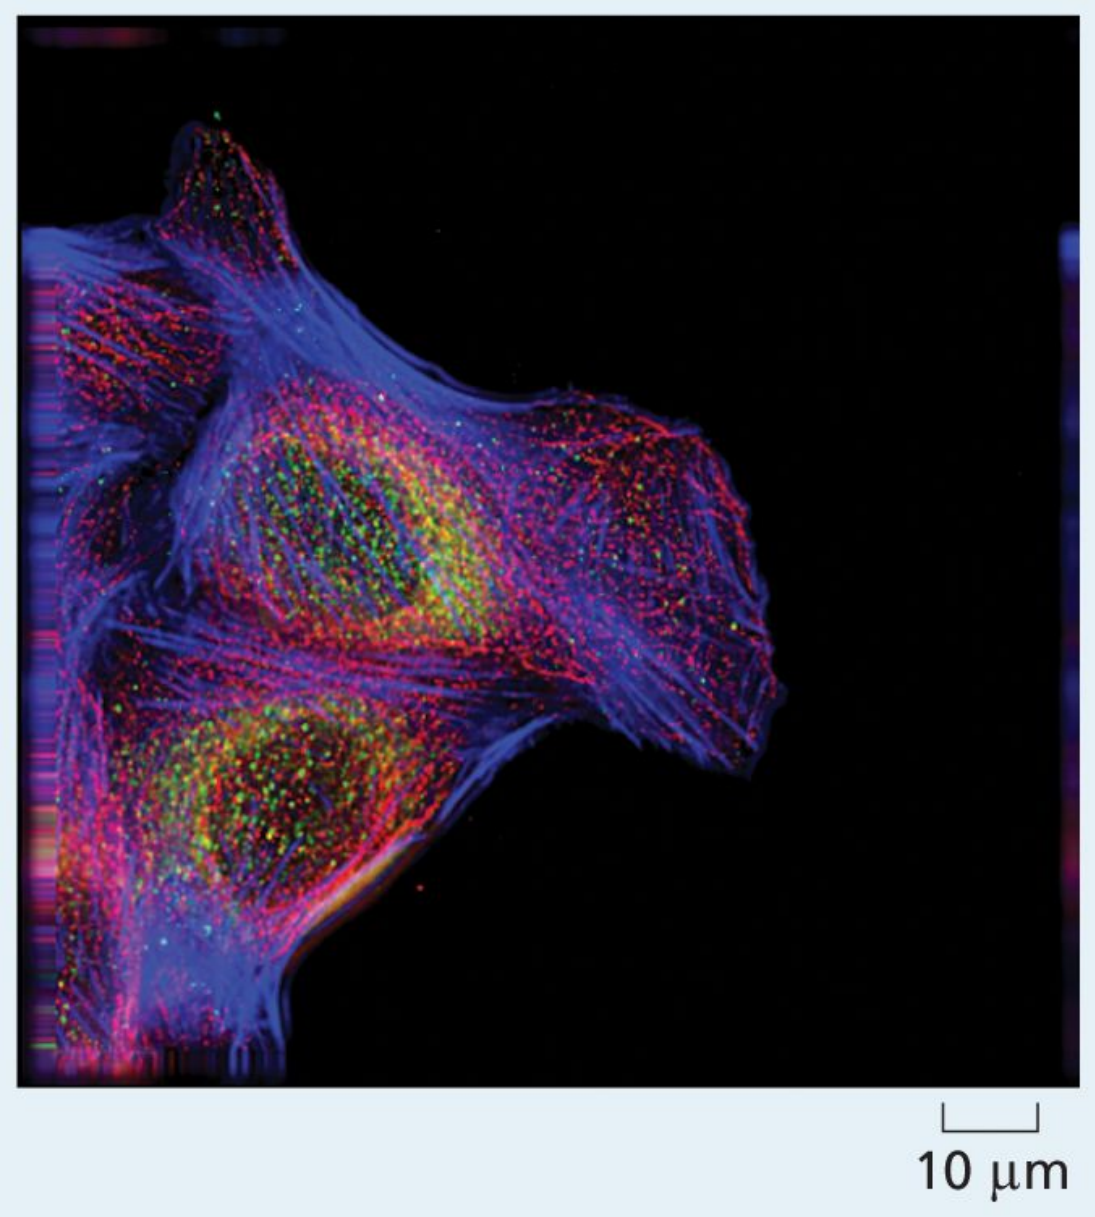
Recent research has turned up other, fully unexpected consequences of APC loss: the protein is involved in still-unclear ways in regulating the microtubules that form the mitotic spindles and part of the cytoskeleton. Cells lacking APC function have been found to exhibit a marked increase in chromosomal instability (CIN), which results in increases and decreases in chromosome number, usually because of inappropriate segregation of chromosomes during mitosis. Some APC-negative cells even accumulate tetraploid (or nearly tetraploid) karyotypes, in which most chromosomes are represented in four copies rather than the usual two. This defect seems to occur because APC molecules localize to components of the microtubule arrays that form the mitotic spindle and are responsible for segregating chromosomes during anaphase and telophase of mitosis. The aneuploidy that results from these chromosomal segregation defects alters the relative numbers of critical growth-promoting and growth-inhibiting genes. These changes, in turn, may well facilitate tumorigenesis by accelerating the

rate with which premalignant cells acquire advantageous genotypes and thus phenotypes.

In addition, APC regulates cell motility, in part through its role in enabling the formation of cytoplasmic protrusions; cells lacking these protrusions show significantly reduced motility (**Figure S7.5**). This may help to explain the inability of *APC*-mutant enterocyte precursors to migrate out of the colonic crypts toward the lumen, as illustrated in Figure 7.20B. It is unclear why evolution has invested this single tumor suppressor protein with these seemingly unrelated functions.



(A)



(B)

Figure S7.5 APC and the cytoskeleton The microtubule-binding domain of APC (see Figure 7.22A) enables this protein to regulate the cytoskeleton and several key aspects of cell physiology, including chromosomal segregation by the microtubule-containing spindle fibers during mitosis. (During mitosis, APC molecules can be found at the kinetochores, cytoplasmic cortex, and centrosomes, and loss of APC leads to chromosomal instability.) The morphology and motility of the human osteosarcoma cells studied here are affected by APC. (A) In the presence of APC, these cells develop large protrusions, at the tips of which APC molecules (*green arrows*) congregate. Microtubules (*red*) are in the core of these

protrusions, and cortical actin (*blue*) is found below the plasma membrane. These protrusions are critical to the motility of these cells. (B) When *APC* expression is suppressed experimentally through use of an siRNA (*s*mall *i*nterfering *RNA*), these protrusions disappear and the microtubules that are usually apparent in cells (panel A) are either absent or reorganized, as is the actin cytoskeleton. Loss of these protrusions is correlated with a significant decrease in cell motility. (Courtesy of K. Kroboth and I. Näthke.)

Glossary

ubiquitylation
: Process by which one or more ubiquitin molecules are attached covalently to a protein substrate molecule, which often results in the degradation of the tagged protein in a proteasome, *alternatively termed* **ubiquitination**.

constitutive proteasome
: Term used to describe the proteasome that is present in a wide variety of cell types and is responsible for the degradation of most cellular proteins; this class of proteasomes is distinguished from immunoproteasomes that degrade intracellular proteins in order to generate the oligopeptides that are loaded onto Class I MHC/HLA proteins and presented on the cell surface. *See also* **proteasome**, **immunoproteasome**.

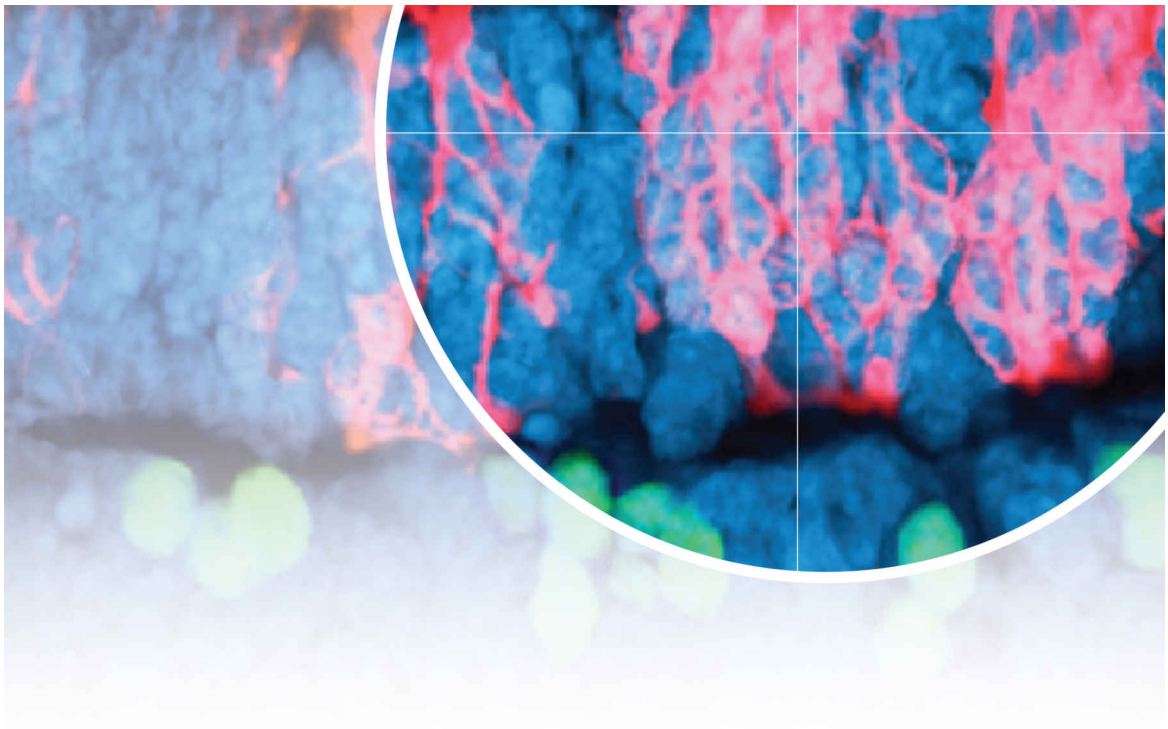
Chapter 8

pRb and Control of the Cell Cycle Clock



A close-up of cells in a mouse retina. Rhodopsin glows red, contrasting dramatically with surrounding dark blue material.

The dream of every cell is to become two cells.

François Jacob, molecular biologist, quoted in 1971

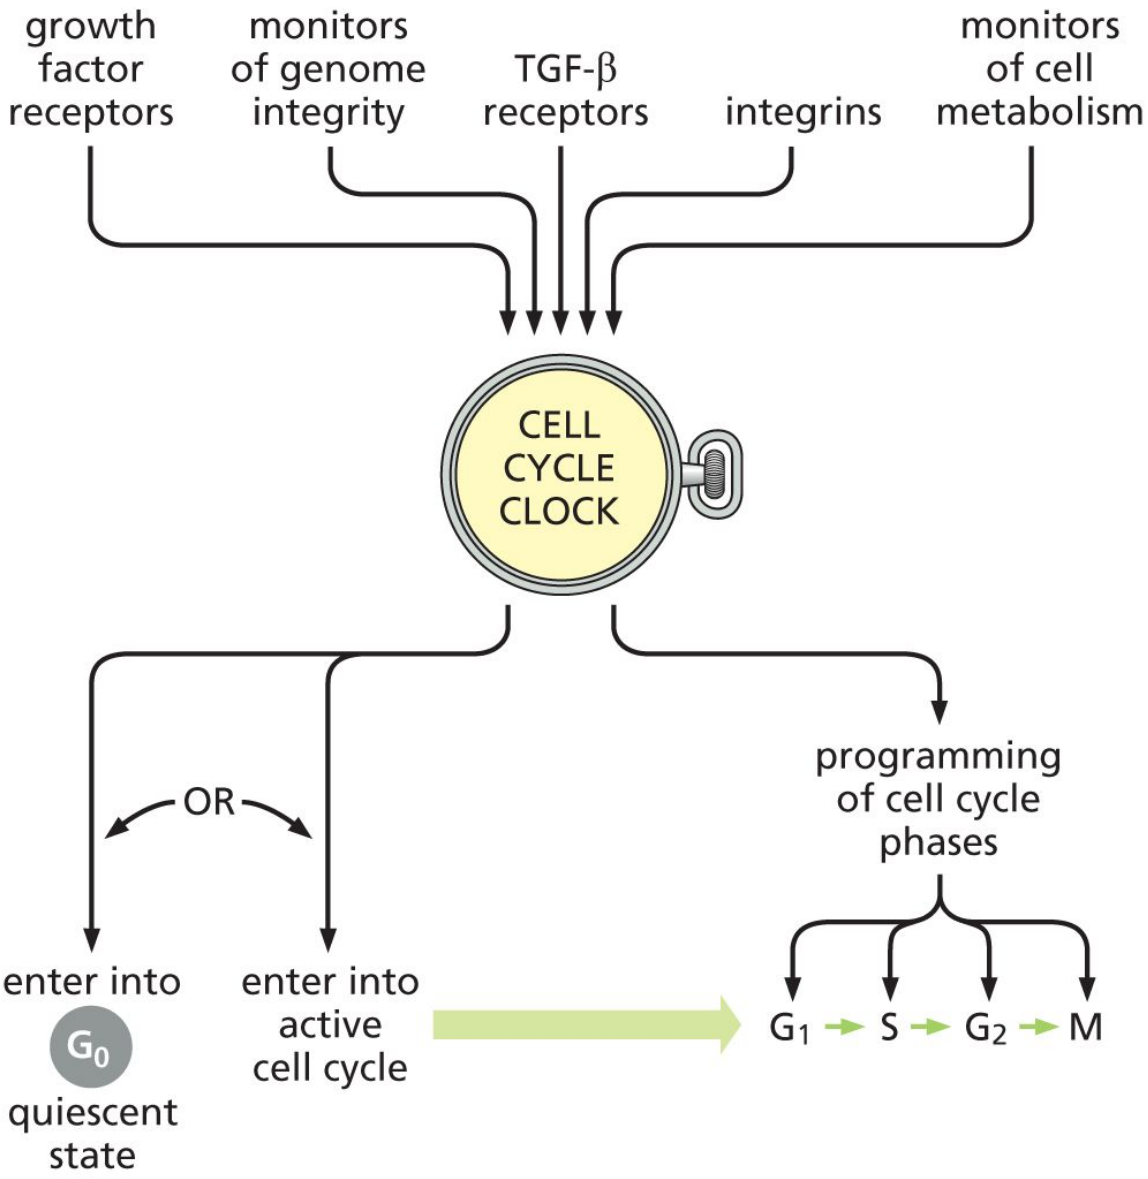
This immediately leads one to ask, if the [hypothetical cellular transformation] loci can get into so much mischief, why keep them around? The logical answer is that they have some necessary function during some stage of the cell cycle, or some stage of embryogenesis.

David E. Comings, geneticist, 1973

The fate of individual cells throughout the body is dictated by the signals that each receives from its surroundings—a point made repeatedly in earlier chapters. Thus, almost all types of normal cells will not proliferate unless prompted to do so by mitogenic growth factors released largely by their neighbors within a tissue. Yet other signaling proteins, notably transforming growth factor-β (TGF-β), may overrule the messages conveyed by mitogenic factors and force a halt to proliferation. In addition, extracellular signals may persuade a cell to enter into a *post-mitotic*, differentiated state from which it will never re-emerge to resume proliferation.

These disparate signals are collected by dozens of distinct cell surface receptors and then funneled into the complex signal-processing circuitry that operates largely in the cell cytoplasm. In some way, this mixture of signals must be processed, integrated, and ultimately distilled down to some simple, binary decisions made by the cell as to whether it should proliferate or become quiescent, and whether, as a quiescent cell, it will or will not differentiate. These behaviors suggest the existence of some centrally acting governor that operates inside the cell—a master clearinghouse that receives a wide variety of incoming signals and makes major decisions concerning the fate of the cell.

This master governor has been identified. It is the cell cycle clock, which operates in the cell nucleus. Its name is really a misnomer, because this clock is hardly a device for counting the passage of time. Nonetheless, we will use this term here for want of a better one. Rather than counting elapsed time, the cell cycle clock is a network of interacting proteins—a signal-processing circuit—that receives signals from various sources both outside and inside the cell, integrates them, and then decides the cell's fate. Should the cell cycle clock decide in favor of proliferation, it proceeds to orchestrate the complex transitions that together constitute the cell's cycle of growth and division; during this cycle, the expression of at least 1000 genes needs to be modulated in highly regulated ways. Should it decide in favor of quiescence, it will use its agents to impose this nonproliferative state on the cell (**Figure 8.1**).



A diagram centered on a cell cycle clock. Inputs include growth factor receptors, monitors of genome integrity, T G F beta receptors, integrins, and monitors of cell metabolism. Depending on the inputs, the cell clock may direct the cell to enter quiescent state G zero, or it may direct the cell to enter an active cell cycle characterized by programmed phases G 1, S, G 2, and M.

Figure 8.1 The central governor of growth and proliferation The term "cell cycle clock" denotes a molecular circuitry operating in the cell nucleus that processes and integrates a variety of afferent (incoming) signals originating from outside and inside the cell and decides whether or not the cell should enter into the active cell cycle or retreat into a nonproliferating

state. In the event that active proliferation is decided upon, this circuitry proceeds to program the complex sequence of biochemical changes in a cell that enable it to double its contents and to divide into two daughter cells. The alternative decision to withdraw from the active cell cycle may allow a cell to retain the option to re-enter into the growth-and-division cycle later or enter into post-mitotic states involving acquisition of differentiated characteristics (*not shown*).

The proliferative behavior of cancer cells indicates that the master governor of the cell's fate is influenced not only by normal proteins but also by oncogene-encoded proteins that insert themselves into various signaling pathways and disrupt normal control mechanisms. Similarly, the deletion of key tumor suppressor proteins evokes equally profound changes in the control circuitry and thus is equally influential in perturbing decision-making by the cell cycle clock. Consequently, sooner or later, the molecular actions of most oncogenes and tumor suppressor genes must be explained in terms of their effects on the cell cycle clock. To this end, we will devote the first half of this chapter to a description of how this molecular machine normally operates and then proceed to study how it is perturbed in human cancer cells.

OceanofPDF.com

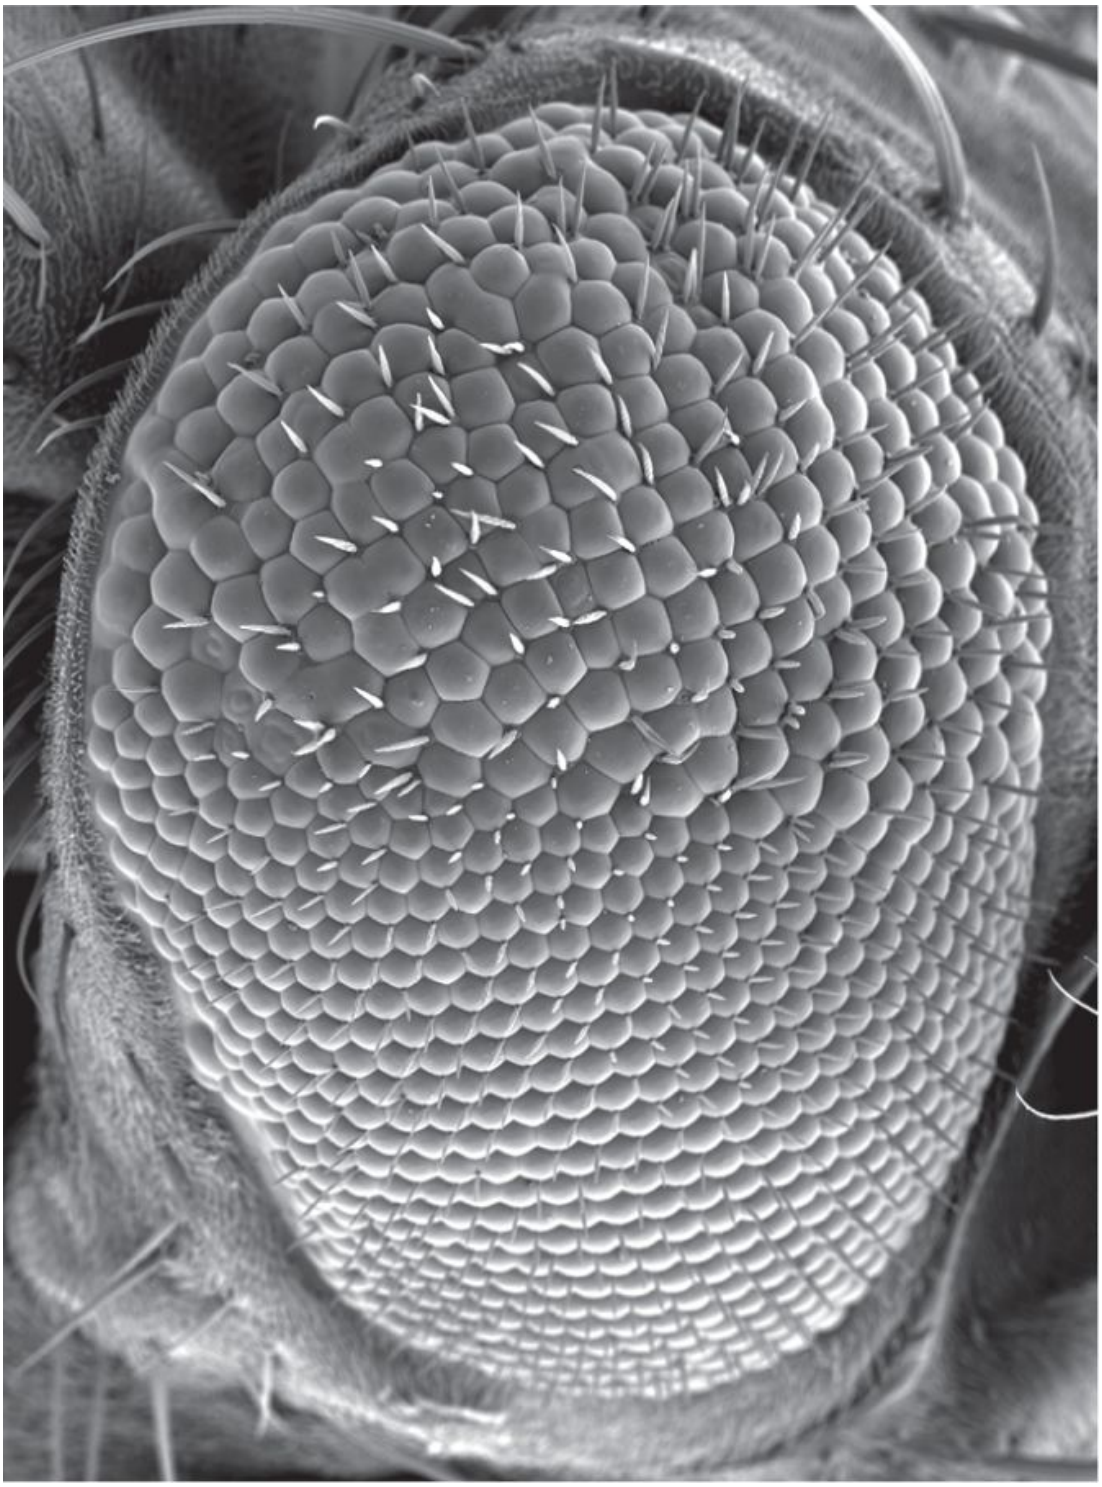
8.1 Cell growth and division is coordinated by a complex array of regulators

When placed into culture under conditions that encourage exponential multiplication, mammalian cells exhibit a complex cycle of growth and division that is usually referred to as the cell cycle. A cell that has recently been formed by the processes of cell division—mitosis and cytokinesis—must decide soon thereafter whether it will once again initiate a new round of active growth and division or retreat into the nongrowing state that we previously termed G_0. As described earlier (Sections 5.1 and 6.1), this decision is strongly influenced by mitogenic growth factors in the cell's surroundings. Their presence in sufficient concentration will encourage a cell recently formed by mitosis to remain in the active growth-and-division cycle; their absence will trigger the default decision to proceed from mitosis into the G_0, quiescent state.

Withdrawal from the cell cycle may be actively encouraged by the presence of growth-inhibitory factors in the medium. Prominent among these anti-mitogenic factors is transforming growth factor-β (TGF-β). Withdrawal from the cell cycle into the G_0, quiescent state, whether caused by the absence of mitogenic growth factors or the presence of anti-mitogens such as TGF-β, is often reversible, in that an encounter by a quiescent cell with mitogenic growth factors on some later occasion may induce this cell to re-enter into active growth and division. However, some cells leaving the active cell cycle may do so irreversibly, thereby giving up all option of ever re-initiating active growth and division, in which case they are said to have become post-mitotic. Many types of neurons in the brain, for example, are widely assumed to fall into this category.

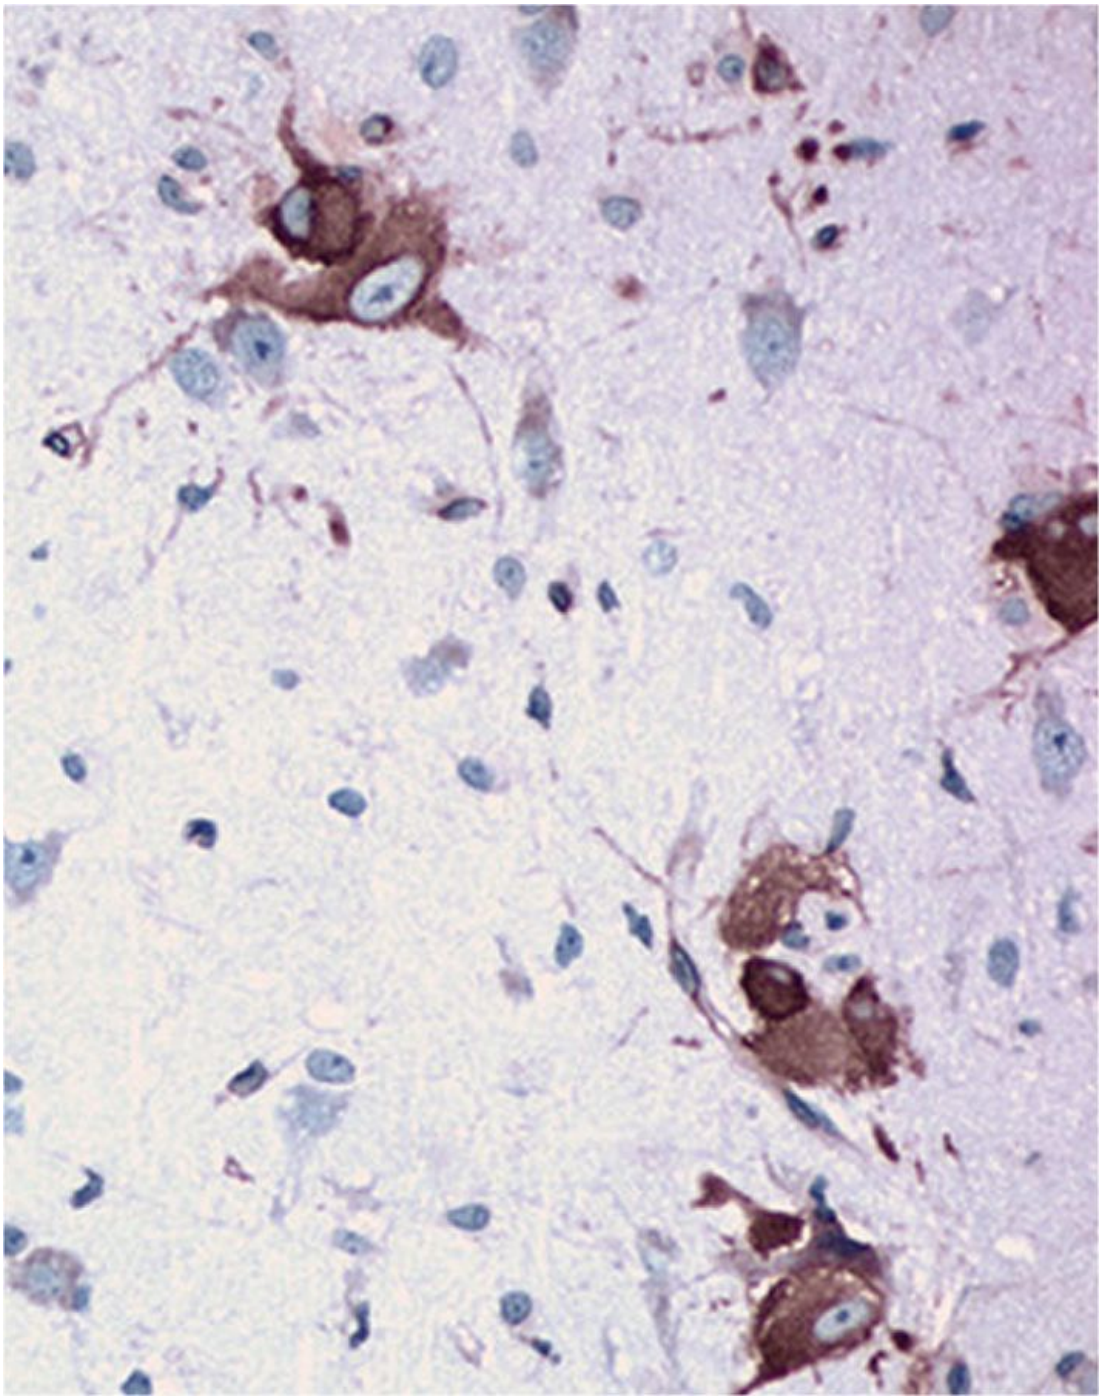
The decision by a cell recently formed by cell division to remain in the active growth-and-division cycle requires that this cell immediately begin to prepare for the next division. Such preparations entail, among other things, the doubling of the cell's macromolecular constituents and organelles to ensure that the two daughter cells resulting from the next round of cell division will each receive an adequate endowment of them. This accumulation of cellular constituents, which drives an increase in cell size, is termed cell *growth* to distinguish it from the process of cell *division*, which yields, via mitosis and cytokinesis, two daughter cells from a mother cell (**Figure 8.2**). However, in the more common usage and throughout this book, the

term “cell growth” implies both the accumulation of cell constituents and the subsequent cell division, that is, the two processes that together yield cell proliferation.



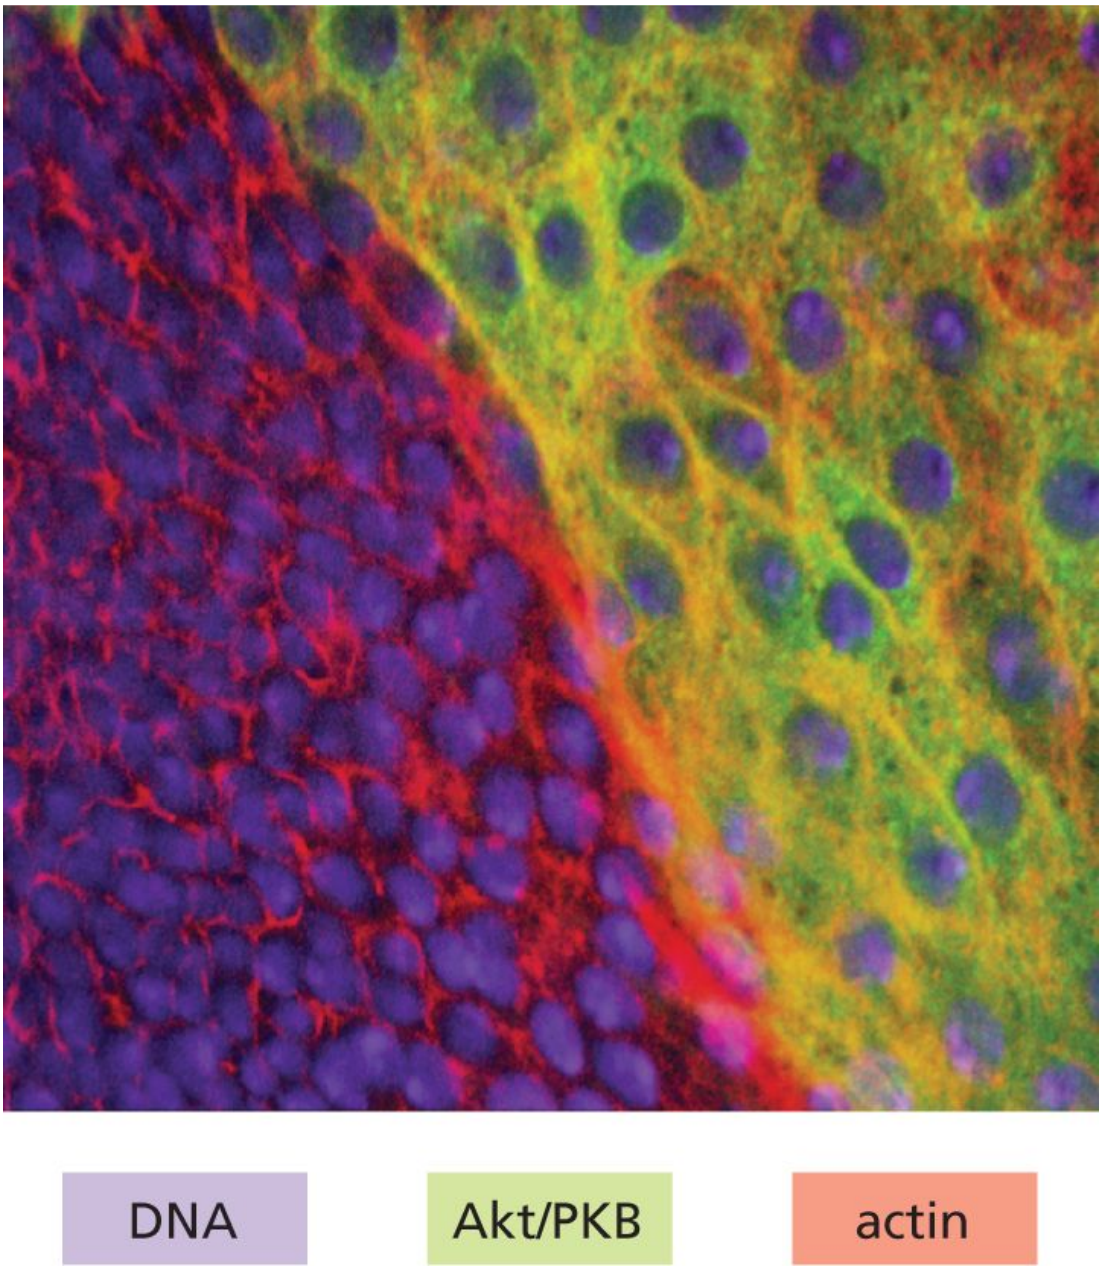
A scanning electron micrograph of a fruit fly’s eye. The light sensing units in the upper part are larger and less regularly arranged than those in the lower

part.
(A)



A histology image in which a few amorphous brown cells appear in a field of otherwise pale pink cells.

(B)



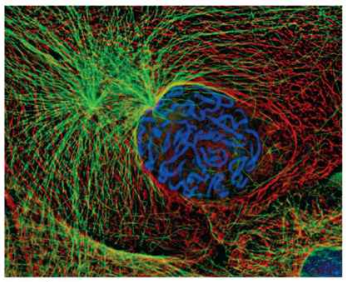
A fluorescent stain image in which the lower left portion shows tightly packed blue nuclei surrounded by cytoplasm in which actin appears in red, and the upper right portion shows much more loosely packed blue nuclei surrounded by cytoplasm in which A k t slash P K B appear in green.

(C)

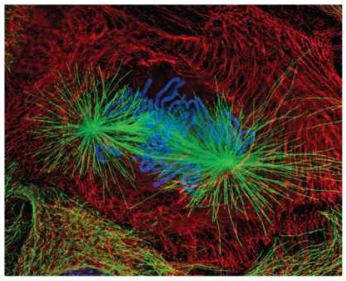
Figure 8.2 Growth vs. proliferation Alterations of certain signaling proteins, such as the one encoded by the *TSC1* tumor suppressor gene, allow the processes of cell growth and division to be uncoupled from one another, enabling cells to

grow in size without concomitant proliferation. (A) In this scanning electron micrograph of a *Drosophila* eye, the ommatidial cells in the upper portion of the eye have been deprived of the fly ortholog of *TSC1*; these cells are physically larger than the wild-type cells shown (*below*), because they have grown more during the cell cycles that led to their formation. (B) The same behavior can be seen in the brains of patients suffering from tuberous sclerosis, in which *TSC1* function has been lost through a germ-line mutation and subsequent somatic loss of heterozygosity. Seen here are the giant cells present in a benign growth (a "tuber"). The giant cells (*brown*) are labeled with an antibody against phosphorylated S6, a ribosomal protein important in regulating protein synthesis and thus cell growth; S6 phosphorylation and functional activation is deregulated in cells lacking *TSC1* function. (C) The Akt/PKB protein is frequently hyperactivated in human cancers. In an imaginal disc of a developing *Drosophila* larva, Akt/PKB (*green*) that has been hyperactivated in a portion of cells (*upper right*) causes a great increase in nuclear and overall cell size relative to cells with normal Akt/PKB (*lower left*), as revealed by the spacing of the nuclei (*blue*) in these two sectors; similar increases in mammalian cells are also observed in response to hyperactive Akt/PKB. (A, from X. Gao and D. Pan, *Genes Dev.* 15:1383–1392, 2001. With permission of Cold Spring Harbor Laboratory Press. B, courtesy of J.A. Chan and D.J. Kwiatkowski. C, from J. Verdu et al., *Nat. Cell Biol.* 1:500–506, 1999. With permission from Nature.)

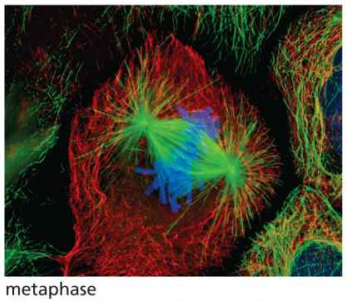
The accumulation of a cell's macromolecules involves, among many other molecules, the duplication of the cell's genome. In many prokaryotic cells, this duplication—the process of DNA replication—begins immediately after daughter cells are formed by cell division. But in most mammalian cells, the overall program of macromolecular synthesis is organized quite differently. Although the accumulation of RNA and proteins is initiated immediately after cell division and proceeds continuously until the next cell division, the task of replicating the DNA is deferred for a number of hours (often as many as 12 to 15) after emergence of new daughter cells from mitosis and cytokinesis. During this period between the birth of a daughter cell and the subsequent onset of DNA synthesis, which is termed the G_1 (first gap) phase of the cell cycle (**Figure 8.3**), cells make critical decisions about growth versus quiescence, and whether, as quiescent cells, they will differentiate.



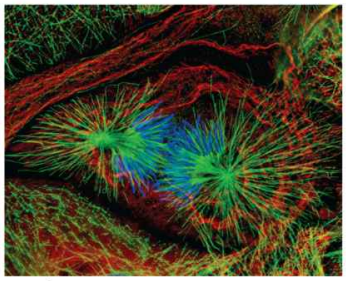
prophase



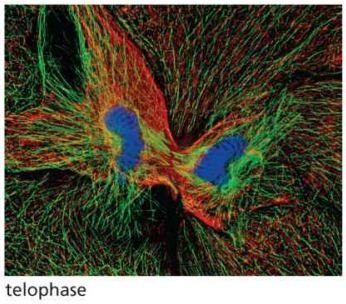
prometaphase



metaphase



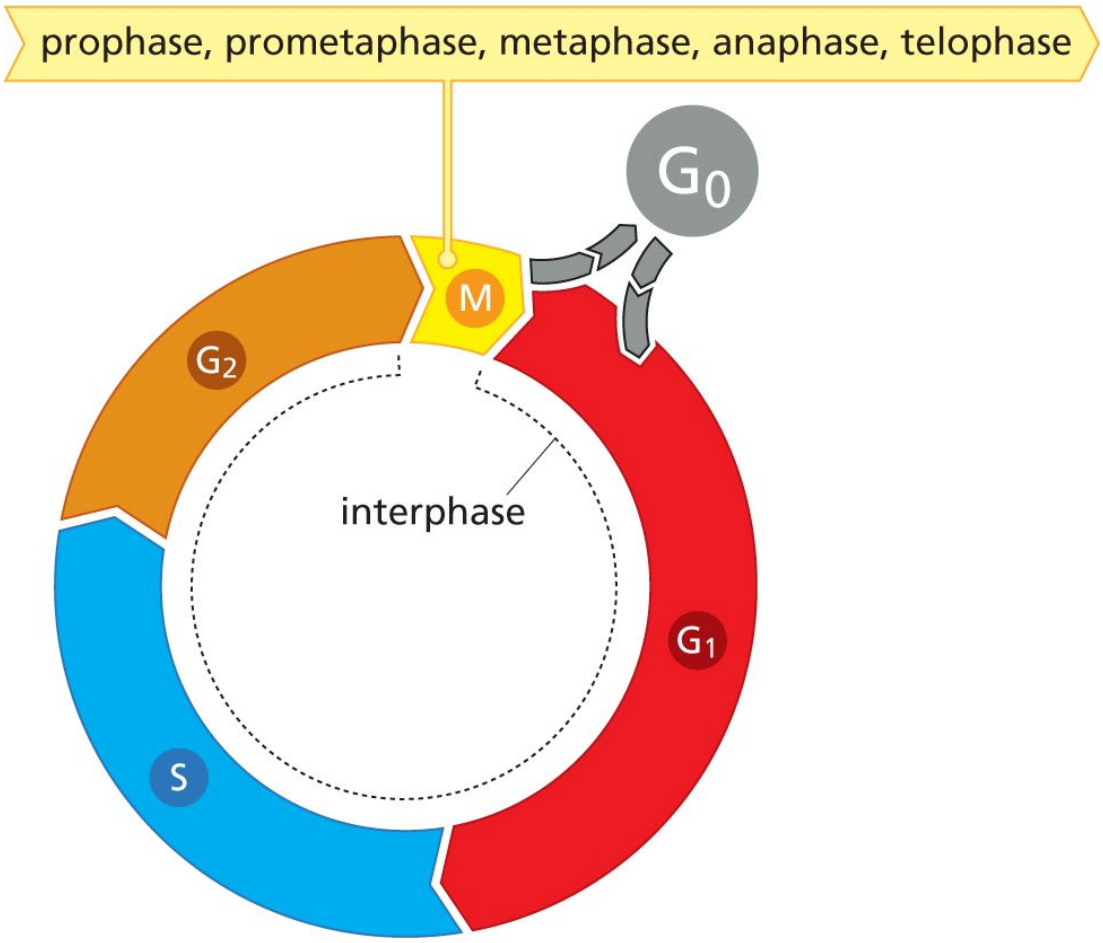
anaphase



telophase

A sequence of five fluorescent stain images showing substages of mitosis: prophase, prometaphase, metaphase, anaphase, and telophase. In prophase, blue chromosomes are visible in the nucleus. The green mitotic spindle extends outwards from central points. In prometaphase, the mitotic spindle starts to attach

to the chromosomes. In metaphase, the centrosomes are opposite of each other and the mitotic spindle is more organised. In anaphase, two groupings of chromatids start to separate. In telophase, the cell starts to divide in half and the chromatids cluster together in each half.
(A)



A diagram shows that mitosis and its five substages are a small part of a cycle that also includes G 1, S, and G 2 phases. These three are collectively known as the interphase. There is also a G zero state that a cell may enter after the M phase, instead of or before passing through the G 1 phase. The five substages of mitosis are prophasem prometaphase, metaphase, anaphase, and telophase.

(B)

Figure 8.3 The vertebrate cell cycle (A) Immunofluorescence is used here to illustrate the five distinct subphases of mitosis (M phase) in newt lung cells (*top to bottom*). During the *prophase* of mitosis, the chromosomes (*blue*), which were

invisible microscopically during *interphase* (the period encompassing G_1 through S and G_2), begin to condense and become visible, while the centrosomes (*light green radiating bodies*) at the poles of the cell begin to assemble (*top image*). During *prometaphase*, the nuclear membrane disappears (*second image*). During *metaphase*, the chromosomes align along a plane that bisects the cell and become attached to the microtubule fibers of the mitotic spindle (*light green, third image*). During *anaphase*, the two halves of each chromosome—the chromatids—are pulled apart by the mitotic spindle (i.e., they segregate) to the two opposite poles of the cell (*fourth image*). During *telophase*, shortly after the chromatids cluster into the two sets seen here (*bottom image*), the chromatids de-condense and a new nuclear membrane forms around each set of chromatids (now called chromosomes). At the same time, during the process of *cytokinesis*, the cytoplasm of the mother cell divides, yielding two daughter cells (*not shown*). Actin fibers are labeled in *red*. (B) The mammalian growth-and-division cycle is divided into four phases—G_1, S (during which DNA is replicated), G_2, and M (mitosis). A fifth state, G_0 (G zero), denotes the resting, nonproliferating state of cells that have withdrawn from the active cell cycle. Although exit from the active cell cycle into G_0 is depicted here as occurring in early G_1, it is unclear when during G_1 this actually occurs. (Some evidence suggests that cells exiting mitosis decide whether or not to enter G_0 on the basis of signals experienced during the preceding G_2.) (A, photomicrographs by Dr. Conly L. Rieder, Wadsworth Center, Albany, New York 12201-0509.)

In many types of cultured mammalian cells, the DNA synthesis that follows G_1 often requires 6 to 8 hours to reach completion. This period of DNA synthesis is termed the S (synthetic) phase, and its length is determined in part by the enormous amount of cellular DNA ($\sim 6.4 \times 10^9$ bp per diploid genome) that must be replicated with fidelity during this time. The actual length of S phase varies greatly among different kinds of cells, being much shorter in certain cell types, such as rapidly dividing embryonic cells and lymphocytes.

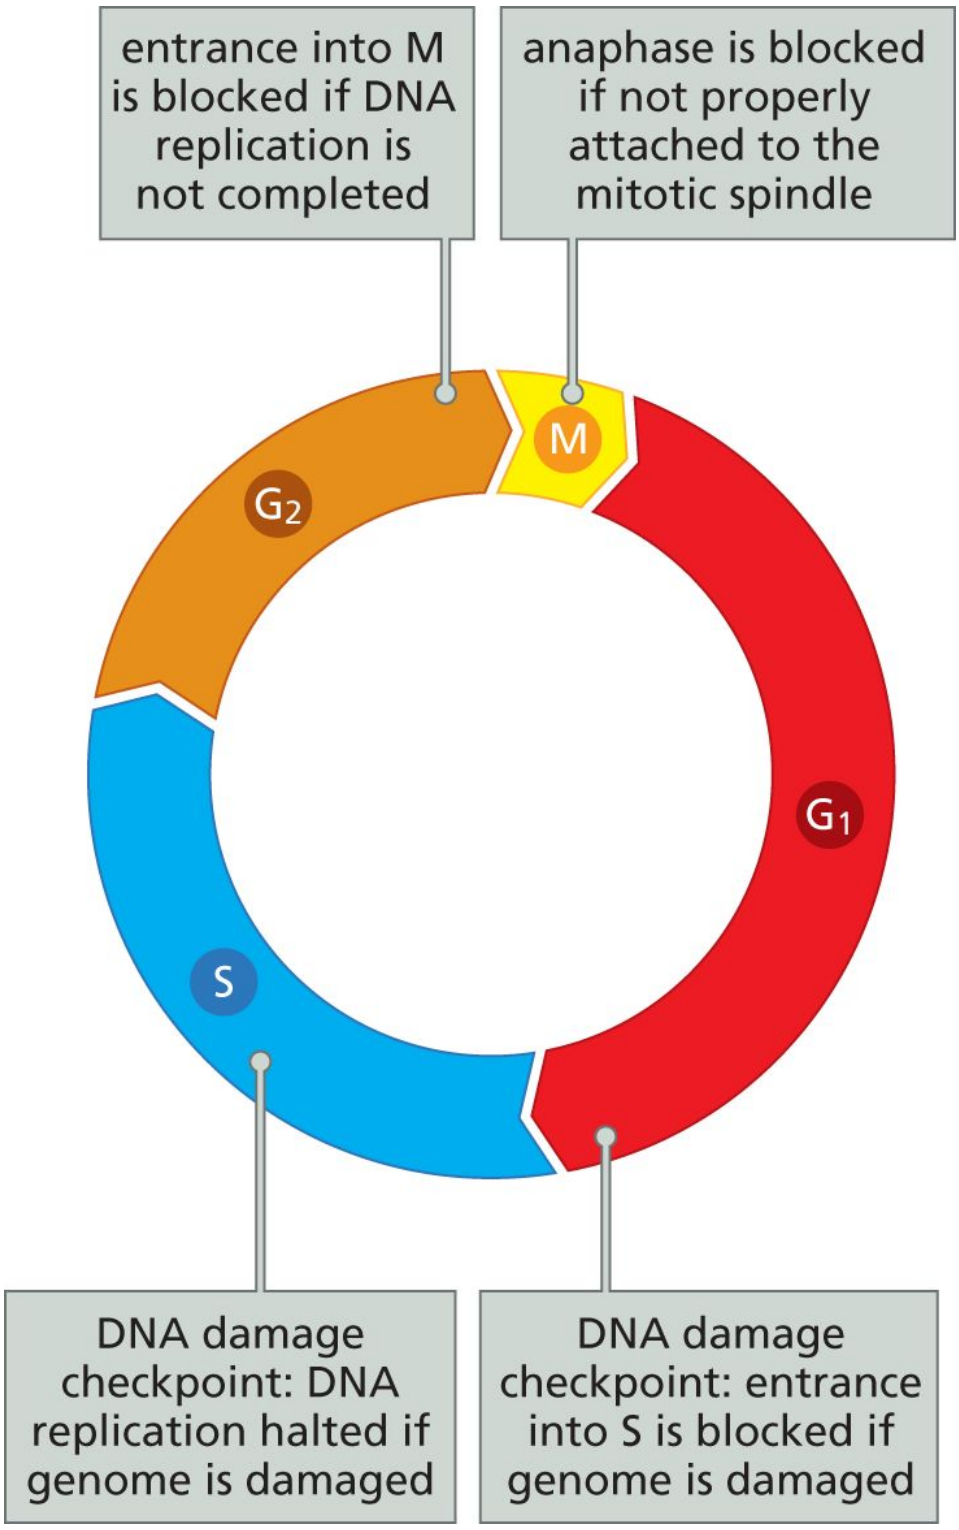
Having passed through S phase, a cell might be thought fit to enter directly into mitosis (M phase). However, most mammalian cells spend 3 to 5 hours in a second gap phase, termed G_2, preparing themselves, in some still-poorly understood fashion, for entrance into M phase and cell division. M phase itself usually encompasses an hour or so, and includes five distinct subphases—prophase, prometaphase, metaphase, anaphase, and telophase; this culminates in cytokinesis, the division of the cytoplasm that allows the formation of two new cells (see Figure 8.3A). Although these times are commonly observed when studying mammalian cells in culture, they do not reflect the behavior of all cell types under all conditions. For example, actively proliferating

lymphocytes may double in 5 to 6 hours, and some cells in the early embryos of certain organisms may do so in as little as 15 minutes, where the G_1 and G_2 phases are essentially absent and all the materials needed to generate the newly formed daughter cells are already present in the fertilized egg.

As is the case with S phase, M phase must proceed with great precision. M phase begins with the two recently duplicated DNA helices within each chromosome; these are carried in the sister chromatids of the chromosome, which are aligned adjacent to one another in the nucleus. The allocation during mitosis of the duplicated chromatids to the two future daughter cells must occur flawlessly to ensure that each daughter receives exactly one diploid complement of chromatids—no more and no less. Once present within the nuclei of recently separated daughter cells, these chromatids become the chromosomes of the newly born cells.

Consequently, the endowment of one genome's worth of genetic material to each daughter cell depends on the precise execution of two processes—the faithful replication of a cell's genome during S phase and the proper allocation of the resulting duplicated DNAs to daughter cells during M phase. As will be discussed later in Chapter 12, defects in either of these processes can have disastrous consequences for the cell and the organism, one of which is the disease of cancer.

Like virtually all machinery, the machine that executes the various steps of the cell cycle is subject to malfunction. This fallibility contrasts with the stringent requirement of the cell that the various phases of the cell cycle are completed flawlessly. For this reason, the cell deploys a series of surveillance mechanisms that monitor each step in cell cycle progression and permit the cell to proceed to the next step in the cycle only if a preceding step has been completed successfully. Thus, if specific steps in the execution of a preceding process go awry, these monitors rapidly call a halt to further advance through the cell cycle until these problems have been successfully addressed. Yet other monitors ensure that once a particular step of the cell cycle has been completed, it is not repeated until the cell passes through the next cell cycle. These monitoring mechanisms are termed variously checkpoints or checkpoint controls (**Figure 8.4**).



A diagram shows some checkpoints in the cell cycle, which contains the four stages G 1, S, and G 2, and M. M is the shortest, G 1 is the longest. At the end of G 1, there is a D N A damage checkpoint: entrance into S is blocked if the genome is damaged. Near the middle of S, there is another D N A damage checkpoint: D N

A replication is halted if the genome is damaged. At the end of G 2, entrance into M is blocked if D N A replication is not completed. In the middle of M, the anaphase is blocked if not properly attached to the mitotic spindle.

Figure 8.4 Examples of checkpoints in the cell cycle Checkpoints impose quality control to ensure that a cell has properly completed all the requisite steps of one phase of the cell cycle before it is allowed to advance into the next phase. A cell will not be permitted to enter into S phase until all the steps of G_1 have been completed. It will be blocked from entering G_2 until all of its chromosomal DNA has been properly replicated during S phase. Similarly, a cell is not permitted to enter into anaphase (when the paired chromatids are pulled apart) until all of its chromosomes are properly assembled on the mitotic spindle during metaphase. In addition, a cell is not allowed to advance into S or M if its DNA has been damaged and not yet repaired. Other controls (*not shown*) ensure that once a specific step in the cell cycle has been completed, it is not repeated until the next cell cycle.

One checkpoint ensures that a cell cannot advance from G_1 into S if the genome is in need of repair. Another, operating in S phase, will slow or pause DNA replication in response to DNA damage. (In mammalian cells, this may cause a doubling of the time required to complete DNA synthesis.) A third will not permit the cell to proceed through G_2 to M until the DNA replication of S phase has been completed. DNA damage will trigger another checkpoint control that blocks entrance into M phase. During M phase, highly efficient checkpoint controls block entrance into anaphase; these blocks are only removed once all the chromosomes have been properly attached to the mitotic spindle. Yet other checkpoint controls, not cited here, have been reported. For example, a decatenation checkpoint in late G_2 prevents entrance into M until the pair of DNA helices replicated in the previous S phase have been disentangled from one another, a step that requires the active involvement of type II topoisomerases. Defects in some of these checkpoint controls can be observed because of their effects on cells' chromosomes (see Figure 1.9B and **Supplementary Sidebar 8.1**).

The operations of these checkpoints also influence the formation of cancers. As tumor development (often called tumor progression, discussed in Chapter 11) proceeds, incipient cancer cells benefit from experimenting with various combinations and permutations of mutant alleles, retaining those that will afford them the greatest proliferative advantage. An increased mutability of their genomes accelerates the rate at which these cells can acquire advantageous combinations of alleles and thus hastens the overall pace of tumor progression. Such mutability and resulting genomic instability are incompatible with normal cell cycle progression, because checkpoint controls usually block advance of the cell through its cycle if its DNA has been damaged or its chromosomes are in disarray. So, in addition to acquiring altered

growth-controlling genes (that is, activated oncogenes and inactivated tumor suppressor genes), many types of cancer cells have inactivated one or more of their checkpoint controls. With these controls relaxed, incipient cancer cells can more rapidly accumulate the mutant genes and altered karyotypes that propel their neoplastic growth. The breakdown of the controls responsible for maintaining the cellular genome in an intact state is one of the main subjects of Chapter 12.

OceanofPDF.com

Glossary

cell cycle
: The sequence of changes in a cell from the moment when it is created by cell division, continuing through a period in which its contents including chromosomal DNA are doubled, and ending with the subsequent cell division and formation of two daughter cells.

mitosis
: (1) Nuclear division, composed of the four steps of prophase, metaphase, anaphase, and telophase, the last including cytokinesis. (2) Process by which a single cell separates its complement of chromosomes into two equal sets in preparation for the division of the cell into two daughter cells achieved by cytokinesis.

cytokinesis
: The late step of mitosis involving the separation of the two daughter cell cytoplasms from one another.

post-mitotic
: Describing a nonproliferating cell that has given up the option of ever again re-entering into an active growth-and-division cycle.

prophase
: First phase of mitosis in which chromosomes begin to condense and centrosomes begin to assemble.

prometaphase
: The phase of mitosis in the early part of metaphase when the nuclear membrane breaks down and the chromosomes form kinetochores. *See* **metaphase, kinetochore**.

metaphase
: Second major phase of mitosis, during which chromosomes complete condensation and attach to the mitotic spindle after the nuclear membrane disappears; chromosomes are now readily observed in the light microscope following appropriate staining.

anaphase
: Third subphase of mitosis, during which the paired chromatids are segregated to the two opposite poles of the cell.

telophase

Fourth subphase of mitosis, during which chromosomes de-condense and the nuclear membranes reassemble in anticipation of separation of the two daughter cells.

chromatid

A half chromosome that exists after S phase and before M phase; paired chromatids are separated at M phase, whereupon each becomes a chromosome.

checkpoint

(1) Control mechanism that ensures that the next step in a process does not proceed until a series of prerequisites and conditions have been fulfilled. Such prerequisites may include, as examples, the successful completion of all previous steps during cell-cycle progression or the integrity of the cell genome. (2) Control mechanism that limits or constrains the immune-mediated attack on targeted cells. *See also* **immune checkpoint**.

checkpoint

(1) Control mechanism that ensures that the next step in a process does not proceed until a series of prerequisites and conditions have been fulfilled. Such prerequisites may include, as examples, the successful completion of all previous steps during cell-cycle progression or the integrity of the cell genome. (2) Control mechanism that limits or constrains the immune-mediated attack on targeted cells. *See also* **immune checkpoint**.

decatenation

Untangling and separation of topologically intertwined circular dsDNA molecules from one another, often accomplished by the topoisomerase II enzyme. *See also* **topoisomerase**.

progression

(1) The process whereby cells evolve progressively from a normal state to a state that enables them to form a high-grade malignancy. (2) The evolution of benign cancer cells to malignant derivatives. (3) The evolution of an initiated cell that is dependent on continued exposure to a tumor-promoting agent for its further proliferation into one that continues to proliferate in the absence of further exposure to the promoter. *See also* **initiation**, **promotion**.

OceanofPDF.com

8.2 Cells make decisions about growth and quiescence during a specific period in the G_1 phase

As mentioned earlier, virtually all normal cell types in the body require external signals, such as those conveyed by mitogenic growth factors, before they undertake growth and division. The only exceptions to this rule appear to be very early embryonic cells, which seem able to proliferate without receiving growth-stimulating signals from elsewhere (**Sidebar 8.1**). The rationale for the contrasting behavior of the normal differentiated cells throughout our tissues is a simple one: because these cells participate in the formation of precisely structured tissues, their proliferation must, by necessity, be coordinated with neighboring cells in those tissues. Put differently, the body cannot give each of its almost 10^{14} component cells the license to decide on its own whether to grow and divide. To do so would invite chaos.

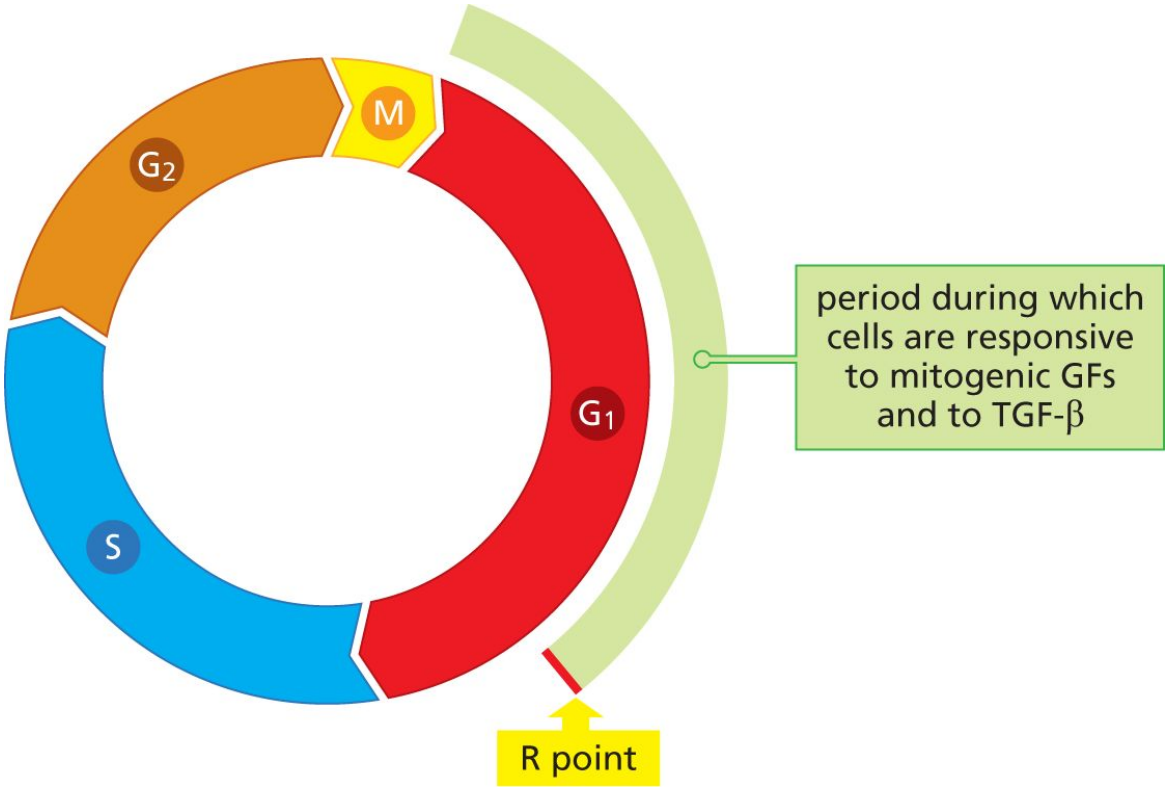
Sidebar 8.1 Embryonic stem (ES) cells show highly autonomous behavior

Our perceptions about the behavior of normal mammalian cells have been conditioned by decades of work with a wide variety of somatic cells present in embryonic and adult tissues. However, cells in the very early embryo clearly operate under a very different set of rules. The pRb pathway and the cell cycle clock machinery to be described in this chapter appear to operate in one form or another in virtually all types of adult cells. In contrast, a variety of experiments indicate that pRb-imposed growth control (to be described in Section 8.5) is not functional in early embryonic cells, including their cultured derivatives, embryonic stem (ES) cells. The same can be said about the p53 pathway (see Chapter 9).

ES cells seem to preserve some of the cell-autonomous behavior that we associate with the single-cell ancestors of metazoa, that is, the behavior of cells that have not yet become dependent on their neighbors for signals controlling growth and survival. The most stunning indication of their extreme autonomy is their ability to form benign tumors (teratomas) when introduced into many anatomical sites in

an adult organism (see Figure 2.10). Because these cells are genetically wild type, they represent the only example of a wild-type cell that is tumorigenic.

Evidence accumulated over the past three decades indicates that cells consult their extracellular environment and its growth-regulating signals during a discrete window of time in the active cell cycle, namely from the onset of G_1 phase until an hour or two before the G_1-to-S transition (**Figure 8.5**). The operations of the G_1 decision-making machinery are indicated by the responses of cultured cells to extracellular signals. If we were to remove serum and thus growth factors from cells before they had completed 80 to 90% of G_1, they would fail to proceed further into the cell cycle and would, with great likelihood, revert to the G_0 state. However, once these cells had moved through this G_1 decision-making period and advanced into the final hours of G_1 (the remaining 10 to 20% of G_1), the removal of serum would no longer affect their progress and they would proceed through the remainder of G_1 and onward through the S, G_2, and M phases. Similarly, anti-mitogenic factors, such as TGF-β, are able to impose their growth-inhibitory effects only during this period in the early and mid-G_1 phase. Once a cell has entered into late G_1, it seems to be oblivious to the presence of this negative factor in its surroundings. (There are isolated reports of the effects of TGF-β at the G_1/S boundary and the G_2/M boundary, but their role in regulating overall cell cycle progression remains unclear.)



A diagram shows when responsiveness to extracellular signals occurs during the cell cycle. The period during which cells are responsive to mitogenic G Fs and to T G F-beta runs from the start of the G 1 phase to a point near the end of the G 1 phase, labeled the R point.

Figure 8.5 Responsiveness to extracellular signals during the cell cycle
Cells respond to extracellular mitogens and inhibitory factors (such as TGF-β) only in a discrete window of time that begins at the onset of G_1 and ends just before the end of G_1. The end of this time window is often designated as the restriction (R) point, which denotes the point in time when the cell must make the commitment to advance through the remainder of the cell cycle through M phase, to remain in G_1, or to retreat from the active cell cycle into G_0.

This schedule of total dependence on extracellular signals followed by entrance in late G_1 into a state of relative independence indicates that a weighty decision must be made toward the end of G_1. Precisely at this point, a cell must make up its mind whether it will remain in G_1, retreat from the active cycle into G_0, or

advance into late G_1 and thereafter into the remaining phases of the cell cycle. This critical decision is made at a transition that has been called the restriction point or R point (see Figure 8.5). In most mammalian cells studied to date, the R point occurs several hours before the G_1/S phase transition.

If a cell should decide at the R point to continue advancing through its growth-and-division cycle, it commits itself to proceed beyond G_1 into S phase and then to complete a rigidly programmed series of events (the entire S, G_2, and M phases) that enable it to divide into two daughter cells. This decision will be respected even if growth factors are no longer present in the extracellular space during these remaining phases of the cell cycle. We know that this series of later steps (S, G_2, and M phases) proceeds on a fixed schedule, because a cell that enters S will, in the absence of a major disaster, invariably complete S and, having done so, enter into G_2 and then advance into M phase.

For those interested specifically in understanding the deregulated proliferation of cancer cells, this fixed program holds relatively little interest, because the late $G_1 \rightarrow S \rightarrow G_2 \rightarrow M$ progression proceeds similarly in normal cells and cancer cells. Students of cancer therefore focus largely on the G_0/G_1 transition and on the one period in the life of an actively growing cell—the time window encompassing most of G_1—when a cell is given the license to make decisions about its fate.

The commitment to advance through the R point and continue all the way to M phase is, as hinted, not an absolute one. Metabolic, genetic, or physical disasters may intervene during S, G_2, or M and force the cell to call a halt, often temporary, to its further advance through the cell cycle until these conditions have been addressed. Still, in the great majority of cases, cells in living tissues seem to succeed in avoiding these various disasters. This leaves the R-point decision as the critical determinant of whether cells will grow or not. An increasingly large body of evidence indicates that deregulation of the R-point decision-making machinery accompanies the formation of most if not all types of cancer cells.

If a cell does not enjoy the proper attachment to the extracellular matrix (ECM), much of it mediated by integrins (see Section 5.9), it will halt further advance through the cell cycle until proper tethering has been achieved. Alternatively, if it has lost all attachment to the ECM, it may activate anoikis, a form of the apoptotic cell suicide program described in the next chapter.

When grown in monolayer culture in Petri dishes, normal cells achieve the required attachment by adhering to ECM that they have deposited on the glass or plastic surfaces of these dishes. This requirement for attachment reflects the phenotype of anchorage dependence (see Section 3.5). Tumorigenic cells, which almost always have lost this dependence and have therefore become anchorage-independent, have inactivated or lost this late G_1 checkpoint. In some fashion, still poorly understood, oncoproteins like Ras and Src are able to mislead a cell into thinking that it has achieved extensive anchorage (see, for example, Section 6.9) when, in fact, none may exist at all.

Yet other, still-fragmentary evidence suggests additional environment-sensing checkpoints that operate before and after the R point. For example, one important checkpoint control operating between the R point and the onset of S phase gauges whether a cell has access to adequate levels of nutrients and halts cell cycle progression until such nutrients become available; another appears to determine whether reactive oxygen species (which in other contexts are thought to be toxic for the cell) are present in adequately high levels before progression is permitted. Such findings suggest that successful advance through late G_1 depends on passing through a succession of checkpoints in addition to the R point described here, not all of which have been well characterized.

OceanofPDF.com

Glossary

teratoma
: Benign tumor formed by embryonic stem cells in which a wide variety of differentiated cell types are formed.

restriction point
: Decision-making point in the late G_1 phase of the cell cycle at which a cell commits itself to either completing the remaining phases of the cell cycle, remaining in G_1, or exiting the active cell cycle and entering into G_0.

R point
: Decision-making point in the late G_1 phase of the cell cycle at which a cell commits itself to either completing the remaining phases of the cell cycle, remaining in G_1, or exiting the active cell cycle and entering into G_0.

anoikis
: Form of apoptosis that is triggered by the failure of a cell to establish anchorage to a solid substrate, such as the extracellular matrix, or by loss of such anchorage.

reactive oxygen species
: A chemically reactive, oxidizing molecule that results from the incomplete reduction of oxygen, including notably superoxide, hydrogen peroxide, and hydroxyl radical; these reactive oxygen species damage a wide range of molecules in the cell, requiring compensatory anti-oxidant defenses to prevent or reverse this damage.

anchorage independence
: Ability of a cell to proliferate without attachment to a solid substrate.

8.3 Cyclins and cyclin-dependent kinases constitute the core components of the cell cycle clock

The existence of the R point leaves us with two major questions that we will spend much of this chapter answering. First, what is the nature of the molecular machinery that decides whether or not a cell in G_1 will continue to advance through the R point and the remainder of the cell cycle or will exit into a nongrowing state? Second, how does this machinery, which we call the cell cycle clock, implement these decisions once they have been made? We begin with the second question and will return later to the first.

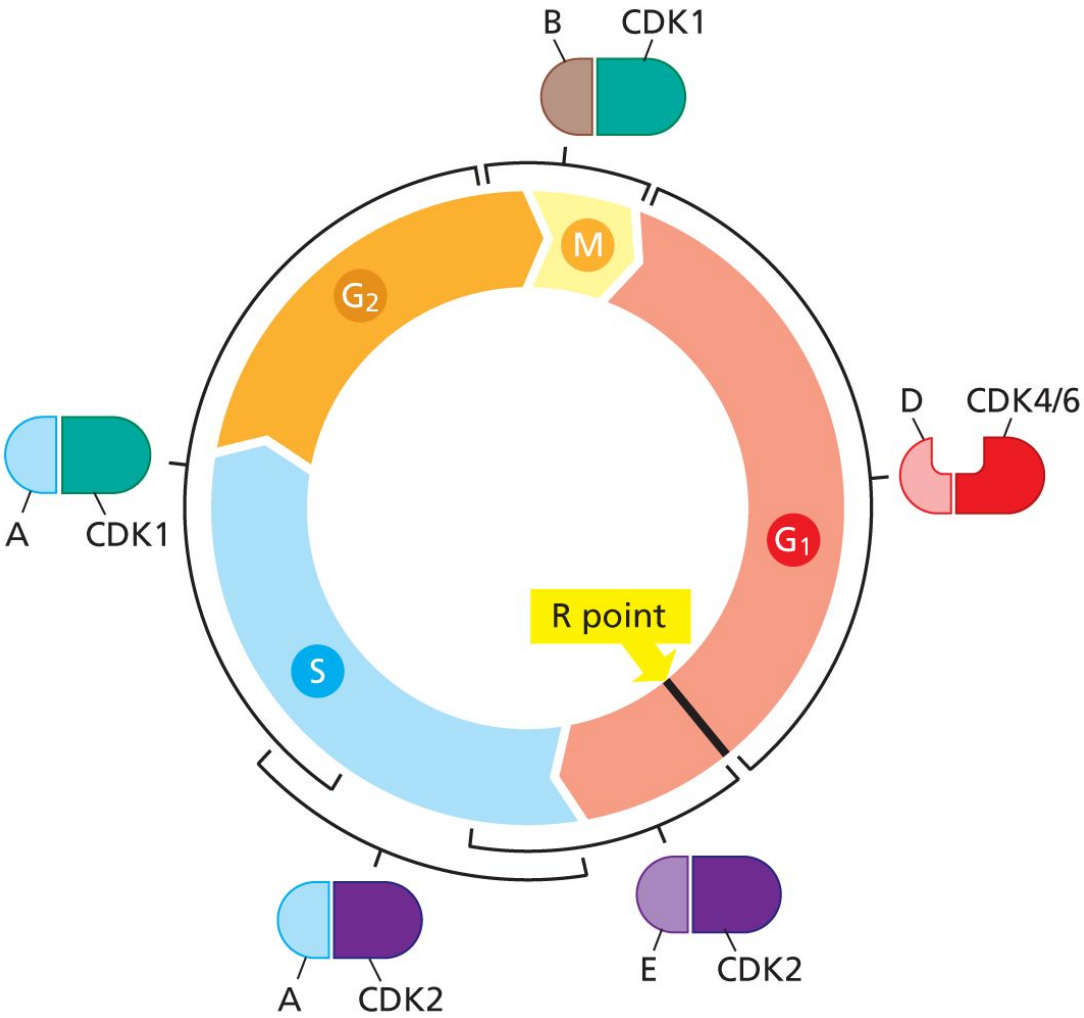
As described earlier (Chapters 5 and 6) by phosphorylating multiple distinct substrates, a single kinase enzyme can create covalent modifications that serve to switch on or off various activities inherent in these substrate proteins. In fact, the cell cycle clock also uses a group of protein kinases to execute the various steps of cell cycle progression. As examples, phosphorylation by these kinases of centrosome-associated proteins at the G_1/S boundary allows their duplication in preparation for M phase. Phosphorylation of other proteins prior to S phase enables DNA replication sites along the chromosomes to be activated. Phosphorylation of histone proteins in anticipation of S and M phases places the chromatin in configurations that permit these two phases to proceed normally. And the phosphorylation of proteins forming the nuclear membrane (sometimes called the *nuclear envelope*), such as lamin and nucleoporins, causes their dissociation and the dissolution of this membrane early in M phase.

The kinases deployed by the cell cycle machinery are called collectively cyclin-dependent kinases (CDKs) to indicate that these enzymes never act on their own; instead, they depend on associated regulatory subunits, the cyclin proteins, for proper functioning. Bimolecular complexes of CDKs and their cyclin partners are responsible for dispatching signals from the cell cycle clock to hundreds of effector molecules that carry out the actual work of moving the cell through its growth-and-division cycle. (A number of structurally related CDKs involved in other cellular processes, such as control of transcription, are not discussed further here.)

The CDKs are serine/threonine kinases, in contrast to the tyrosine kinase activities that are associated with growth factor receptors and with nonreceptor kinase molecules like Src. The CDKs show about 40% amino acid sequence identity with one another and therefore are considered to form a distinct subfamily within the large (approximately

430) throng of Ser/Thr kinases encoded by the human genome (see **Supplementary Sidebar 17.7**). The cyclins associated reversibly with their CDK partners activate the catalytic activity of these partners (**Supplementary Sidebar 8.2**). (In the well-studied example of the binding of cyclin A to CDK2, the association of the two proteins increases the enzymatic activity of CDK2 a staggering 400,000-fold!) At the same time, the cyclins serve as guide dogs for the CDKs by helping the cyclin–CDK complexes recognize appropriate protein substrates in the cell. The cyclins, for their part, also constitute a distinct family of cellular proteins that share in common a domain of approximately 100 amino acid residues that is involved in the binding and functional activation of CDKs.

It is actually cyclin–CDK complexes that constitute the engine of the cell cycle clock machinery. During much of the G_1 phase of the cell cycle, two similarly acting CDKs —CDK4 and CDK6—are guided by and depend upon their association with one of a trio of related cyclins (D1, D2, and D3) that collectively are called the D-type cyclins (**Figure 8.6**). After the R point in late G_1, the E-type cyclins (E1 and E2) associate with CDK2 to enable the phosphorylation of appropriate substrates required for entry into S phase. As cells enter into S phase, the A-type cyclins (A1 and A2) replace E cyclins as the partners of CDK2 and thereby enable S phase to progress (see Figure 8.6). Later in S phase, the A-type cyclins switch partners, leaving CDK2 and associating instead with another CDK called either CDC2 or CDK1. (We will use CDK1 here.) As the cell moves further into G_2 phase, the A-type cyclins are replaced as CDK1 partners by the B-type cyclins (B1 and B2). Finally, at the onset of M phase, the complexes of CDK1 with the B-type cyclins trigger many of the events of the prophase, metaphase, anaphase, and telophase that together constitute the complex program of mitosis.

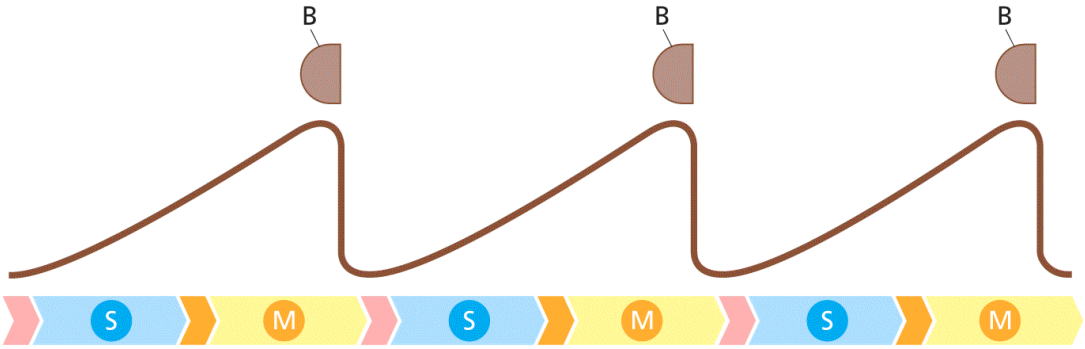


A diagram shows pairings of cyclins with cyclin-dependent kinases during different parts of the cell cycle. From the start of the G 1 phase to the R point, D-type cyclins bind C D K 4 or 6. After the R point and a short distance into the S phase, E-type cyclins bind C D K 2. During the first half of the S phase and nearly all of the G 2 phase, A-type cyclins bind C D K 2. During the last two-thirds of the S phase, A-type cyclins bind C D K 1. During the very end of the G 2 phase and all of the M phase, B-type cyclins bind C D K 1.

Figure 8.6 Pairing of cyclins with cyclin-dependent kinases Each type of cyclin pairs with a specific cyclin-dependent kinase (CDK) or set of CDKs. The D-type cyclins (D1, D2, and D3) bind CDK4 or CDK6, the E-type cyclins (E1 and E2) bind CDK2, the A-type cyclins (A1 and A2) bind CDK2 or CDK1, and the B-type cyclins (B1 and B2) bind CDK1. The brackets indicate the periods during the cell cycle when these various cyclin–CDK complexes are active.

As is the case with all well-regulated systems, the activities of the various cyclin–CDK complexes must be modulated in order to impose control on specific steps in the cell cycle. The most important way of achieving this regulation depends upon changing the levels and availability of cyclins during various phases of the cell cycle. In contrast, the levels of most CDKs vary only minimally.

The first insights into cyclin–CDK control came from studies of the governors of mitosis in early frog and sea urchin embryos. As these experiments showed, levels of B-type cyclins increase strongly in anticipation of mitosis, allowing B cyclins and CDK1 to form complexes that initiate entrance into M phase. At the end of M phase, cyclin B levels plummet because of the scheduled degradation of this protein. Early in the next cell cycle, cyclin B is virtually undetectable in cells, and it accumulates gradually later in this cycle in preparation of the next M phase. Because the growth-and-division cycles of all of the cells in these early embryos are synchronous (that is, take place coordinately), all cells in the embryo go through S and M at the same time. This behavior results in repeated rounds of cycling of the levels of these cyclin proteins—the behavior that inspired their name (**Figure 8.7**).

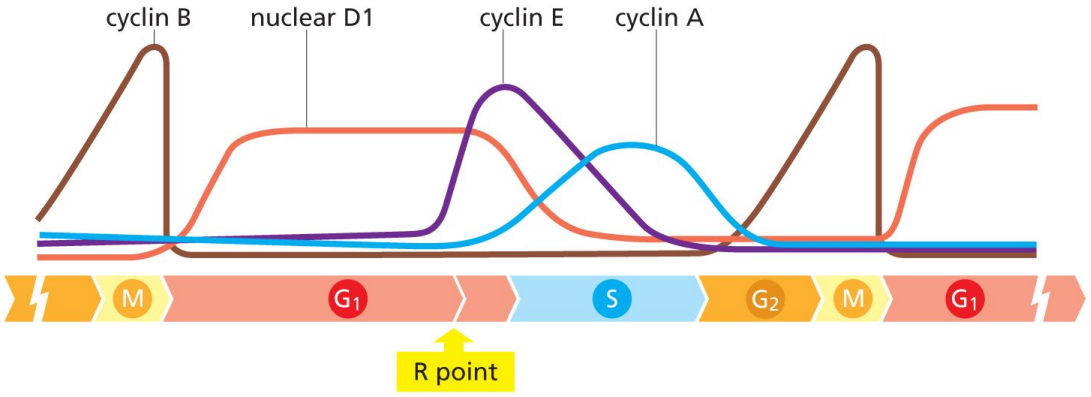


A linear sequence of cell cycle phases, with associated cyclin B levels. The G 1 and G2 phases are very short and the S and M phases are long. A line above the sequence indicates that cyclin B levels are lowest during G 1 and rise steadily through S and G 2 to the end of M before dropping down to repeat the cycle. This repeats three times.

Figure 8.7 Cell cycle–dependent fluctuations in cyclin B levels The cyclic fluctuations in the levels of cyclin B in early frog and sea urchin embryos gave cyclins their name. These fluctuations were noticeable because the cell cycles in these early embryos are synchronous, i.e., all cells in an embryo enter into M phase simultaneously. In these early embryos, the G_1 and G_2 phases of the cell cycle (*orange–pink chevrons*) are virtually absent and the cells, in effect, alternate between M and S phases. (Although cyclin B levels are already substantial prior to

the onset of M phase, cyclin B molecules are unable to form catalytically active B–CDK1 (also termed CDC2) complexes until the G_2-to-M transition.)

This theme of dramatic cell cycle phase–dependent changes in the levels of cyclin B is repeated by other cyclins as well. Cyclin E levels are low throughout most of G_1, rise abruptly after a cell has progressed through the R point, and collapse as the cell enters S phase (**Figure 8.8**), while cyclin A increases in concert with the cell's entrance into S phase. (Although there are at least two subtypes of cyclin A, cyclin B, and cyclin E, we will refer to these simply as cyclins A, B, and E, respectively, because the two subtypes of each of these cyclins appear to operate identically.)

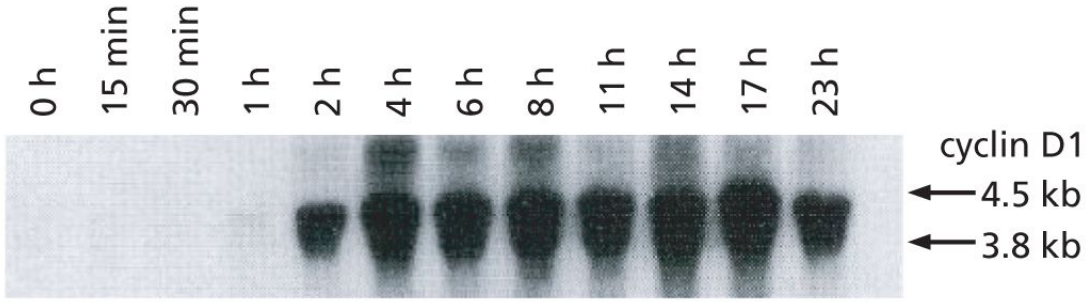


A linear sequence of cell cycle phases, with associated cyclin A, B and E levels. The G 1 phase is longest and M phase is shortest. The S phase and G 2 phases are intermediate. Lines above the sequence indicate cyclin levels. Cyclin A levels are low during M and G 1, rise during S, and fall at the end of S and into G 2. Cyclin B levels are low during G 1 and S, rise steadily during G 2 and M, and drop abruptly at the end of M. Cyclin E levels are low during G 2, M and G 1 up to the R point, rise steeply after the R point, and drop back down during S.

Figure 8.8 Fluctuation of cyclin levels during the cell cycle The levels of most of the mammalian cyclins fluctuate dramatically as cells progress through the cell cycle. For most of these cyclins, these fluctuations are tightly coordinated with the schedule of advances through the various cell cycle phases. However, in the case of the D-type cyclins, extracellular signals, notably those conveyed by growth factors, strongly influence their levels. (Although cyclin D1—and possibly other D-type cyclins—is present in other cell cycle phases besides G_1, following the G_1/S transition it is exported from the nucleus into the cytoplasm, where it can no longer influence cell cycle progression. The precise time point at which cyclin D–CDK4/6 complexes lose activity is not well defined.)

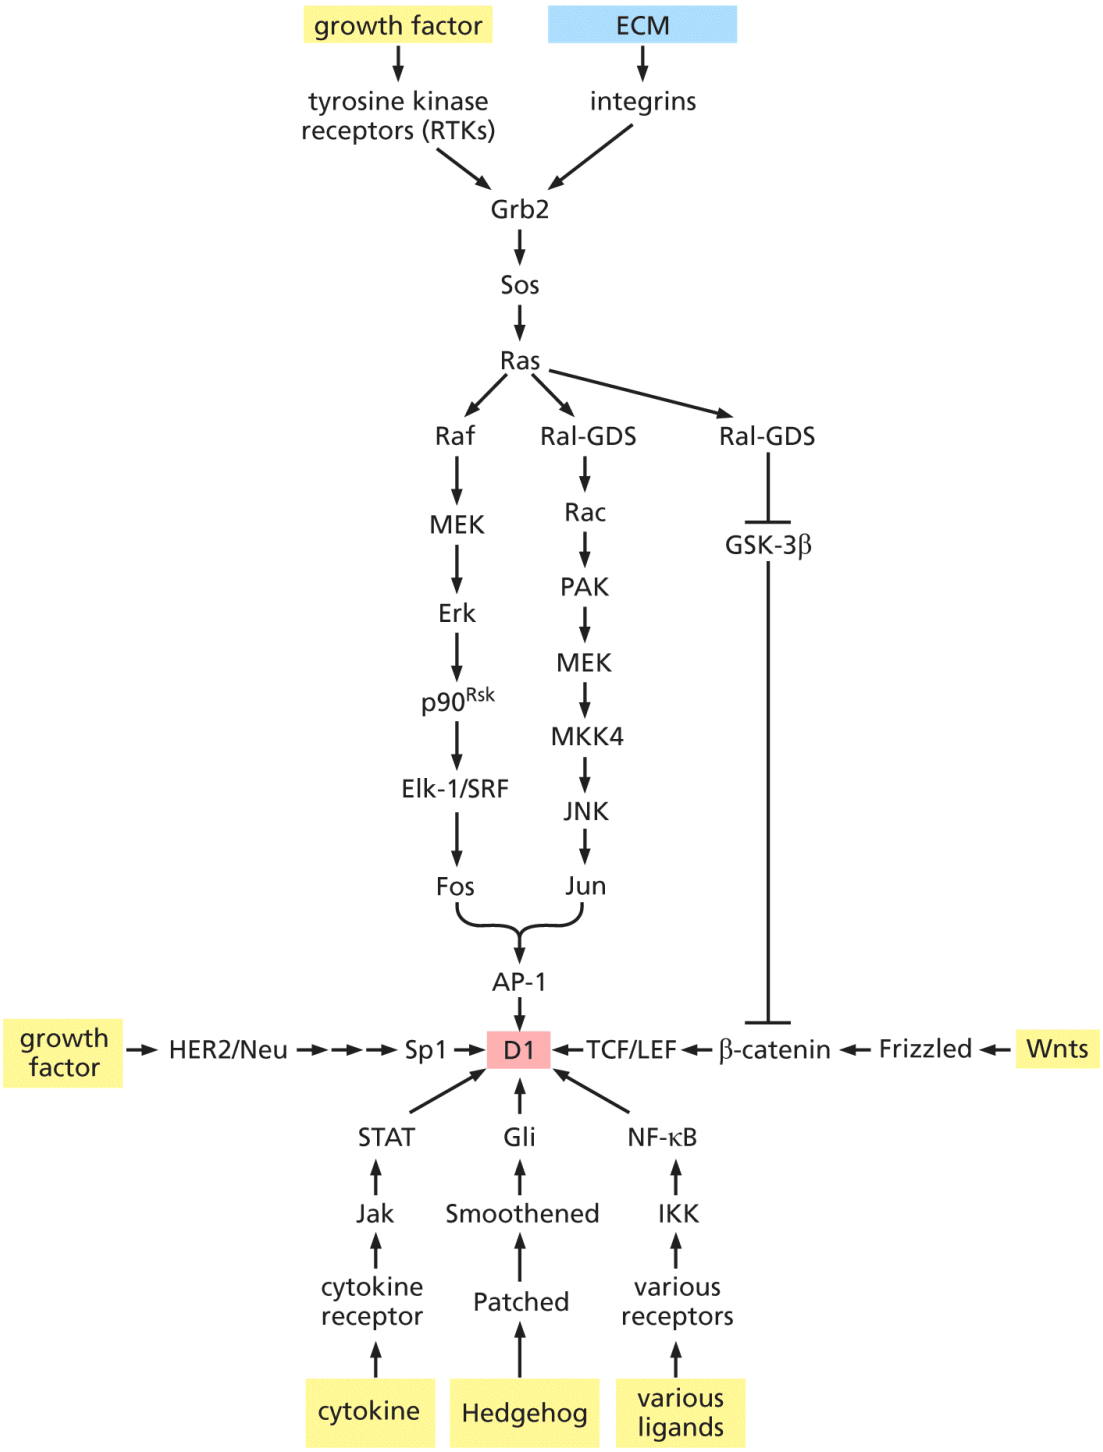
The collapse of various cyclin species as cells advance from one cell cycle phase to the next results from their rapid degradation, which is triggered by the actions of highly coordinated ubiquitin ligases. The ubiquitin ligases attach polyubiquitin chains to these cyclins (see **Supplementary Sidebar 7.5**). This polyubiquitylation leads to proteolytic breakdown within the proteasomes. The gradual accumulation of cyclins followed by their rapid destruction has an important functional consequence for the cell cycle, because it dictates that the cell cycle clock can move in only one direction, much like a ratchet. This behavior ensures, for example, that cells that have exited one M phase cannot inadvertently slip backward into another one, but instead must advance through G_1, S, and G_2 until they have once again accumulated the B cyclins required for entrance into M phase.

The D-type cyclins present the sole exception to these well-programmed fluctuations in the levels of cyclins. The levels of these three, similarly structured cyclins are not found to vary dramatically as a cell advances through the various phases of its growth-and-division cycle. Instead, the levels of D-type cyclins are controlled largely by extracellular signals, specifically those conveyed by a variety of mitogenic growth factors. In the case of cyclin D1—the best-studied of the three D-type cyclins—growth factor activation of tyrosine kinase receptors and the resulting stimulation of several downstream signaling cascades results in rapid accumulation of cyclin D1 (**Figure 8.9**). Conversely, removal of growth factors from a cell's medium results in an equally rapid collapse of its cyclin D1 levels with a half-life of about 30 minutes.



A series of blots over time. There are no blots at times 0, 15 seconds and 30 seconds. There is a very faint blot at 1 hour. There are pronounced blots at 2, 4, 6, 8, 11, 14, 17 and 23 hours. In each case, the darkest blot is for cyclin D 1 lying between 3.8 and 4.5 kilobases.

(A)



A signal transduction cascade with six separate starting points. One signaling sequence begins with growth factor which leads to R T Ks and E C M which leads to integrins. Those paths combine at pass throguh several more proteins before reaching A P 1 and then D 1. A second cascade begins with growth factor. The other four begin with W n tees, cytokine, hedgehog, and various

ligands, respectively. These have much shorter cascades. All six sequences converge on D 1.
(B)

Figure 8.9 Control of cyclin D1 levels (A) Cyclin D1 was discovered as a protein whose levels are strongly induced by exposure of macrophages to the mitogen CSF-1 (colony-stimulating factor-1). Here, macrophages that had been starved of CSF-1 were exposed to fresh CSF-1 and the amounts of cyclin D1 mRNA at subsequent times thereafter were determined by RNA (Northern) blotting. (B) The control of cyclin D1 levels by extracellular mitogens can be explained, in part, by a signal transduction cascade that leads from growth factor receptors (RTKs) to the AP-1 transcription factor (TF), one of a number of factors that modulate the transcription of the *cyclin D1* gene. (AP-1 is a heterodimeric TF formed from Fos and Jun subunits, each encoded by a proto-oncogene.) In addition, a number of other signaling cascades converge on the promoter of this gene, not all of which are illustrated in this figure. (A, from H. Matsushime et al., *Cell* 65:701–713, 1991. With permission from Elsevier.)

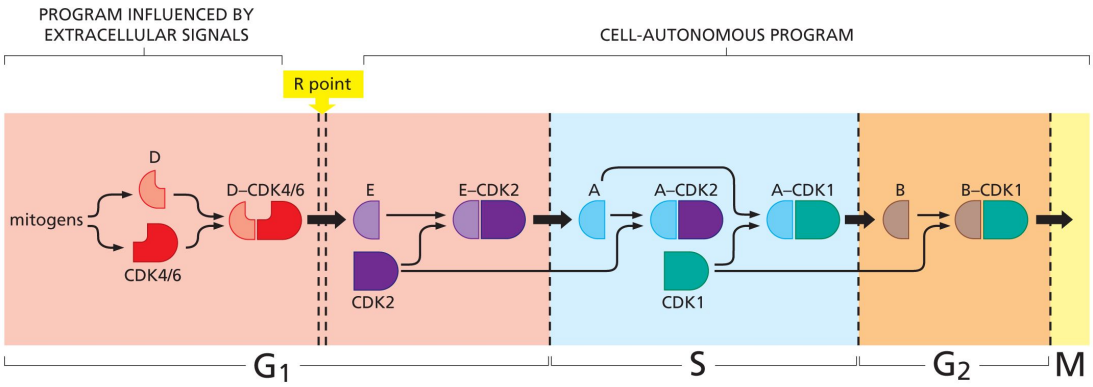
The distinctive behavior of the D-type cyclins has been rationalized as follows: They serve to convey signals from the extracellular environment to the cell cycle clock operating in the cell nucleus. Because the levels of D-type cyclins fluctuate together with the levels of extracellular mitogens, D-type cyclins continuously inform the cell cycle clock of current conditions in the environment around the cell.

After D-type cyclins are synthesized in the cytoplasm and migrate to the nucleus, they assemble in complexes with their two alternative CDK partners, CDK4 and CDK6. Because these two CDKs operate so similarly to one another within the cell cycle machinery, we will refer to them hereafter as CDK4/6. (CDK6 has several distinct functions not shared with its CDK4 cousin, being overexpressed in certain leukemias and lymphoma and capable of phosphorylating glycolytic enzymes, thereby affecting energy metabolism.) In general, the cyclin D–CDK4/6 complexes seem to have similar enzymatic activities and substrate specificities, independent of whether they contain cyclin D1, D2, or D3. This raises the question of why mammalian cells employ three distinct D-type cyclins to push cells through the G_1 phase of their cell cycles (**Supplementary Sidebar 8.3**). Moreover, each of the cyclins has additional functions unrelated to the cell cycle (**Sidebar 8.2**) and is regulated by an elaborate series of transcriptional and post-transcriptional controllers (**Supplementary Sidebar 8.4**).

Sidebar 8.2 Cyclins have other jobs besides cell cycle control

Over three decades of cell cycle research have created the impression that cell cycle control is the sole function of cyclins. In fact, cyclin D1 has been shown to associate with both the estrogen receptor (ER) and the transcription factor C/EBPβ. By binding the ER, cyclin D1 may mimic the normal ligand of this receptor—estrogen—in stimulating the receptor's transcriptional activities. The great majority (>70%) of breast cancers express the ER, and its expression explains the mitogenic effects that estrogen has on the cells in these tumors. Because cyclin D1 is overexpressed in most of these tumors and can also activate this receptor, the D1–ER complexes may also play an important role in driving the proliferation of cells in these tumors. The association of cyclin D1 with C/EBPβ results in activation of this transcription factor, which is thought to play a key role in programming the differentiation of a variety of cell types. Knockout of cyclin D1 in the mouse germ line results in viable mice that have severely underdeveloped mammary glands. This effect can be reversed by providing the mammary glands with a mutant cyclin D1 that can bind C/EBPβ but cannot activate CDK4/6. Hence, in this case, the non-CDK-associated functions of this cyclin are far more important than its effects on CDK4/6 activation. More globally, the use of chromatin immunoprecipitation (ChIP) has revealed at least 700 sites in the genome, most affiliated with gene promoters, to which cyclin D1 is bound, indicating that the two associations of cyclin D1 with transcription factors, as cited above, are likely only the tips of a far larger iceberg.

Once they are formed, the cyclin D–CDK4/6 complexes are capable of ushering a cell all the way from the beginning of the G_1 phase up to and perhaps through the R-point gate. After the cell has moved through the R point, the remaining cyclins—E, A, and B—behave in a pre-programmed fashion, executing the fixed program that begins at the R point and extends all the way to the end of M phase (**Figure 8.10**). Indeed, once the cell has passed through its R point, its cell cycle machinery takes on a life of its own that is quite autonomous and apparently no longer responsive to extracellular signals. (As cells enter into S phase, D-type cyclins are exported to the cytoplasm, where they can no longer influence cell cycle advance.)



External and cell-autonomous control of pairings of cyclins with C D Kays during different parts of the cell cycle. From the start of the G 1 phase to the R point, mitogens induce D-type cyclins to bind C D K 4 or 6. This program is influenced by extracellular signals, namely the mitogens. The rest of the program is a cell autonomous program. After the R point, E-type cyclins bind C D K 2. During the S phase, A-type cyclins bind first C D K 2 and then C D K 1. During the G 2 and M phases, B-type cyclins bind C D K 1.

Figure 8.10 Control of cyclin levels during the cell cycle Although extracellular signals strongly influence the levels of D-type cyclins during most of the G_1 phase of the cell cycle, the levels of the remaining cyclins are controlled by intracellular signaling and precisely coordinated with cell cycle advance. Thus, after cells pass through the R point and cyclin E–CDK2 complexes are activated, the activation of the remaining cyclin–CDK complexes occurs on a predictable schedule that appears to be independent of extracellular physiologic signals. In part, this coordination is achieved because the cyclin–CDK complexes in one phase of the cell cycle are responsible for activating those in the subsequent phase (*indicated here*) and for shutting down those that were active in the previous phase (*not shown*).

In ways that remain poorly understood, cyclin–CDK complexes in later phases suppress the activities of the cyclin–CDK complexes that have preceded them in earlier phases of the cell cycle. For example, when cyclin A is activated by the actions of cyclin E–CDK2 complexes during the G_1/S transition, the activities of cyclin A–CDK2 result in, among other things, the inactivation of the transcription factor that served previously during the R-point transition to induce cyclin E expression. In late S and early G_2 phases, the cyclin A–CDK1 complex begins to prepare for the activation of cyclin B–CDK1 complexes that are required later for entrance into mitosis. Once the latter complexes are activated, they seem to cause a shutdown of cyclin A synthesis, and so forth. Although the program depicted in Figure 8.10 has been validated in a number of cultured cell types, it may not apply to all cells, as indicated by studies of genetically modified mice (see **Supplementary Sidebar 8.5**).

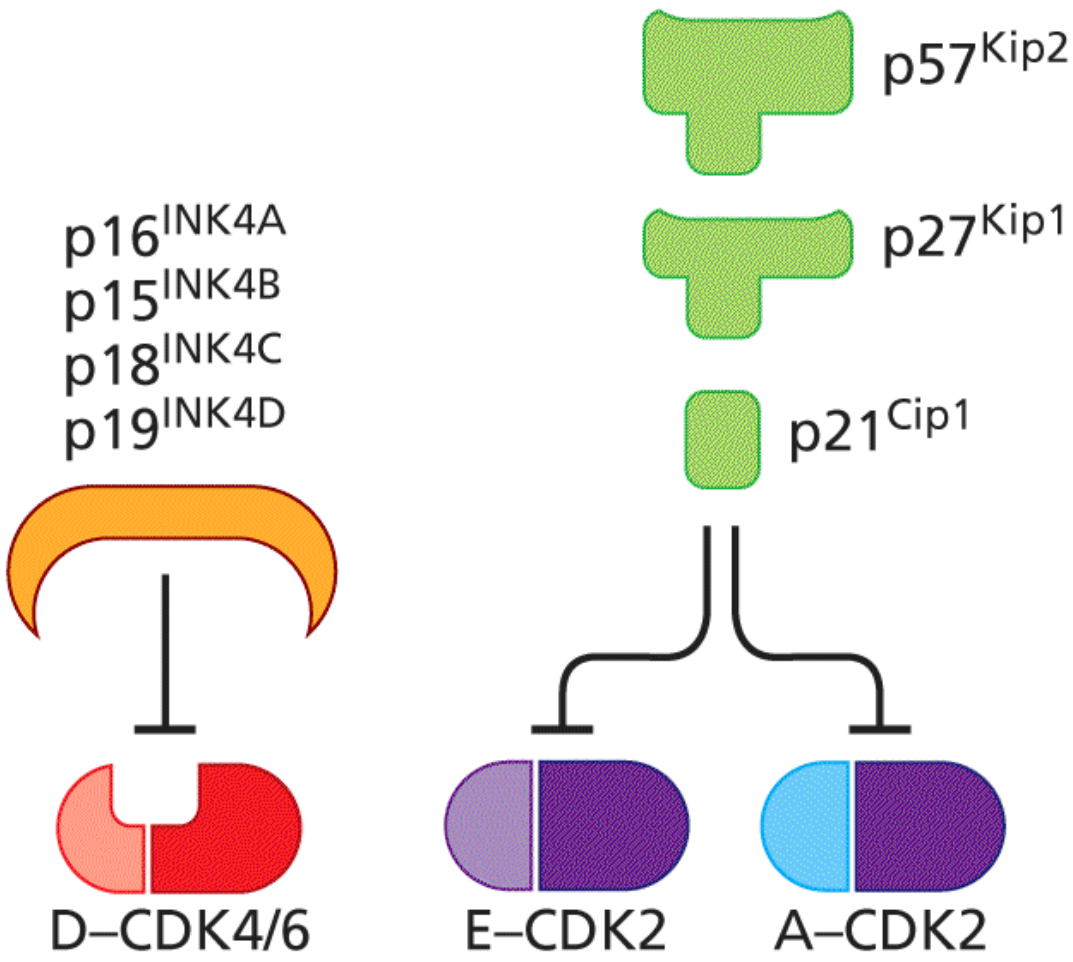
8.4 Cyclin–CDK complexes are also regulated by CDK inhibitors

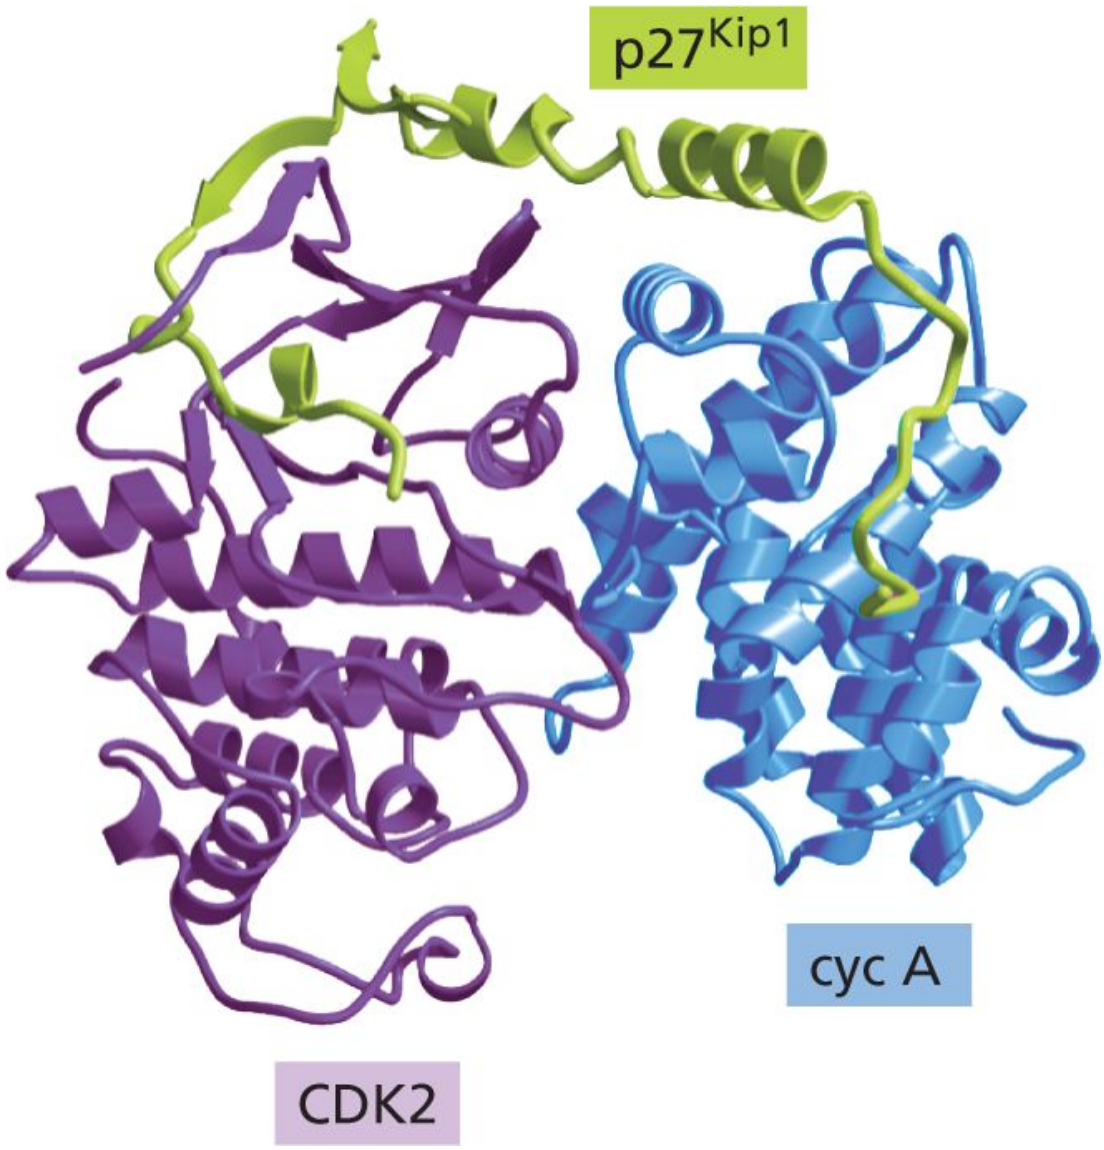
The scheme of cell cycle progression laid out above implies that physiological signals are able to influence the activity of the cell cycle clock only through their modulation of cyclin levels. In truth, there are several other layers of control that modulate the activity of the cyclin–CDK complexes and thereby regulate advance through the cell cycle.

The most important of these additional controls is imposed by a class of proteins referred to generically as CDK inhibitors or simply CKIs. To date, seven of these proteins have been found that are able to antagonize the activities of the cyclin–CDK complexes. A group of four of these, the INK4 proteins (named originally as **in**hibitors of CD**K4**), target specifically the CDK4 and CDK6 complexes; they have no effect on CDK1 and CDK2. These inhibitors are $p16^{INK4A}$, $p15^{INK4B}$, $p18^{INK4C}$, and $p19^{INK4D}$. The three remaining CDK inhibitors, $p21^{Cip1}$ (sometimes termed $p21^{Waf1}$), $p27^{Kip1}$, and $p57^{Kip2}$ (encoded by the human *CDKN1A*, *CDKN1B*, and *CDKN1C* genes, respectively) are more widely acting, being able to inhibit the cyclin–CDK complexes that function in G1/S (E–CDK2) or S (A–CDK2) phases of the cell cycle (**Figure 8.11**). (Each one of this trio of CKIs has been found to affect other specific processes unrelated to cell cycle progression, including transcriptional regulation, apoptosis, cell fate determination, cell migration, and cytoskeletal organization; however, because these other functions appear to play relatively minor roles in cancer development, we will not discuss them further.) $p57^{Kip2}$ plays a key role in certain tissues by imposing quiescence on stem cells but a minor role in cancer development; for this reason, our discussion will focus on its two cousins, $p21^{Cip1}$ and $p27^{Kip1}$.



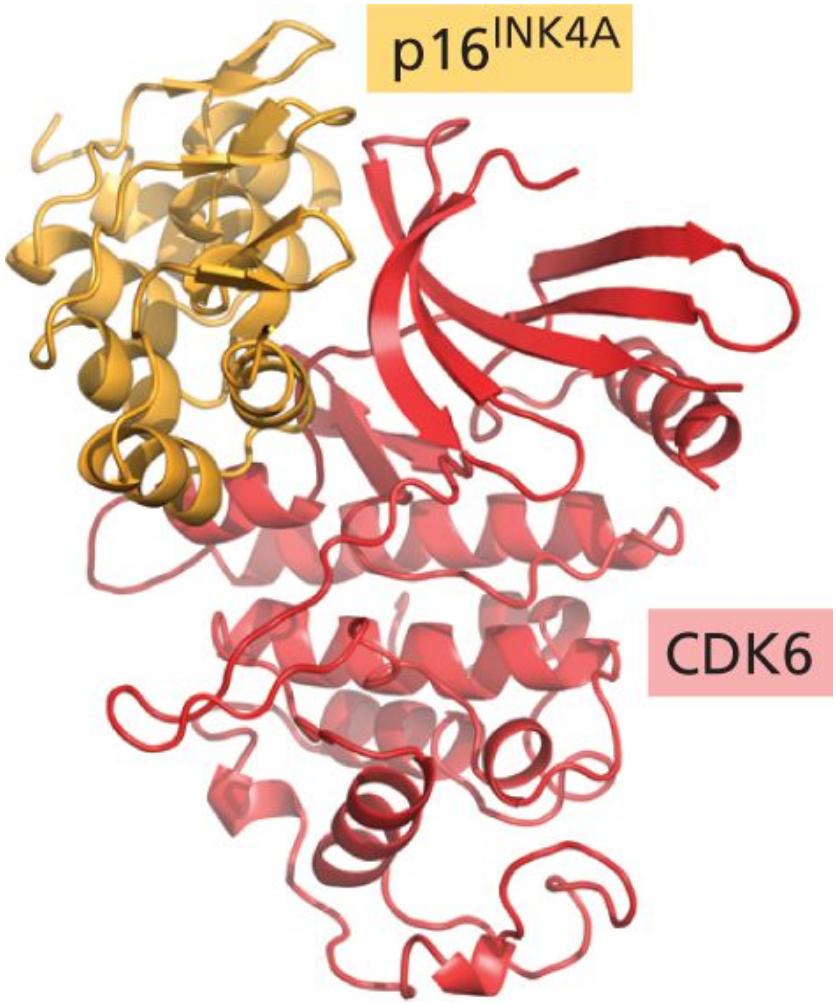
A schematic showing that p16 INK4A, p15 INK4B, p18 INK4C, and p19 INK4D all inhibit the action of the D-C D K 4 and D-C D K 6 complexes, and that p57 Kip2, p27 Kip1 and p21Cip1 all inhibit the action of both E–C D K 2 and A–C D K 2.

(A)



A ribbon diagram of p27 Kip 1 bound to cyclin A–C D K 2.

(B)



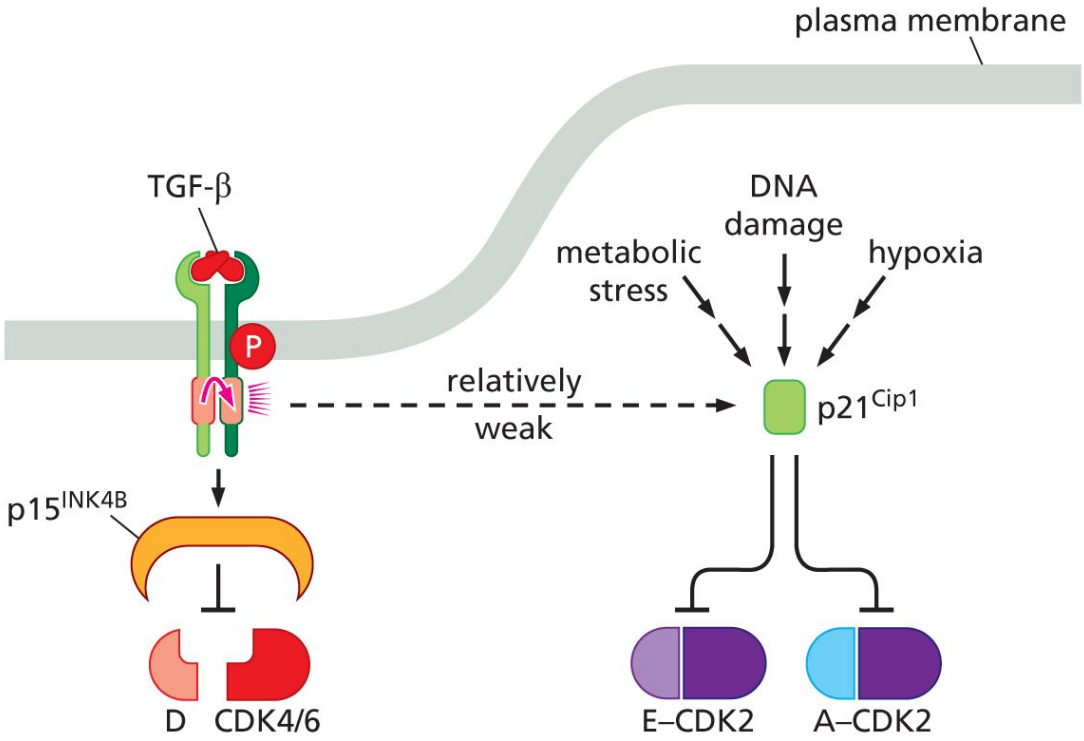
A ribbon diagram of p16 INK4A bound to C D K 6.

(C)

Figure 8.11 Actions of CDK inhibitors (A) The CDK inhibitors block the actions of CDKs at various points in the cell cycle. The four INK4 proteins ($p16^{INK4A}$, $p15^{INK4B}$, $p18^{INK4C}$, and $p19^{INK4D}$) are specialized to inhibit the D–CDK4 and D–CDK6 complexes that are active in early and mid-G_1. Conversely, the three Cip/Kip CKIs ($p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$) can inhibit E–CDK2 and A–CDK2, cyclin–CDK complexes that are active in the G1/S and S phases of the cell cycle. Under certain conditions, signals originating within the cell (e.g., signals indicating damage to the cell's DNA) can halt advance through the cell cycle by blocking the actions of cyclin/CDK complexes that are active in the S and G_2 phases of the cell cycle. Paradoxically, $p21^{Cip1}$ and $p27^{Kip1}$ are known to *promote* formation and catalytic activity of D–CDK4/6 complexes during the G_1 phase (see Figure 8.14). (B) This depiction illustrates how one domain of $p27^{Kip1}$ (*light*

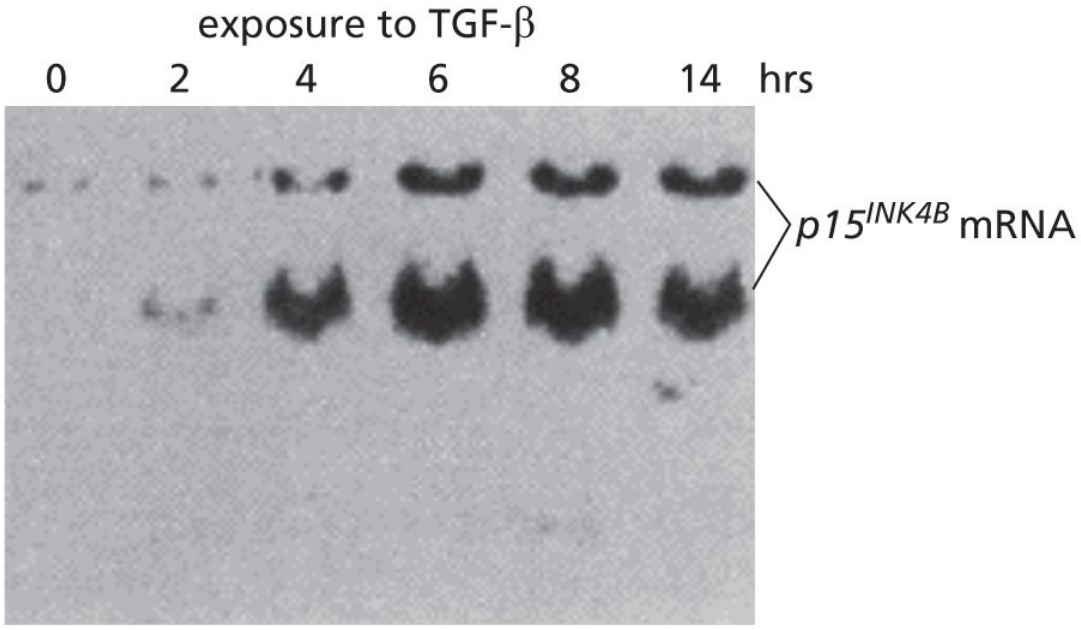
green) blocks cyclin A–CDK2 function by obstructing the ATP-binding site in the catalytic cleft of the CDK. (C) Inhibitors of the INK4 class, such as $p16^{INK4A}$ shown here (*brown*), bind to CDK6 (*reddish*) and to CDK4 (*not shown*). These CDK inhibitors distort the cyclin-binding site of CDK6, reducing its affinity for D-type cyclins. At the same time, they distort the ATP-binding site and thereby compromise catalytic activity. Identical interactions likely characterize the responses of CDK4 to $p16^{INK4A}$ binding. (B, from A.A. Russo et al., *Nature* 382:325–331, 1996. C, from A.A. Russo et al., *Nature* 395:237–243, 1998. Both with permission from Nature.)

The actions of these two classes of CDK inhibitors are nicely illustrated by $p15^{INK4B}$ and the pair $p21^{Cip1}$ and $p27^{Kip1}$. When TGF-β is applied to epithelial cells, it elicits a number of downstream responses that antagonize cell proliferation. Among these are substantial increases in the levels of $p15^{INK4B}$, which proceeds to block the formation of cyclin D–CDK4/6 complexes (**Figure 8.12**) and to inhibit those that have already formed. Without active D–CDK4/6 complexes, the cell is unable to advance through early and mid-G_1 and reach the R point. Once a cell has passed through the R point, the actions of the D–CDK4/6 complexes seem to become unnecessary. This behavior may explain why TGF-β inhibits growth during early and mid-G_1 and loses most (perhaps all) of its growth-inhibitory powers after a cell has passed through the R point.



A diagram showing that when a receptor in the plasma membrane is bound by T G F beta and activates through transphosphorylation, it strongly promotes p15 INK 4 Bees inhibition of the joining of D-type kinase to C D K 4 or 6. It also, more weakly, is one of several factors that promote the inhibition of E–C D K 2 and A–C D K 2 by p21 Cip1. The other factors are metabolic stress, D N A damage, and hypoxia.

(A)



A series of blots showing the results of exposure to T G F-beta after 0, 2, 4, 6, 8 and 14 hours. Each blot has a small upper part and a larger lower part. The blots get progressively darker from 0 to 6 hours. They indicate the growing presence of p15 INK4B m R N A.

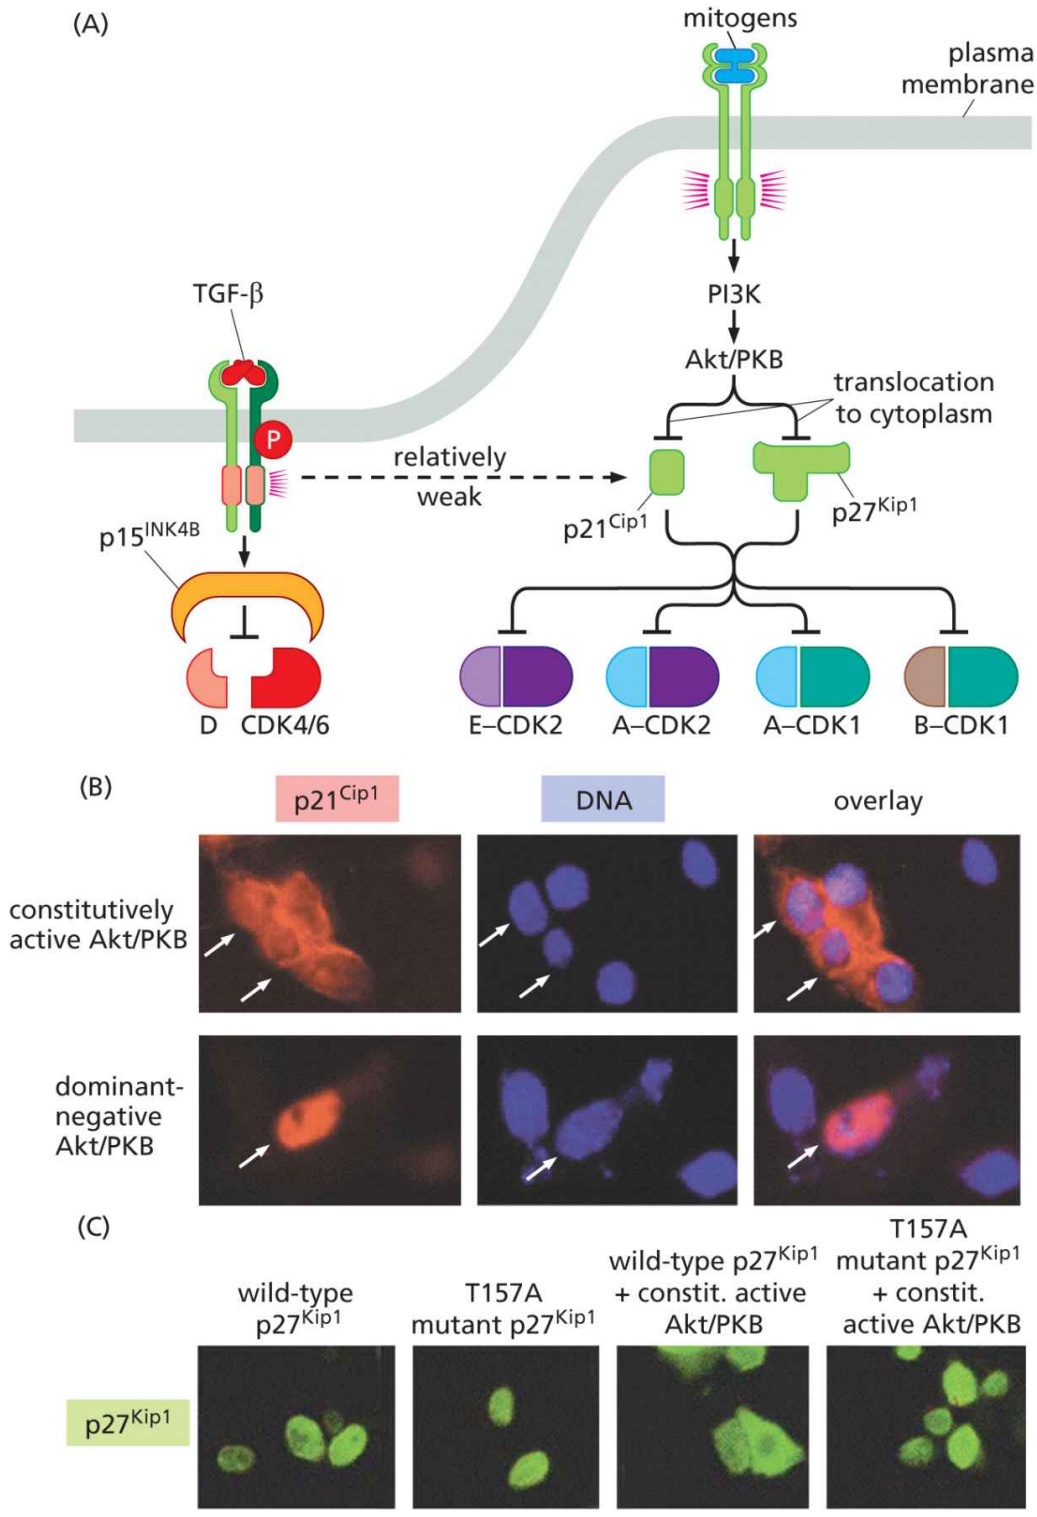
(B)

Figure 8.12 Control of cell cycle progression by TGF-β (A) TGF-β (*top left*) controls the cell cycle machinery in part through its ability to modulate the levels of CDK inhibitors. It acts to strongly induce increased expression of $p15^{INK4B}$ and, weakly, of $p21^{Cip1}$. The former can block the actions of cyclin D–CDK4/6 complexes, whereas the latter can block the actions of the E–CDK2 and A–CDK2 complexes. Independent of this, damage to cellular DNA causes strong, rapid increases in $p21^{Cip1}$, which in turn can shut down the cyclin–CDK complexes that are active in the phases of the cell cycle after the cell has passed through the R point in the late G_1 phase. (B) When TGF-β is applied to human keratinocytes, it

evokes a dramatic 30-fold induction of *p15*^{INK4B} mRNA synthesis as demonstrated here by RNA (Northern) blotting analysis. These cells were exposed to TGF-β for the time periods (in hours) indicated. (B, from G.J. Hannon and D. Beach, *Nature* 371:257–261, 1994. With permission from Nature.)

$p21^{Cip1}$, a more widely acting CDK inhibitor, is also induced by TGF-β, albeit weakly. Far more important are increases in the levels of $p21^{Cip1}$ that occur in response to various physiological stresses (see Figure 8.12A); once present at significant levels, $p21^{Cip1}$ can act throughout much of the cell cycle to stop a cell in its tracks. Prominent among these stresses is damage to the cell's genome. As long as the genomic DNA remains in an unrepaired state, the $p21^{Cip1}$ that has been induced in response will shut down the activity of already-formed cyclin–CDK complexes—such as E–CDK2 and A–CDK2—that happened to be active when this damage was first incurred; once the damage is repaired, the block imposed by $p21^{Cip1}$ may then be relieved. Such a strategy makes special sense in G_1: if a cell's genome becomes damaged during this period through the actions of various mutagenic agents, $p21^{Cip1}$ will block advance through the R point (by inhibiting E–CDK2 complexes) until the damage has been repaired, ensuring that the cell does not stumble into S phase and inadvertently copy still-damaged DNA sequences. In addition, $p21^{Cip1}$ can inhibit the functions of a key component of the cell's DNA replication apparatus, termed PCNA (proliferating cell nuclear antigen), ensuring that already-initiated DNA synthesis is halted until DNA repair has been completed. We will return to the mechanisms controlling $p21^{Cip1}$ expression in the next chapter.

Although DNA damage and, to a much lesser extent, TGF-β can elicit increases in the levels of $p21^{Cip1}$ (thereby blocking cell cycle advance), mitogens act in an opposing fashion to mute the actions of this CDK inhibitor and in this way favor cell cycle advance. One mechanism by which they do so depends on the phosphatidylinositol 3-kinase (PI3K) pathway (see Section 6.6), which is activated directly or indirectly by the mitogens that stimulate many receptor tyrosine kinases (**Figure 8.13A**). Akt/PKB, the important kinase activated downstream of mitogen-activated PI3K, phosphorylates $p21^{Cip1}$ molecules located in the nucleus, thereby causing them to be exported into the cytoplasm, where they can no longer engage and inhibit cyclin–CDK complexes (Figure 8.13B). Similarly, Akt/PKB phosphorylates $p27^{Kip1}$ (which functions much like $p21^{Cip1}$) and prevents its export from its cytoplasmic site of synthesis into the nucleus, where it normally does its critical work (Figure 8.13C and **Supplementary Sidebar 8.6**). Taken together, these signaling responses illustrate how extracellular growth-inhibitory signals (conveyed by TGF-β) impede the advance of the cell cycle clock, while growth-promoting signals promote its forward progress.



A three-part figure depicting the control of cell cycle advance by extracellular signals. Part A is a diagram showing that when a receptor in the plasma membrane is bound by T G F beta and phosphorylates and activates, it strongly promotes p15 INK 4 Bees inhibition of the joining of D-type kinase to C D K 4 or 6. It also,

more weakly, promotes the inhibition of E–C D K 2, A–C D K 2, A–C D K 1 and B–C D K 1 by p21 Cip1 and p27 Kip1. In doing so, T G F beta partly counteracts the effects of mitogens that bind to receptors and, via PI3K and A k t slash P K B translocated to the cytoplasm, inhibit the actions of p21 Cip1 and p27 Kip1. Part B is a two by three array of fluorescent stain images. The top row is for constitutively active A k t slash P K B, while the bottom row is for dominant negative A k t slash P K B. In both cases, the left image shows the localization of p21 Cip1, the middle image shows the locations of nuclear D N A, and the right image superimposes the two images. With constitutively active A k t slash P K B, p21 Cip1 is localized in cytoplasm; by contrast, with dominant negative A k t slash P K B, p21 Cip1 is localized in a nucleus. Part C is a sequence of four images showing the localization of p27 Kip1. Wild-type p27 Kip1 is localized to nuclei, and so is T157A mutant p27 Kip1. By contrast, wild-type p27 Kip1 with constitutively active A k t slash P K B is localized to cytoplasm. However, T157A mutant p27 Kip1 with constitutively active A k t slash P K B is localized to nuclei.

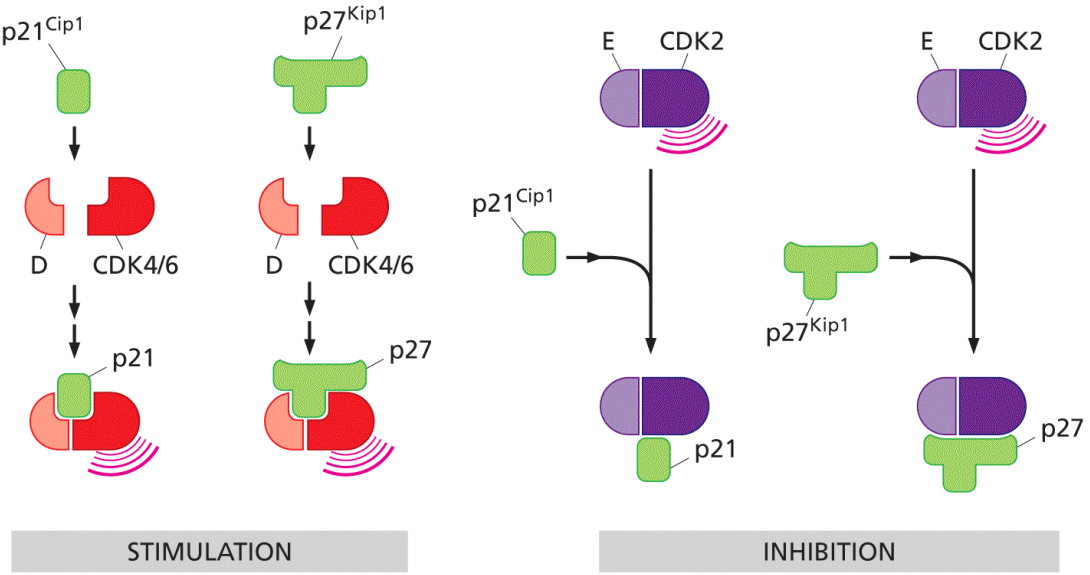
Figure 8.13 Control of cell cycle advance by extracellular signals

Countervailing extracellular signals influence the cell cycle machinery, in part through their ability to control the levels and intracellular localization of CDK inhibitors. (A) During the G_1 phase, TGF-β induces $p15^{INK4B}$ and (weakly) $p21^{Cip1}$ expression, negatively affecting the D–CDK4/6 and E–CDK2 complexes, respectively (see also Figure 8.12). Conversely, mitogens, acting through Akt/PKB, cause the phosphorylation and cytoplasmic localization of both $p21^{Cip1}$ and $p27^{Kip1}$, which prevents these CDK inhibitors from entering the nucleus and blocking the activities of various cyclin–CDK complexes operating there. (The growth factor receptors can also reduce the levels of the two CKIs depicted here, $p21^{Cip1}$ and $p27^{Kip1}$; these CKIs can inhibit, in turn, cyclin–CDK complexes active in late G_1 and S. It is unclear, however, whether these cyclin–CDK complexes are actually affected by mitogens in the later phases of the cell cycle.) (B) Ectopic expression of a constitutively active Akt/PKB (*upper row*) causes $p21^{Cip1}$ (*orange, left*) to be localized largely in the cytoplasm. Compare its localization with that of the cell nuclei (*blue, middle*); the overlap of these two images is also seen (*right*). Conversely, expression of a dominant-negative Akt/PKB (*lower row*), which interferes with ongoing Akt/PKB function, allows $p21^{Cip1}$ to localize to the cell nucleus, where it can interact with cyclin–CDK complexes and inhibit cell cycle progression. (C) In normal cells (*first panel*), ectopically expressed wild-type $p27^{Kip1}$ (*green*) is found to be exclusively nuclear. This localization is not changed if a $p27^{Kip1}$ mutant is expressed that lacks the threonine residue normally phosphorylated by Akt/PKB (*second panel*). (The T157A mutant carries an alanine in place of this threonine.) If a mutant, constitutively active Akt/PKB is expressed, however, much of wild-type $p27^{Kip1}$ is now seen in the cytoplasm (*third panel*). But if the $p27^{Kip1}$ mutant that cannot be

phosphorylated by Akt/PKB is expressed, it resists the actions of constitutively activated Akt/PKB and remains in the nucleus (*fourth panel*), where it can continue to influence cell cycle advance. (B, from B. Zhou et al., *Nat. Cell Biol.* 3:245–252, 2001. C, from G. Viglietto et al., *Nat. Med.* 8:1136–1144, 2002. Both with permission from Nature.)

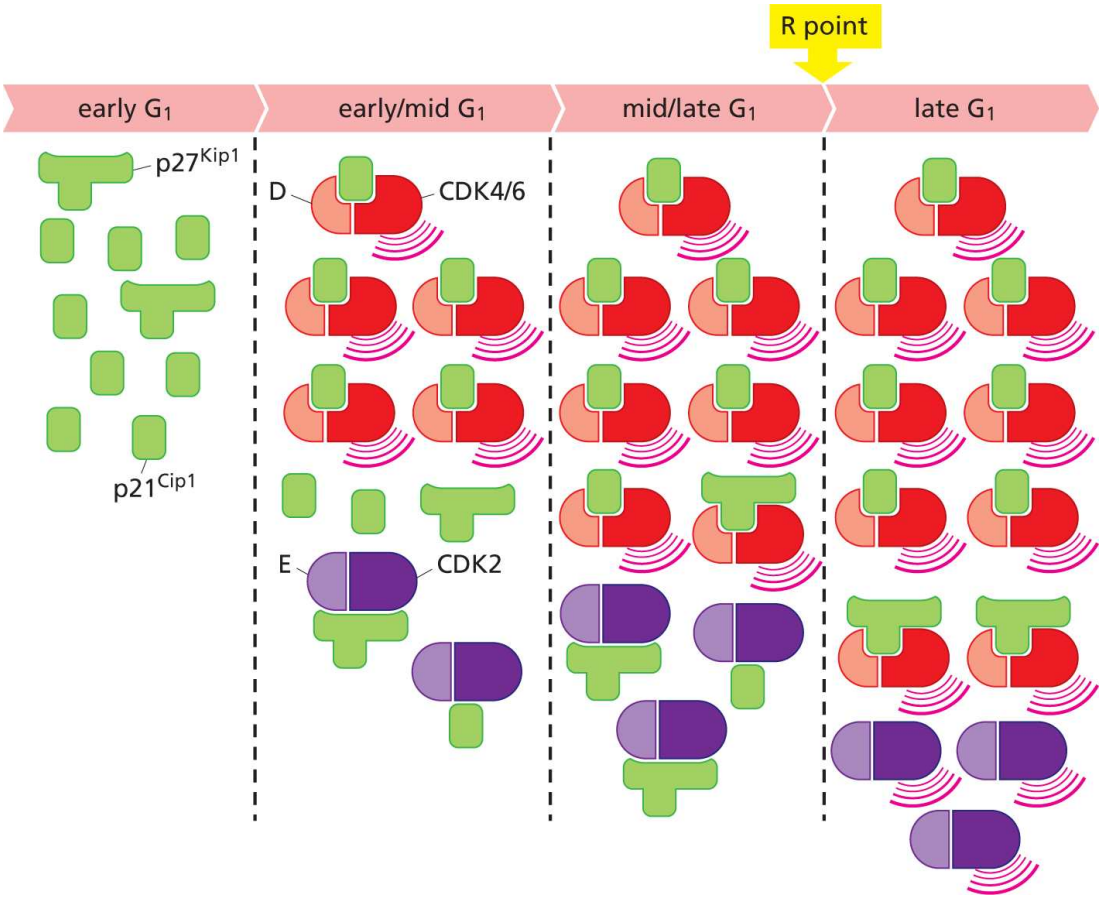
These effects on intracellular localization appear to have clinical consequences. For example, in low-grade (that is, less advanced) human mammary carcinomas, levels of activated Akt/PKB are low and $p27^{Kip1}$ is able to carry out its anti-proliferative functions in the cell nucleus. In high-grade tumors, however, activated Akt/PKB is abundant and much of $p27^{Kip1}$ is now found in the cell cytoplasm, where it does not have access to the cell cycle machinery. This intracellular localization is correlated with, and likely causally linked to, the progression of these cancers to fatal endpoints (see **Supplementary Sidebar 8.6**).

One aspect of the behavior of $p21^{Cip1}$ and $p27^{Kip1}$ seems quite paradoxical. Although they inhibit the actions of cyclin E–CDK2 and cyclin A–CDK2, they actually *stimulate* the formation of active cyclin D–CDK4/6 complexes (**Figure 8.14A**). Moreover, once a ternary (three-part) complex has formed between D–CDK4/6 and either of these CDK inhibitors, this cyclin–CDK complex can still phosphorylate its normal substrates. So the term "CDK inhibitor" is in fact a misnomer: the two proteins ($p21^{Cip1}$ and $p27^{Kip1}$) act on most cyclin–CDK complexes in an inhibitory manner and on the cyclin D–CDK4/6 complexes in a stimulatory fashion.



Two examples of stimulation, namely p21 Cip1 and p27 Kip1 each bringing together D-kinase and C D K 4 or 6 to form a complex. Part A also gives two

examples of inhibition, namely p21 Cip1 and p27 Kip1 each binding to E-C D K 2.
(A)



A sequences of events within the G 1 phase of the cell cycle. In early G 1, p21 Cip1 and p27 Kip1 are present and not bound to anything. In early to mid G 1, p21 Cip ones have started to form D-C D K 4 slash 6 complexes and p27 Kip ones have started to attach to E-C D K twos. In mid to late G 1, these processes are complete. The D-C D K 4 slash sixes are signaling, while the E-C D K twos are silent. After the R-point, in late G 1, the p27 Kip ones on the E-C D K twos have disappeared and the E-C D K twos are also signaling.

(B)

Figure 8.14 Interactions of CDK inhibitors with cyclin–CDK complexes (A) The various CDK inhibitors affect cyclin–CDK complexes in different ways. The CDK inhibitors of the $p21^{Cip1}$ and $p27^{Kip1}$ family, while inhibiting the cyclin–CDK complexes active in late G_1 and S phases (involving CDK2); only E–CDK2 is shown here, *right*), actually stimulate the formation of the D–CDK4/6

complexes that are active in the early and mid-G_1 phase and nevertheless permit these complexes to be catalytically active (*left*; see also Figure 8.11). (B) Cells in early G_1 often have substantial concentrations of $p21^{Cip1}$ and $p27^{Kip1}$ molecules (*green; left*). As cyclin D–CDK4/6 complexes (*pink/red*) accumulate throughout early to mid-G_1 (being induced by extracellular mitogens), they bind and thereby sequester an ever-increasing proportion of the $p21^{Cip1}$ and $p27^{Kip1}$ molecules, both those molecules that are present in soluble pools (unbound to any cyclin–CDK complexes) as well as those that are associated with the small number of cyclin E–CDK2 complexes that are present in G_1 (*light, dark purple*). The binding by D–CDK4/6 complexes of these two CDK inhibitors does not negatively affect their catalytic activity (see panel A). However, as this process continues, the D–CDK4/6 complexes succeed in abstracting most of the $p21^{Cip1}$ and $p27^{Kip1}$ molecules away from E–CDK2 complexes (*purple*) in late G_1 (*right*). This finally liberates the E–CDK2 complexes from control by $p27^{Kip1}$ (*bottom right*), permitting these complexes to hyperphosphorylate pRb, thereby triggering the R-point transition. At the same time, the rapid increase in active E–CDK2 complexes drives the phosphorylation and subsequent degradation of $p27^{Kip1}$ molecules (see Figure 8.20), ensuring that cells advance irreversibly through the R point and into S phase.

Although $p27^{Kip1}$ functions similarly to $p21^{Cip1}$ in many ways, it has its own, highly interesting behavior. When cells are in the G_0 quiescent state, $p27^{Kip1}$ is present in high concentrations, and therefore binds to and suppresses the activity of the few cyclin E–CDK2 complexes that happen to be present in the cell. When cells are exposed to growth factors, cyclin D–CDK4/6 complexes accumulate, because these mitogens cause an increase in the levels of the D-type cyclins. Each time a new cyclin D–CDK4/6 complex forms, it captures and binds another molecule of free $p27^{Kip1}$; consequently, the pool of free $p27^{Kip1}$ molecules in the cell dwindles as they become progressively sequestered by cyclin D–CDK4/6 complexes. Once a small portion of cyclin E–CDK2:$p27^{Kip1}$ complexes are liberated from the inhibitory effects of $p27^{Kip1}$, these complexes are free to begin triggering passage of the cell through the R point (Figure 8.14B). This means that the *timing* of the R point during G_1 is dictated by the rates at which cyclin D–CDK4/6 complexes accumulate in the cell during G_1; stated differently, by encouraging the formation of these complexes, mitogens govern the length of time during G_1 required for a cell to activate its R point transition.

In the context of cancer development, the overexpression of D-type cyclins, which occurs in a variety of tumors, leads to premature sequestration of $p27^{Kip1}$ and attendant R-point activation, whereas the inactivation of CDK4/6 by pharmacological inhibitors,

some of which are employed clinically (see Chapter 17), prevents $p27^{Kip1}$ sequestration and thereby obstructs activation of the R-point transition. In addition to these dynamic changes in CKIs, they also act in a static fashion to impose post-mitotic states on differentiated normal cells (**Supplementary Sidebar 8.7**). In fact, yet another level of control of cyclin–CDK complexes is imposed by covalent modifications of the CDK molecules themselves (**Sidebar 8.3**).

Sidebar 8.3 Phosphorylation of CDK molecules also controls their activity

An additional level of control placed on the cell cycle clock machinery can be traced to the covalent modifications of the CDK molecules themselves. More specifically, CDKs must be phosphorylated at specific amino acid residues in order to be active. At the same time, inhibitory phosphorylations of other amino acid residues must be removed. The stimulatory phosphorylations are imparted by a serine/threonine kinase termed CAK (for CDK-activating kinase). CAK itself operates as a component of a cyclin–CDK complex, which phosphorylates the activation loops (often called T-loops) of CDKs (see **Supplementary Sidebar 8.2**), causing them to swing out of the way of the catalytic clefts of these serine/threonine kinases which they would otherwise obstruct.

Equally important are the effects of *inhibitory* phosphorylations affecting CDK1 and CDK2, which are removed by a class of phosphatases called CDC25A, -B, and -C. Although the effects of these enzymes in G_1, S, and G_2 are poorly understood, it is clear that they play critical roles in triggering the G_2/M transition. Thus, cyclin B, which has lingered during G_2 in the cytoplasm, moves into the nucleus just before the G_2/M transition; phosphorylation of a threonine residue and a tyrosine residue that are located near the ATP-binding site of CDK1 and inhibit kinase activity are then removed by CDC25B and CDC25C phosphatases, enabling the rapid activation of B–CDK1 complexes that proceed to trigger entrance into M phase. The activities of CDC25A are focused on the G_1 and S phases of the cell cycle. CDC25A and CDC25B are overexpressed in some cancers, and there is evidence from mouse models of cancer development that their overexpression can lead to acceleration of tumor development.

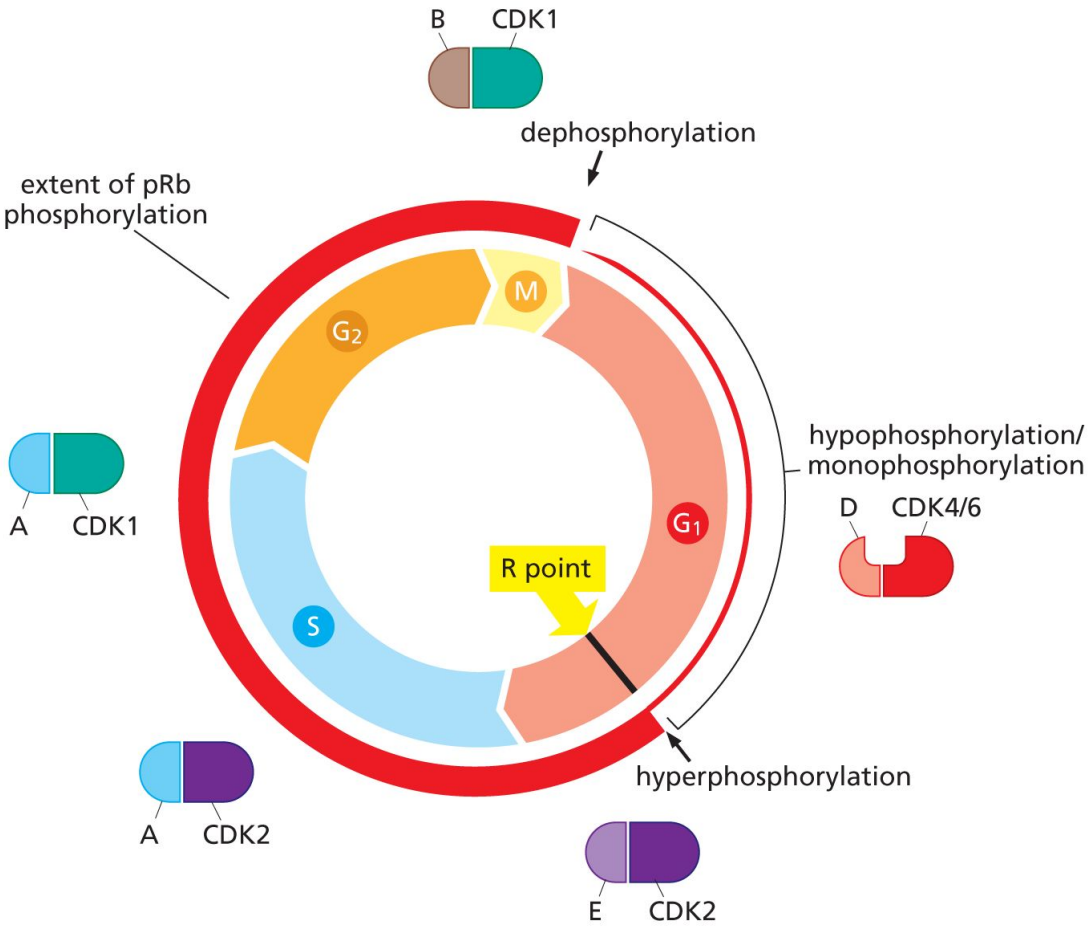
8.5 Viral oncoproteins reveal how pRb blocks advance through the cell cycle

We have viewed the cell cycle from several angles here, including its clearly delineated G_1, S, G_2, and M phases and the cyclins and CDKs that orchestrate advances through these phases. In addition, we have traced these advances back to the extracellular signals that persuade the cell to enter into the active cell cycle and to progress through the restriction (R) point gate. These descriptions, however, fail to reveal precisely how the R-point transition is executed at the molecular level.

The solution to this puzzle was provided by the isolation of the *Rb* tumor suppressor gene, defective versions of which are involved in the pathogenesis of retinoblastomas, sarcomas, and small-cell lung carcinomas as well as other tumors (see Table 7.1). Soon after the *Rb* gene was isolated in 1986, it became apparent that it encodes a nuclear phosphoprotein of a mass of about 105 kD. This protein, called variously pRb or RB, was found to be absent, or present in a defective form, in the cells of many of the above-named tumor types.

Initial experiments with pRb revealed that it undergoes phosphorylation in concert with the advance of cells through their cell cycle. More specifically, pRb is essentially unphosphorylated immediately after cells exit mitosis or when they are in G_0; becomes weakly phosphorylated (hypophosphorylated) on serine and threonine residues after entrance into G_1; and becomes extensively phosphorylated (hyperphosphorylated) on a much larger number (~14 in all) of serine and threonine residues in concert with advance of cells through the R point (**Figure 8.15**). Once cells have passed through the R point, pRb usually remains hyperphosphorylated throughout the remainder of the cell cycle. After cells exit mitosis, the phosphate groups on pRb are stripped off by the enzyme termed protein phosphatase type 1 (PP1). This removal of phosphate groups, in turn, sets the stage for the next cell cycle and thus for a new cycle of pRb phosphorylation.

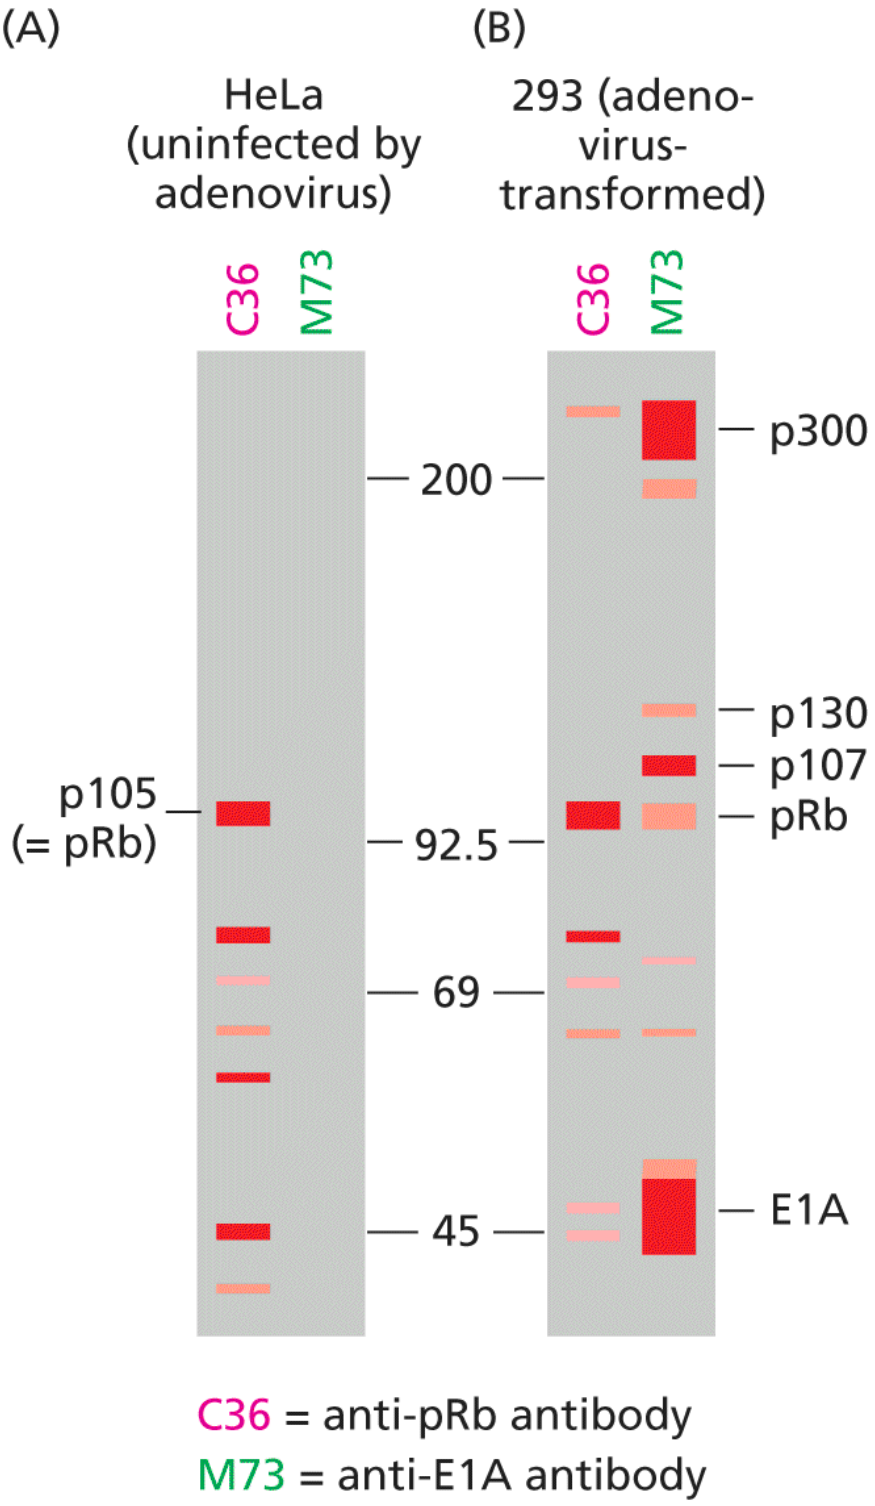


A diagram shows cell cycle–dependent phosphorylation of p R b. In the G 1 phase up to the R point, monophosphorylation is performed by D-C D K 4 or 6. After the R point, hyperphosphorylation is accomplished by E-C D K 2 and then, during the S, G2 and M phases, by A-C D K 2, A-C D K 1, and B-C D K 1. Dephosphorylation is abrupt, at the end of the M phase.

Figure 8.15 Cell cycle–dependent phosphorylation of pRb The phosphorylation state of pRb (*red circle*) is closely coordinated with cell cycle advance. As cells pass through the M/G_1 transition, virtually all of the existing phosphate groups are stripped off pRb by phosphatase PP1, leaving it in an *unphosphorylated* configuration. As cells progress through G_1, a single phosphate group is attached as any one of ~14 distinct phosphorylation sites (by cyclin D-CDK4/6 complexes), yielding *hypophosphorylated* (more precisely *monophosphorylated*) pRb. Later, when cells pass through the restriction (R) point (*yellow arrow*), cyclin E–CDK2 complexes phosphorylate pRb on at least 12 more sites in this group of 14, placing it in a *hyperphosphorylated* state. Throughout the remainder of the cell cycle, the extent of pRb phosphorylation remains constant or increases slightly until cells enter into M phase.

The fact that pRb hyperphosphorylation occurs in concert with passage through the R point provided the first hint that this protein is the molecular governor of the R-point transition. An additional, critical clue came from discoveries in 1988 of physical interactions between DNA tumor virus–encoded oncoproteins and pRb. Recall that DNA tumor viruses are able to transform cells and do so through the use of virus-encoded oncoproteins. Unlike the oncoproteins of RNA tumor viruses such as RSV, the DNA tumor viruses employ oncoproteins that have little if any resemblance to proteins that exist naturally within uninfected cells (see Sections 3.4 and 3.6).

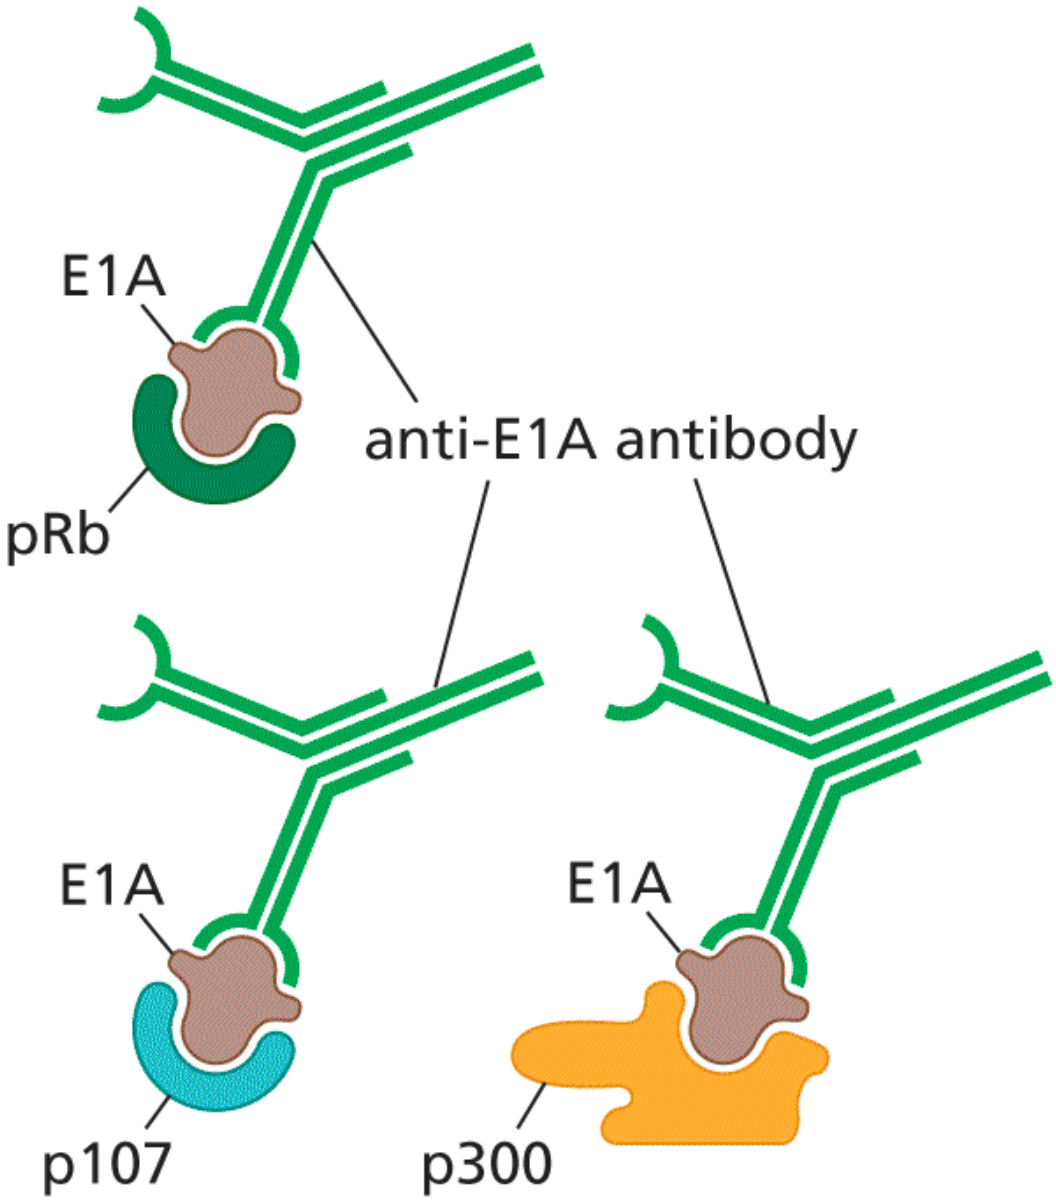
The 1988 work revealed one important mechanism whereby a DNA tumor virus–encoded oncoprotein can disrupt the cellular growth-regulating circuitry: biochemical characterization of the oncoprotein made by the E1A oncogene of human adenovirus type 5 showed that in adenovirus-transformed cells, this oncoprotein is tightly bound to a number of cellular proteins, among them pRb (**Figure 8.16**; **Sidebar 8.4**). Soon thereafter, the SV40 virus–encoded large T oncoprotein and the E7 oncoprotein of certain strains of human papillomavirus (HPV) implicated in causing human cervical carcinoma were also found capable of forming physical complexes with pRb in virus-transformed cells.



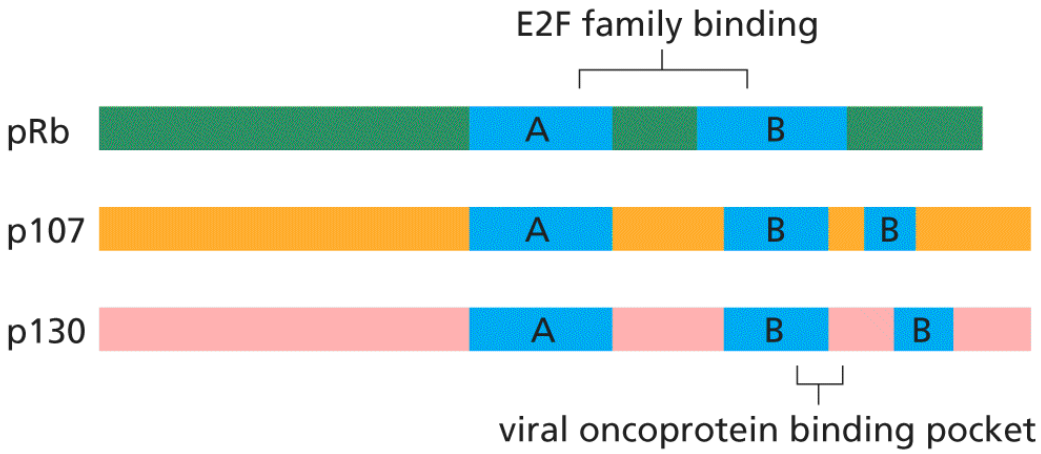
A schematic of a gel image for HeLa cells, uninfected by adenovirus. In the C36 channel, for the anti-p R b antibody, there is a line at 105 k D corresponding to p R b. There are other lines further down. There are no lines in the M73 channel, for the anti-E1A antibody.

A schematic of a gel image for 293 cells, which are adenovirus-transformed. In both the C36 channel and the M37 channel there are lines corresponding to p R b and other lines above and below. In the M37 channel, there are lines above p R b for p107, p130 and, high up, above 200 k D, a thick line for p300 There is also a thick line for E1A at about 45 k D.
(D)

(C)



Three anti-E1A antibodies with E1A attached at one of the antigen binding sites. p R b, p107 and p300 can each attach to E1A, so that E1A forms a bridge enabling the host-cell proteins to attach to the antibody.



The structures of p R b, p107 and p300. p R b has an A domain and a B domain. p107 and p300 each have an A domain and two smaller B domains. The A and B domains are for E2F family binding. A viral oncoprotein binding pocket is also indicated.

Figure 8.16 Co-precipitation of cellular proteins with adenovirus E1A (A) Incubation of the C36 anti-pRb monoclonal antibody with a lysate of HeLa cells revealed that pRb migrated with the mobility of a protein of ~105 kD, with more rapidly migrating cleavage fragments evident below it (*left channel*). Use of the M73 antibody reactive with the adenovirus E1A oncoprotein revealed no reactive proteins in these cells, which lack adenovirus genomes. This also indicated that this antibody did not have undesired cross-reactions with cellular proteins. (B) Incubation of the anti-pRb antibody with lysates of adenovirus-transformed 293 cells revealed once again the presence of pRb and some lower–molecular-weight fragments. However, when the M73 anti-E1A antibody was used, it precipitated not only the adenovirus E1A protein but also a series of host-cell proteins, including pRb, p107, p130, and p300. (C) Because the anti-E1A antibody had no reactivity with host-cell proteins (see panel A), E1A must have formed a bridge between the antibody molecules and a number of host-cell proteins with which it was physically complexed in virus-transformed cells. (D) pRb is one of three structurally related proteins that together are often called “pocket proteins.” All three are bound by viral oncoproteins, such as adenovirus E1A (see panel B), SV40 large T, and human papillomavirus E7. All three pocket proteins are phosphorylated by cyclin D–CDK4/6 complexes, and each binds its own subset of E2F transcription factors, as discussed later. The “pocket” that interacts with both viral oncoproteins and cellular E2F transcription factors is composed of A and B domains (*blue*). (A, B, Adapted from P. Whyte et al., *Nature* 334:124–129, 1988.)

Sidebar 8.4 Adenovirus deploys a single viral oncoprotein to bind and sequester multiple cellular proteins

As seen in Figure 8.16, when a lysate of adenovirus-transformed cells is incubated with an anti-E1A monoclonal antibody, the resulting immunoprecipitate contains the E1A oncoprotein plus a number of other proteins. These other proteins are not bound directly by the antibody; instead, in each case, the E1A oncoprotein acts as a bridge to link the antibody molecule to a second protein, indicating that within adenovirus-transformed cells the E1A protein had previously formed physical complexes with each of these other cellular proteins. (Before the immunoprecipitates were analyzed by gel electrophoresis and autoradiography, these multiprotein complexes were treated with a strong detergent to dissociate the component proteins from one another.)

The first of these associated proteins to be identified was pRb, with two other cellular proteins, termed p107 and p130, being characterized soon thereafter; these two are paralogous cousins of pRb. These observations indicated that during the course of its evolution, adenovirus has configured the E1A protein in a way that enables it to bind these three cellular proteins, ostensibly in order to sequester or inactivate them. pRb and its two cousins are often called generically pocket proteins (Figure 8.16D), because each carries a cavity into which viral oncoproteins such as E1A can insert. Later, a higher–molecular-weight cellular partner protein, termed p300, was also characterized, and a number of other cellular targets remain to be characterized.

The rationale for why adenovirus deploys its oncoprotein to sequester these four proteins must be understood in terms of the viral replication cycle. A virus needs to reconfigure the regulatory circuitry of an infected cell in order to create an intracellular environment that supports various steps of viral replication. Most important is its requirement for viral DNA replication, which can apparently occur efficiently only if the virus is able to liberate an infected cell from its quiescent pre-restriction point state by functionally inactivating the cellular proteins that are holding it in that state; this liberation permits the infected cell, in turn, to advance into S phase, where the cellular DNA replication machinery is now active and can be exploited by the virus.

These three different DNA tumor virus oncoproteins (E1A, large T antigen, and E7) are structurally unrelated to one another, yet all of them target a common cellular protein—pRb. Moreover, the molecular biology of adenovirus replication cycles otherwise shows no resemblance to those of SV40 and HPV. This suggests that convergent evolution led to the development of viral oncoproteins capable of perturbing cellular pRb. Stated differently, because evolution selects for viruses that can multiply more effectively, these discoveries suggested that sequestration or functional inactivation of pRb by the three viral oncoproteins is necessary for optimal viral replication in infected cells. Finally, to state the obvious, DNA tumor viruses use

an entirely different genetic strategy to transform cells than do tumorigenic retroviruses: rather than acquiring and exploiting host-cell proto-oncogenes, the DNA tumor viruses have evolved proteins that interfere with the actions of host-cell tumor suppressor genes, that is, the proteins encoded by these genes. As it turned out, these viral oncoproteins could also bind and ostensibly inactivate two paralogs of pRB—p107 and p130—that exert cell cycle controls complementary to that of pRB (see Figure 8.16B).

The discoveries of these viral–host protein complexes had profound effects on our understanding of how DNA tumor viruses succeed in transforming the cells that they infect. The speculation went like this: Within a normal cell, the *Rb* gene was known to function as a tumor suppressor gene. Hence, the *Rb* gene, acting through its protein product, pRb, must inhibit cell proliferation in some fashion. DNA tumor viruses can sabotage the activities of pRb by dispatching viral oncoproteins that seek out and bind pRb, sequestering and apparently inactivating it. This sequestration removes pRb from the regulatory circuitry of the cell, yielding the same outcome as when a cell loses the two copies of its chromosomal Rb gene through mutations (see Figure 7.5). This suggested, furthermore, that the DNA tumor viruses succeed in transforming cells through their ability to disable this key cellular growth-inhibitory protein, thereby liberating the virus-infected cell from the growth suppression that pRb normally imposes. (In fact, the HPV E7 protein goes beyond simple sequestration of pRb, because it also tags pRb for ubiquitylation and thus proteolytic degradation; see **Supplementary Sidebar 7.5**.)

Another clue to pRb function was provided by the discovery that the oncoproteins of the DNA tumor viruses bind preferentially to the hypophosphorylated forms of pRb, that is, the forms of pRb that are present in the cell through most of the G_1 phase (see Figure 8.15). Conversely, the hyperphosphorylated pRb forms that are present in late G_1 and in the subsequent phases of the cell cycle are ignored by the viral oncoproteins. This observation led to yet another speculation: tumor virus oncoproteins focus their attention on sequestering—and thereby inactivating—the only forms of pRb in the cell that are worthy of their attention, these being the growth-inhibitory forms of pRb found in early and mid-G_1. Conversely, the viral oncoproteins ignore those forms of pRb that are already inactivated by another mechanism, phosphorylation.

Such logic indicated that the hypophosphorylated forms of pRb present in early and mid-G_1 cells are actively growth-inhibitory, whereas the hyperphosphorylated forms found after the R point have lost their growth-inhibitory powers, having been functionally inactivated by this phosphorylation. This meant that the R-point transition, which is defined by a physiological criterion (acquisition of growth factor independence), is accompanied by a biochemical alteration of pRb that converts it

from a growth-inhibitory protein to one that is functionally inert. These speculations were soon validated by various types of experiments.

In addition, further research has revealed that the control of pRb phosphorylation is more reversible than is indicated by the diagram in Figure 8.15. Thus, if a cell should experience serious physiological stresses while in S phase or G_2, pRb phosphorylation can be reversed by phosphatases such as PP1, thereby returning pRb to its actively growth-inhibitory state. These stresses include, for example, hypoxia, DNA damage, and disruption of the mitotic spindle. Such reactivation of pRb-mediated growth inhibition is presumably only transient and is reversed once the physiological stresses or damage have been resolved.

OceanofPDF.com

Glossary

hypophosphorylated
: Referring to relatively low level of phosphorylation (of a protein).

hyperphosphorylated
: Referring to the elevated phosphorylation state (e.g., of a protein).

pocket protein
: Term referring to pRb and two related proteins, p107 and p130.

convergent evolution
: The independent development by multiple species of a common trait during the course of evolution.

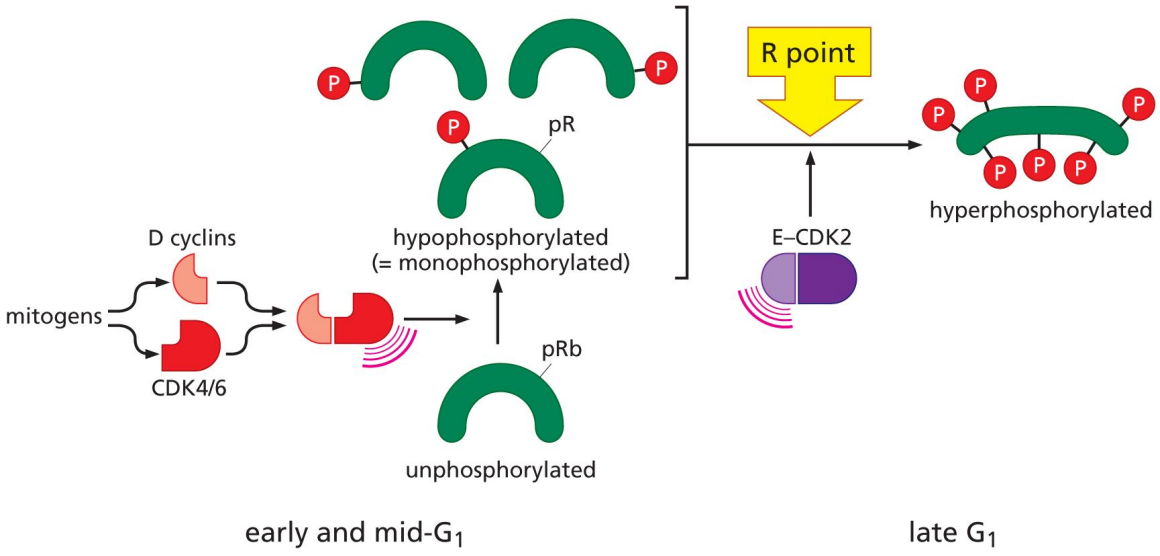
8.6 pRb is deployed by the cell cycle clock to serve as a guardian of the restriction-point gate

As described above, various lines of evidence converge on the conclusion that pRb, which inhibits growth through early to mid-G_1 phase, becomes inactivated by extensive phosphorylation when the cell passes through the R-point gate and thereafter is largely or completely inert as a growth suppressor. In effect, pRb serves as a guardian at this gate, holding it shut unless and until it becomes hyperphosphorylated, in which case pRb loses its growth-inhibitory powers, opens the gate, and permits the cell to enter into late G_1 and advance thereafter into the remaining phases of the cell cycle.

Because pRb is the ultimate arbiter of growth versus nongrowth, its phosphorylation must be carefully controlled. Not unexpectedly, its phosphorylation is governed by components of the cell cycle clock. In early and mid-G_1, D-type cyclins together with their CDK4/6 kinase partners are responsible for initiating pRb phosphorylation, leading to its hypophosphorylation. In fact, the “hypophosphorylated pRb” cited above is actually a collection of various *mono*phosphorylated pRb species, each of which carries a single phosphate on one or another of its serine or threonine residues. (Why and how cyclin D—CDK4/6 complexes attach only a single phosphate to each pRb molecule but not more than one remains a mystery.) Because the levels of D-type cyclins appear to be controlled largely by extracellular signals, notably mitogenic growth factors, we can now plot out a direct line of signaling: growth factors induce the expression of D-type cyclins; D-type cyclins, collaborating with their CDK4/6 partners, initiate pRb phosphorylation (**Figure 8.17**).



A schematic shows the control of the restriction point transition by mitogens. In the early and mid-G1 phases of the cell cycle, mitogens bring D cyclin and CDK4 or 6 together to form activated complexes that cause unphosphorylated p R b to become hypophosphorylated–that is, monophosphorylated. At the R-point, E–C D K 2 then completes the phosphorylation, leading to a hyperphosphorylated p R b.

Figure 8.17 Control of the restriction-point transition by mitogens The levels of D-type cyclins are controlled largely by extracellular signals (mitogens, *left*). The D-type cyclins, acting with their CDK4 and CDK6 partners, are able to drive monophosphorylation at multiple alternative serine and threonine residues of pRb. Eventually, accumulation of D-CDK4/6 complexes leads to the abstraction of $p27^{Kip1}$ away from its association with E-CDK2 complexes (see Figure 8.14B) and the resulting activation of E-CDK2 complexes. Cyclin E–CDK2 complexes then assume the work of decommissioning pRb by placing it in a hyperphosphorylated state, causing a >10-fold increase in its phosphorylation that results in the complete functional inactivation of pRb.

During a normal cell cycle, this initial hypophosphorylation of pRb on single amino acid residues is not sufficient for the subsequent functional inactivation of pRb at the R point, which requires its hyperphosphorylation on multiple residues. In fact, cyclin E levels increase dramatically at the R point. The cyclin E then associates with its CDK2 partner, and this complex drives pRb phosphorylation to completion, leaving pRb in its *hyperphosphorylated*, functionally inactive state

(see Figure 8.17). The phosphorylation and functional inactivation of pRb's cousins, p107 and p130, are also under the control of cyclin D–CDK4/6 and cyclin E–CDK2 complexes. The roles of these pRb cousins in cancer pathogenesis is unclear and, for this reason, they will not be discussed further here.

Once the cell advances through the R point, the continued hyperphosphorylation and functional inactivation of pRb is apparently maintained and further increased by CDK complexes carrying cyclin E, then cyclin A, and finally cyclin B, none of which is responsive to extracellular signals—precisely the properties of the cell cycle clock machinery that, we imagine, operates after the R-point transition and guarantees execution of the rigidly programmed series of transitions in S, G_2, and M phases.

This scheme reveals why pRb is such a critical player in the regulation of cell proliferation. If its services are lost from the cell (through mutation of the chromosomal *Rb* gene copies, methylation of the *Rb* gene promoter, or the actions of DNA tumor virus oncoproteins), then this protein can no longer stand as the guardian of the R-point gate. Moreover, as we will see, in some cancer cells, pRb phosphorylation is deregulated, resulting in inappropriately phosphorylated and thus functionally inactivated pRb. In certain other cancer cells, there is evidence that the dephosphorylation (and attendant activation) of pRb, which normally happens at the M/G_1 transition through the action of the PP1 phosphatase, never occurs, leaving pRb in its hyperphosphorylated, inactivated state throughout the entire growth-and-division cycle of these cells. Without pRb on watch, cells move through G_1 into S phase without being subjected to the usual controls that are designed to ensure that cell cycle advance can proceed only when certain preconditions have been satisfied. Indeed, as we will see, the deregulation of pRb phosphorylation is so widespread that one begins to think that this important signaling pathway is perturbed in virtually all human tumors.

The activities of pRb seem to overlap with those of its cousins, p107 and p130, raising the question why pRb is the only one of these three pocket proteins to play a clear and obvious role in cancer pathogenesis. A definitive answer to this puzzle is still elusive. It may come from the specific times in the cell cycle when these two pRb-related proteins are active. Whereas p130 is specialized to suppress cell proliferation while a cell resides in G_0, p107 appears to be most active in the late G_1 and S phases. Only pRb is well positioned to control the transition at the R point from mitogen-dependent to mitogen-independent growth. (Yet another

physical complex of important regulatory proteins operates at the late G_2/M transition to enable the complicated molecular events associated with mitosis; we focus in this chapter on late G_1 and the R point, simply because it is here that the decisions of cell proliferation versus quiescence are made that are so critical to cancer pathogenesis.)

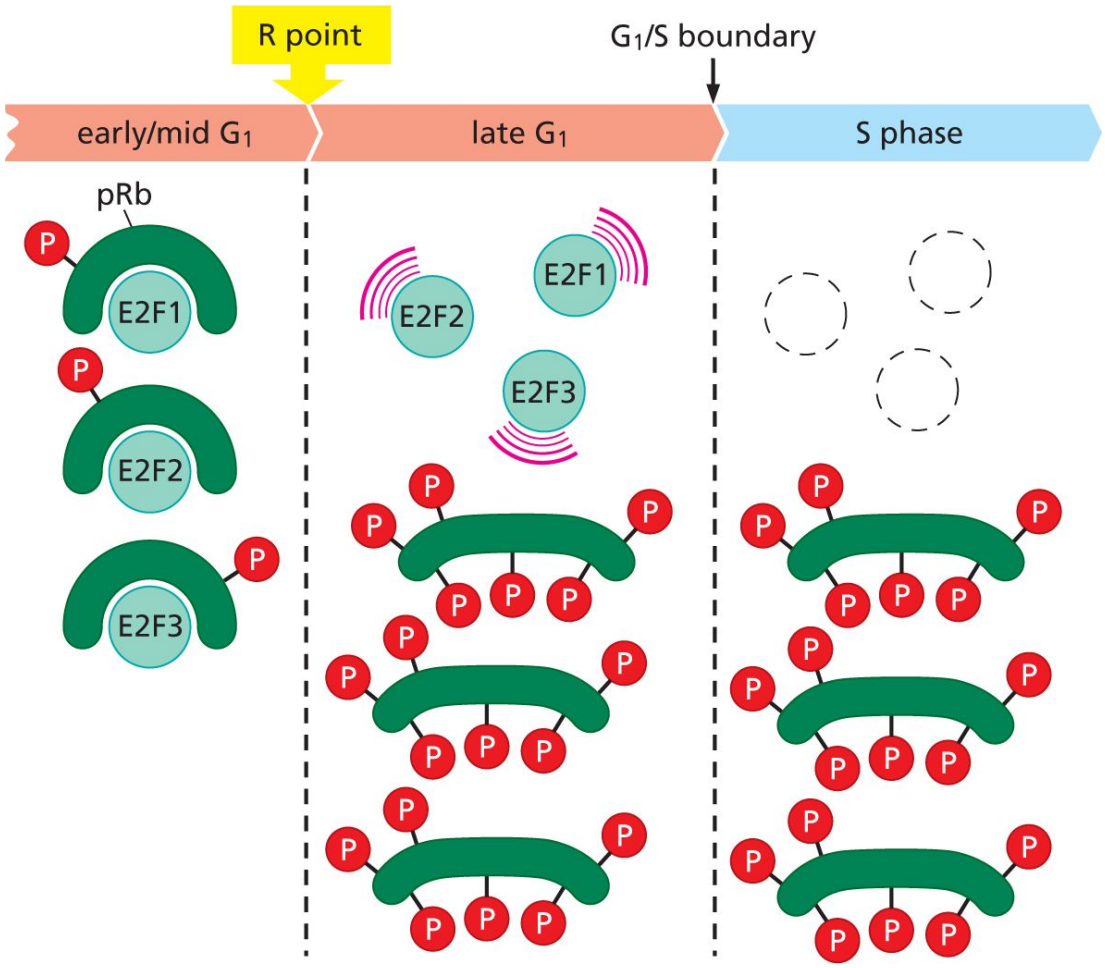
8.7 E2F transcription factors enable pRb to implement growth-versus-quiescence decisions

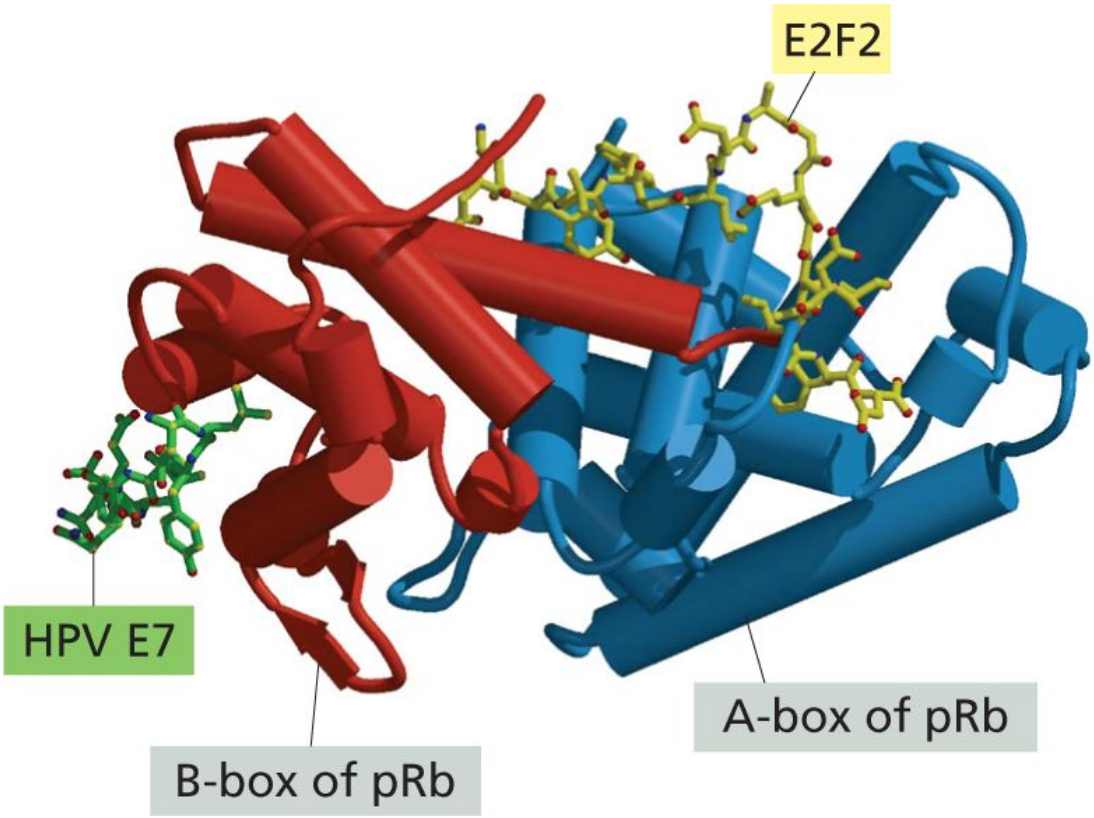
As described above, a number of lines of evidence indicate that hypophosphorylated pRb is active in suppressing G_1 advance and loses this ability when it becomes hyperphosphorylated. Still, this behavior provides no clue as to precisely how pRb succeeds in *imposing* this control. Research conducted in the early 1990s indicated that pRb exercises much of this control through its effects on a group of transcription factors termed E2Fs.

When pRb (and its two cousins, p107 and p130) are in their unphosphorylated or hypophosphorylated state, they bind E2Fs, including E2Fs that are already bound to DNA; however, when hyperphosphorylated (see Figure 8.15), pRb and its cousins dissociate from the E2Fs (**Figure 8.18A**). This suggested a simple model of how pRb is able to control cell cycle advance. In the early and middle parts of G_1, E2Fs are associated with the promoters of a number of genes under their control. At the same time, these transcription factors are bound by pocket proteins (pRb, p107, p130). This pocket protein association prevents the E2Fs from acting as stimulators of transcription. Accordingly, during much of the G_1 phase of the cell cycle, genes that depend on E2Fs for their expression remain repressed. However, when the pocket proteins (most importantly, pRb) undergo hyperphosphorylation at the R point in late G_1, they release their grip on the E2Fs, permitting the E2Fs to stimulate transcription of their clientele of genes. The products of these genes, in turn, usher the cell from late G_1 into S phase. Similarly, when viral oncoproteins are present, they mimic pRb hyperphosphorylation by preventing pRb from binding E2Fs, doing so throughout the cell cycle (Figure 8.18B).



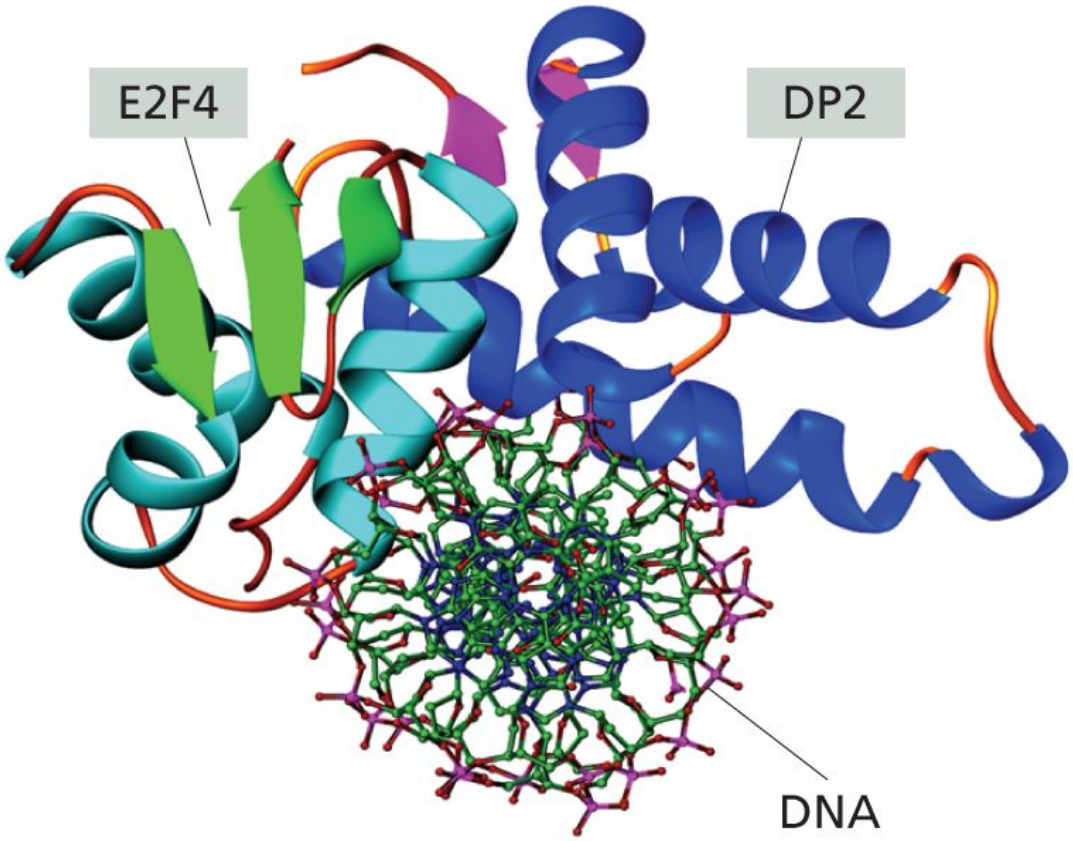
The early-mid G1, late G1, and S phases of the cell cycle. In early-mid G1, before the R point, E 2 effs 1, 2 and 3 each bind with a monophosphorylated p R b. In early-mid G1, before the R point, E 2 effs 1, 2 and 3 each bind with a monophosphorylated p R b. In late G1, the p R bees are hyperphosphorylated and the E 2 effs are free-floating and signaling. In S phase, the E 2 effs are no longer present.

(A)



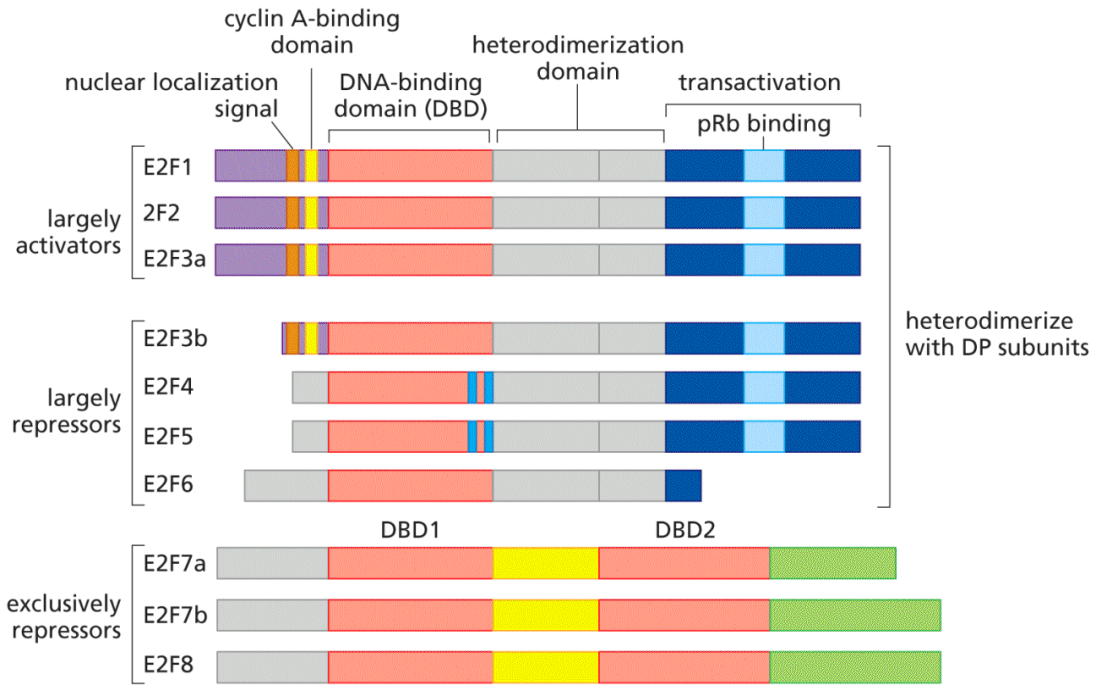
A combination ball and stick and ribbon diagram in which H P V E7 and E2F2 bind to the A- and B-boxes of p R b.

(B)



A combination ball and stick and ribbon diagram in which D N A binds to E2F4 and D P2.

(C)



An overview of the structures of ten E2 effs. E 2 effs 1, 2 and 3a are largely activators. On the left they each have a nuclear localization signal followed by a short cyclin A binding domain. Then comes a longer D N A binding domain, a heterodimerization domain, and a transactivation domain with a p R b binding domain in the middle. E 2 effs 3b, 4, 5 and 6 are largely repressors. Except for E2F3b, they lack the nuclear localization signal and short cyclin A binding domain. E2F sixes transactivation domain is short and lacks a p R b binding domain within it. E2 effs 1 through 6 heterodimerize with D P subunits. E2 effs 7a, 7b and 8 are exclusively repressors. Their structure is different from that of E2 effs 1 through 6, in that their main feature is not 1 but 2 D N A binding domains, D B D1 and D B D2.

(D)

Figure 8.18 E2Fs and their interactions (A) By binding various DNA-bound E2F transcription factors, the three related pocket proteins, pRb, p107, and p130, modulate the expression of E2F-responsive genes in various phases of the cell cycle. When pRb binds to E2Fs 1, 2, and 3 (*left*), it blocks their transcription-activating domains; other proteins that serve to modify chromatin and repress transcription (*not shown*) are attracted to the pRb–E2F complexes. Because they are bound to the promoters of certain genes via the E2Fs, these multiprotein complexes repress the expression of such genes, doing so by attracting chromatin-modifying proteins such as histone methyltransferases and deacetylases. (The behavior of p107 and p130, *not shown*, is similar to that of pRb.) After being

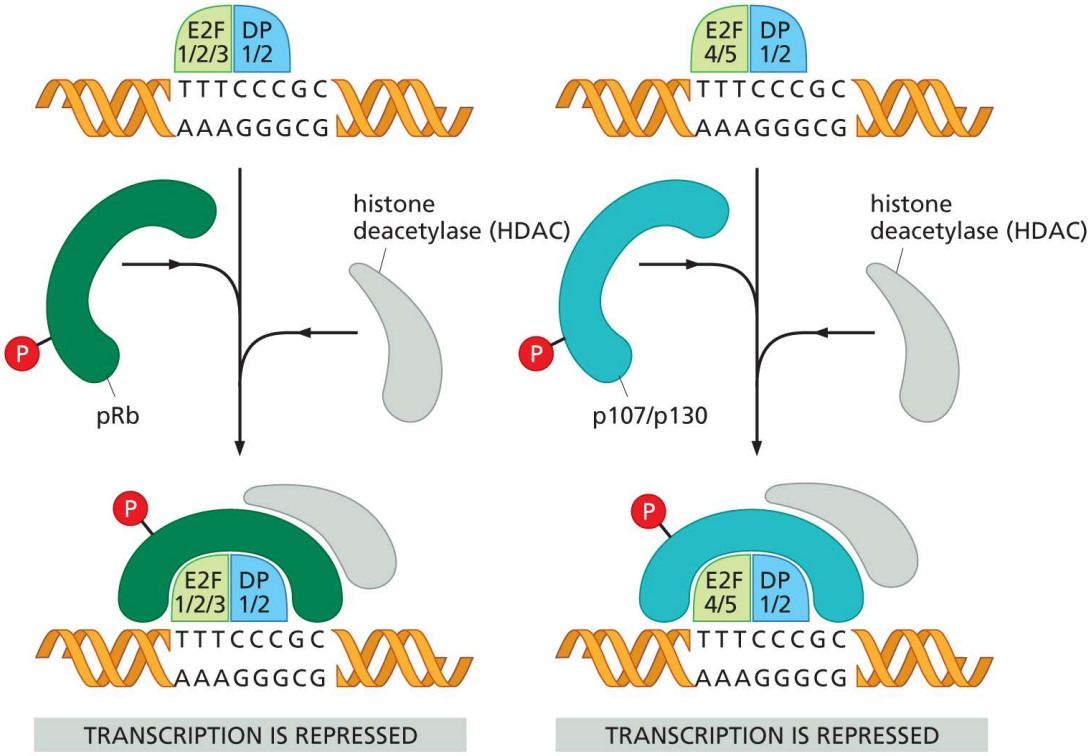
hyperphosphorylated at the R point, the pocket proteins release their grip on the E2Fs, allowing the latter to activate transcription of those genes (late G_1, *middle*). However, because E2Fs 1, 2, and 3 induce expression of E2F7 and E2F8, which function as transcriptional repressors (see panel D), the ability of these three E2Fs to activate signaling is curtailed toward the end of G_1. Moreover, as cells enter into S phase (*right*), E2Fs 1, 2, and 3 are inactivated or degraded. Hence, E2Fs 1, 2, and 3 appear to function as active inducers of transcription only in the narrow window of time in late G_1 phase that begins at the R point (*yellow arrow*) and ends as cells enter S phase. (B) The binding of E2Fs, such as E2F2 (*yellow stick figure*) by pRb (*red and blue*), is prevented by several DNA tumor virus oncoproteins. Here we see in a crystallographic structure how a segment of the human papillomavirus (HPV) E7 oncoprotein (*green stick figure, left*) binds to a shallow groove of pRb; this binding, together with other secondary binding sites, perturbs the pocket cavity formed by the B- and A-boxes of pRb, thereby precluding the binding of the C-terminal, transcription-activating domain of E2F2 (*yellow*) to this pocket. This loss of E2F binding effectively neutralizes the ability of pRb to inhibit cell cycle advance (*cylinders* = α-helices). (C) With the exception of E2F7 and E2F8, each of the E2F transcription factors binds DNA as a heterodimeric complex formed by an E2F subunit together with a DP partner. Shown is the binding of an E2F4–DP2 complex (*ribbon diagram*) to the DNA double helix (*stick figure*), as revealed by X-ray crystallography. (D) Because of the existence of variant forms of several E2Fs, they are actually represented by at least 10 distinct protein species. E2Fs 1, 2, and 3a represent transcription-activating E2Fs, whereas E2F3b, E2F4, E2F5, and E2F6 are largely or exclusively involved in transcriptional repression. E2Fs 7a, 7b, and 8 are atypical E2Fs, in that each has a duplicated DNA-binding domain (DBD) that enables DNA binding in the absence of a DP subunit as partner (see Panel C); these particular E2Fs are involved exclusively in repression. E2F1, 2, and 3 induce their expression, suggesting the operation of a negative-feedback loop designed to shut down E2F1, 2, and 3 signaling. Overall, E2Fs 4 and 5 are involved in repression in early/mid-G_1, whereas E2Fs 7 and 8 are involved in repression in late G_1 at the G_1/S transition. (B, courtesy of Y. Cho, from C. Lee et al., *Genes Dev.* 16:3199–3212, 2002. C, courtesy of R. Latek, from N. Zheng et al., *Genes Dev.* 13:666–674, 1999. Both with permission from Cold Spring Harbor Laboratory Press. D, adapted from H.-Z. Chen et al., *Nat. Rev. Cancer* 9:785–797, 2009. With permission from Nature.)

Although the above scheme is correct in outline, the details are more interesting and complex. The term “E2F” is now known to include a family of proteins composed of eight members—E2F1 through E2F8; the first six of these can bind to either a DP1 or a DP2 subunit to form heterodimeric transcription factors (Figure 8.18C and D); the

two others—E2F7 and E2F8—have two DNA-binding domains (DBDs), allowing each to bind DNA without an associated DP1/2 subunit. (In the discussions that follow, we focus on the behavior of the various E2F subunits, with association to their DP1 or DP2 partner subunits being assumed.) Once assembled, E2F–DP complexes recognize and bind to a sequence motif in the promoters of various genes that seems to be TTTCCCGC or slight variations of this sequence.

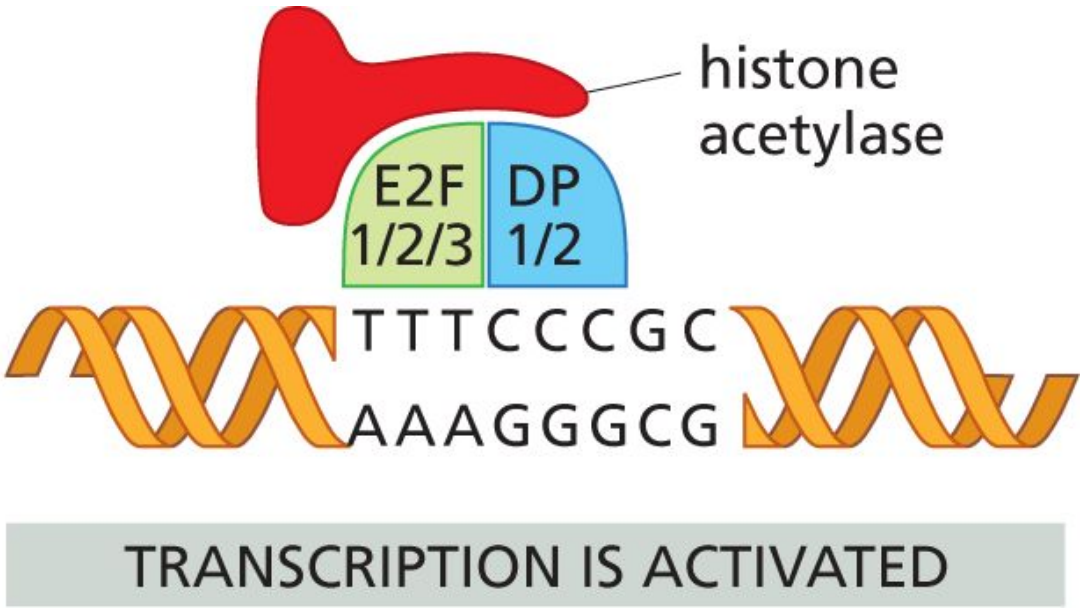
Throughout this book, we have portrayed transcription factors as proteins that bind to the promoters of genes and then proceed to activate transcription. In fact, transcription factors operating like E2Fs can exert two opposing effects on transcriptional control. When bound to the promoters of genes in the absence of any associated pocket proteins (that is, pRb, p107, or p130), E2Fs such as E2Fs 1, 2, and 3 can indeed trigger gene expression by attracting other proteins—such as histone acetylases—that function to remodel the nearby chromatin and recruit RNA polymerase to initiate transcription.

However, when pRb is hypophosphorylated, it physically associates with its E2F partners, which themselves are already sitting on the promoters of various genes and remain so after pRb binds to them. Once bound to these E2Fs, hypophosphorylated pRb molecules block the transactivation domains of the E2Fs that they employ to activate transcription (see Figure 8.18C). At the same time, pRb recruits other proteins that actively repress transcription. One important means of doing so, but hardly the only one, is to recruit a histone deacetylase (HDAC) to this complex (see Section 1.8); by removing acetyl groups from nearby histone molecules, an HDAC remodels the nearby chromatin into a configuration that is incompatible with active transcription (**Figure 8.19A**).



A complex consisting of E2F 1, 2 or 3 and D P 1 or 2 is attached to D N A. Then a pocket-shaped, singly phosphorylated p R b attracts a histone deacetylase (H D A C), and the resulting complex attaches onto the back of the E2F D P complex. When this happens, the transcription is repressed. A second flowchart shows the exact same process, but with E2F 4 or 5 taking the place of E2F 1, 2, or 3, and p107 or 130 taking the place of p R b. Transcription is repressed in this scenario as well.

(A)



Histone acetylase attaches to the back of a complex consisting of E2F 1, 2 or 3 and D P 1 or 2. This causes D N A transcription to be activated.

(B)

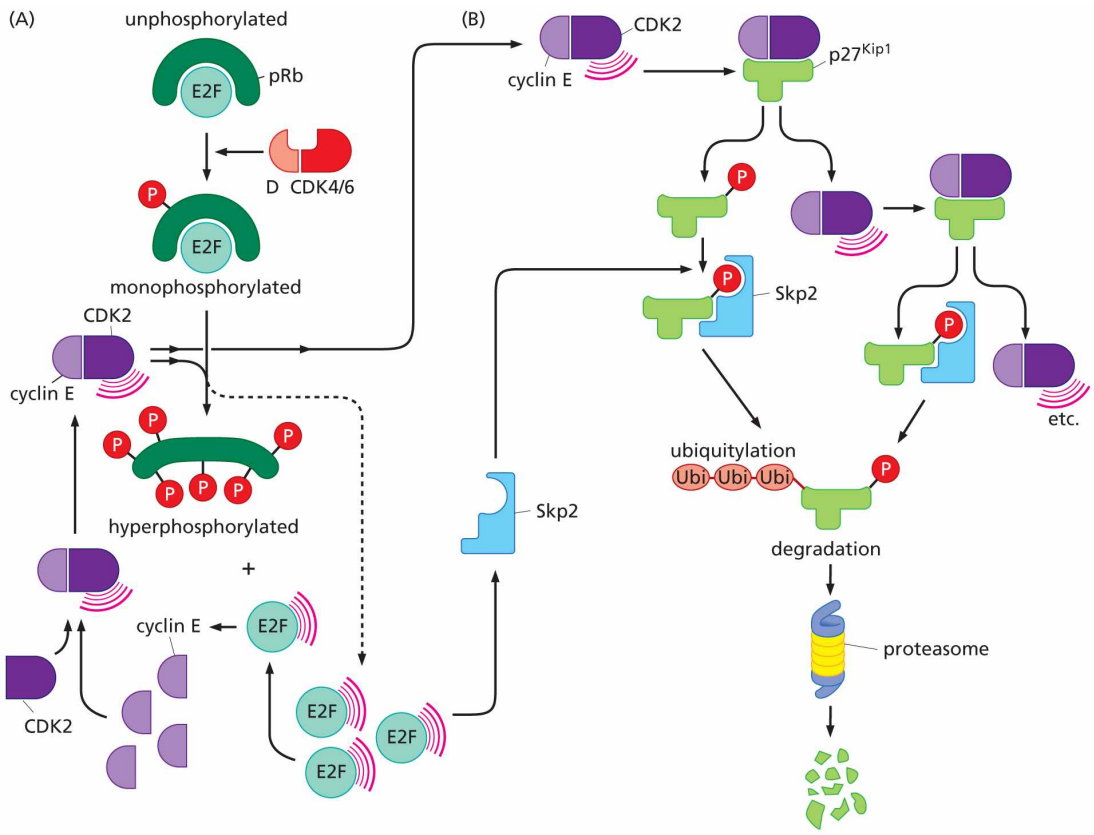
Figure 8.19 Modification of chromatin by pocket proteins (A) Hypophosphorylated pRb (*dark green*) discourages transcription by attracting histone deacetylase (HDAC) enzymes (*gray*) to pRb–E2F complexes that are bound, in turn, to gene promoters (*left*); these enzymes prevent transcription by removing acetyl groups from nearby histones, causing the latter to shift into a configuration that is incompatible with the progression of RNA polymerase through the chromatin. A similar repressive role is exercised by the pRb-related p107 and p130 (*right*), which bind E2F4/5; the latter appear to never be involved in induction of active transcription. (B) When the E2Fs 1/2/3 are not complexed with pRb after the latter undergoes hyperphosphorylation, they attract histone acetylases (*red*), which place chromatin in a configuration that is conducive for transcription, which occurs largely in late G_1.

This means that, in addition to occluding (physically blocking) the transactivation domains of E2Fs, pRb actively functions as a transcriptional repressor. E2Fs 4 and 5 seem to be involved primarily in the repression of genes and act largely through associated p107 and p130 proteins to attract repressors of transcription to promoters and thereby shut down gene expression. E2Fs 6, 7, and 8, which do not associate with pocket proteins, appear to act exclusively as transcriptional repressors.

In quiescent G_0 cells, for example, E2F4 and E2F5 are present in abundance (and are associated largely with p130), whereas E2Fs 1, 2, and 3 are hardly present at all, being expressed largely in proliferating cells. Moreover, cells that have been genetically deprived of E2F4 and E2F5 have lost responsiveness to the growth-inhibitory effects of the $p16^{INK4A}$ CDK inhibitor. This implies that the lion's share of the downstream effects that result from inhibiting the cyclin D–CDK4/6 complexes and thus blocking the hyperphosphorylation of pocket proteins is mediated via the binding of p107 and p130 to these two E2Fs. Ultimately, this binding results in the repression of a constituency of genes that carry TTTCCCGC sequences in their promoters (see Figure 8.19A).

Once hyperphosphorylated, pRb releases its grip on E2F1, 2, and 3 complexes, and these E2Fs can then attract transcription-activating proteins, including histone acetylases, which convert the chromatin into a configuration that encourages transcription (Figure 8.19B). A series of genes that are expressed specifically in late G_1 and are known or assumed to be important for S-phase entry has been found to contain binding sites in their promoters for E2Fs. Included among these are some genes encoding proteins involved in synthesizing DNA precursor nucleotides (such as dihydrofolate synthetase and thymidine kinase), as well other genes involved directly in DNA replication, such as that encoding DNA polymerase α. Yet other target genes are involved in activating certain aspects of energy metabolism. (One survey indicates that at least 500 genes are direct targets of transcriptional activation by E2Fs.)

Prominent among the E2F-activated genes are the genes encoding cyclin E and E2F1. Consequently, the levels of cyclin E and E2F1 mRNAs rise quickly after passage through the R point and the levels of their protein products increase shortly thereafter. Recall that cyclin E, for its part, is responsible, together with CDK2, for driving the hyperphosphorylation of pRb. Hence initial pRb inactivation leads to increases in cyclin E levels, and cyclin E, once formed, drives further pRb inactivation (**Figure 8.20**). These relationships enable the operations of a powerful, self-amplifying positive-feedback loop that is triggered as cells pass through the R point. (Such regulation can also be termed a "feed-forward loop.")



A two-part figure showing a sequence of events that begins with and unphosphorylated E2F p R b complex. In Part A, under the influence of D C D K4 or 6, this complex becomes monophosphorylated. Small numbers of recently liberated, signaling E–C D K2 molecules then drive hyperphosphorylation of p R b, which liberates small numbers of E2F transcription factors from p R b control. They trigger increased transcription of the cyclin E gene, leading in turn to the synthesis of more cyclin E protein and the formation of more E–C D K2 molecules, which drive more p R b hyperphosphorylation. Two outputs of this cycle are a large number of E–C D K2 signaling molecules and the activation of S k p 2. In Part B, E–C D K2 repeatedly monophosphorylates p 27 Kip1, after which the latter binds to S k p 2, undergoes ubiquilation, and then is degraded in a proteasome.

Figure 8.20 Positive-feedback loops and the irreversibility of cell cycle advance The irreversibility of certain key steps in cell cycle progression and the rapidity of their execution is ensured, in part, by the activation of certain interconnected, self-amplifying positive-feedback loops, such as those illustrated here that operate at the R point. This cascade of events is triggered when small numbers of E-CDK2 molecules are liberated from inhibition by $p27^{Kip1}$, as shown in Figure 8.14B. (A) When the liberated E–CDK2 complexes drive pRb hyperphosphorylation, this liberates small numbers of E2F transcription factors

(specifically E2F1/2/3, *below*) from pRb control, enabling the E2Fs to trigger increased transcription of the cyclin E gene, leading in turn to the synthesis of more cyclin E protein and the formation of more E–CDK2 complexes, which then function to drive more pRb hyperphosphorylation. At the same time, the newly liberated E2F proteins drive expression of E2F1 itself, further amplifying E2F activity (*not shown*). Also not shown here is the interaction of monophosphorylated pRb with Skp2, which blocks the ability of the latter to drive $p27^{Kip1}$ degradation, leading to $p27^{Kip1}$ accumulation through much of the G_1 phase of the cell cycle; hence, monophosphorylated pRb can also halt cell proliferation via an E2F-independent mechanism. (The active E2F transcription factors shown are actually heterodimers of E2F subunits plus DP subunits, as shown in Figure 8.19B). (B) The initial activation of a small number of active E–CDK2 complexes enables the latter to phosphorylate $p27^{Kip1}$, marking it for recognition and binding by Skp2, ubiquitylation and destruction in proteasomes. Yet another positive-feedback loop leads to E2F-mediated increased transcription of the *Skp2* gene (as seen in panel A), whose protein product drives ubiquitylation and thus degradation of $p27^{Kip1}$; this liberates even more E-CDK2 complexes from inhibition by the $p27^{Kip1}$ CKI.

Yet another positive-feedback loop is activated simultaneously at the R point through the following mechanism: cyclin E–CDK2 complexes phosphorylate $p27^{Kip1}$, and the latter, once phosphorylated, is ubiquitylated and rapidly degraded (Figure 8.20B). The destruction of $p27^{Kip1}$ molecules, which normally inhibit E–CDK2 firing, liberates additional cyclin E–CDK2 complexes that proceed to phosphorylate and thereby inactivate even more $p27^{Kip1}$ molecules. Such positive-feedback mechanisms operate in many control circuits to guarantee the rapid execution of a decision once that decision has been made. Equally important, they ensure that the decision, once made, is essentially irreversible—a situation that corresponds precisely with the behavior of cells advancing through the R point.

The period of active transcriptional promotion by E2Fs 1, 2, and 3 appears to be rather short-lived (see Figure 8.18A). This time window begins at the R point when pRb becomes hyperphosphorylated and liberates these E2Fs. The three E2Fs then proceed to induce expression of critical late G_1 genes, the products of which are required to prepare the cell for entrance into S phase, as described above. Soon thereafter, as the cell traverses the G_1/S transition into S phase, cyclin A becomes activated and, acting together with its CDK2 partner, phosphorylates both the E2F and DP subunits of these heterodimeric transcription factors; this results in the dissociation of the E2F–DP complexes and in the attendant loss of their transcription-activating abilities. At the same time, E2F1 (and possibly other E2Fs) are tagged for proteasome-mediated

degradation by ubiquitylation, and E2F7 and E2F8, which seem to function largely to antagonize E2F-mediated gene activation, are expressed and appear to block any residual E2F-dependent expression that persists after cells have entered S phase. Together, these changes effectively shut down further transcriptional activation by the E2F factors, whose brief moment of glory as active transcription factors will come again only during the end of the G_1 phase of the next cell cycle.

pRb has been reported to bind to a variety of transcription factors, and these might, in principle, be controlled by pRb and its state of phosphorylation. In the great majority of cases, however, detailed functional analyses of their interactions with pRb have not been undertaken. There is a compelling reason to believe that, among all of the transcription factor clients of pRb, the E2Fs are of preeminent importance in controlling cell cycle advance: when E2F1 protein molecules are micro-injected into certain types of serum-starved, quiescent cells (which are therefore in G_0), these transcription factor molecules, acting on their own, are able to induce these cells to enter G_1 and advance all the way into S phase; E2F2 and E2F3 have similar powers.

8.8 A variety of mitogenic signaling pathways control the phosphorylation state of pRb

It is worthwhile at this point to step back and summarize briefly the ways in which these various mitogenic signals regulate distinct components of the cell cycle clock. Prominent among the signals impinging on this nuclear regulatory machinery are those conveyed by the mitogenic signaling pathways, as we saw in Figure 8.9B. Because excessive signals flow through these pathways in virtually all types of cancer cells, the connections between these pathways and the cell cycle clock are critical to our understanding of cell transformation and tumor pathogenesis.

Mitogenic signals transduced via Ras result in the mono- and eventual hyperphosphorylation of pRb. This phosphorylation is initiated by inducing the expression of genes encoding the D-type cyclins, notably cyclin D1. When Ras signaling is blocked (through the introduction of a dominant-negative mutant Ras protein), cell proliferation is blocked in wild-type cells exposed to serum, whereas mutant $Rb^{-/-}$ cells lacking Ras function enter S phase quite normally. This demonstrates dramatically that the main function of Ras during the G_1 phase is to ensure that the mitogenic signals released by ligand-activated growth factor receptors succeed in causing the phosphorylation and functional inactivation of pRb. Moreover, the block to S-phase entrance imposed by the dominant-negative Ras protein can be circumvented by ectopically expressing either cyclin E or E2F1 genes in cells. Together, these observations suggest a linear chain-of-command of the following sort:

growth factors → growth factor receptors → Ras → cyclins D1 and E → inactivation of pRb → activation of E2Fs → S-phase entrance.

There are yet other mechanisms, still poorly characterized, that enable mitogenic growth factors to energize the cell cycle apparatus. For instance,

the physical association of D-type cyclins with CDK4 also depends, for unknown reasons, on mitogenic signaling. The elucidation of this and other connections between growth-promoting signals and the cell cycle clock will surely come from future research.

OceanofPDF.com

Glossary

dominant-negative
: Referring to a mutant allele of a gene that, when co-expressed with the wild-type allele of the gene, is able to interfere with the functioning of the latter. *Also termed* **dominant-interfering**.

8.9 The Myc protein governs decisions to proliferate or differentiate

As we have read, pRb function is compromised in neoplastic human cells through multiple mechanisms, including mutation of the *Rb* gene and its functional inactivation through hyperphosphorylation. A functionally similar outcome can be observed in cells that have been infected and transformed by human papillomavirus (HPV); thus, pRb binding by the viral E7 oncoprotein (see Figures 8.16D and 8.18B) plays a key role in the development of the great majority (>99.7%) of cervical carcinomas, which occur in large numbers throughout the world.

In fact, human cancer cells devise a diverse array of alternative molecular strategies to derail the normal control of cell cycle progression. We begin with the Myc protein which, when expressed in a deregulated fashion, operates as an oncoprotein. More than 70% of human tumors overexpress either Myc (often termed c-Myc) or one of its two close cousins—N-Myc and L-Myc. The Myc family oncoproteins function very differently from most of the oncoproteins that we encountered in Chapters 4, 5, and 6. These others, notably Ras and Src, operate in close proximity to cytoplasmic membranes and trigger complex signaling cascades that activate cytoplasmic signal-transducing proteins and, ultimately, nuclear transcription factors. Myc and its cousins are found, by contrast, in the nucleus, where they function directly as growth-promoting transcription factors (**Sidebar 8.5**).

Sidebar 8.5 Many oncoproteins function as transcription factors

Myc is only one of a large group of transcription factors that can function as oncoproteins (**Table 8.1**). We first encountered oncoproteins of this type in our discussion of the immediate early genes *myc*, *fos*, and *jun* (see Section 6.1), each of which encodes a transcription factor that can function as an oncoprotein. Later, we read about STAT proteins (Section 6.8), NF-κB, Notch, and Gli (Section 6.12), which also can play these dual roles. These various transcription factors act on a variety of target genes to induce a subset of the phenotypes that we associate with transformed cells.

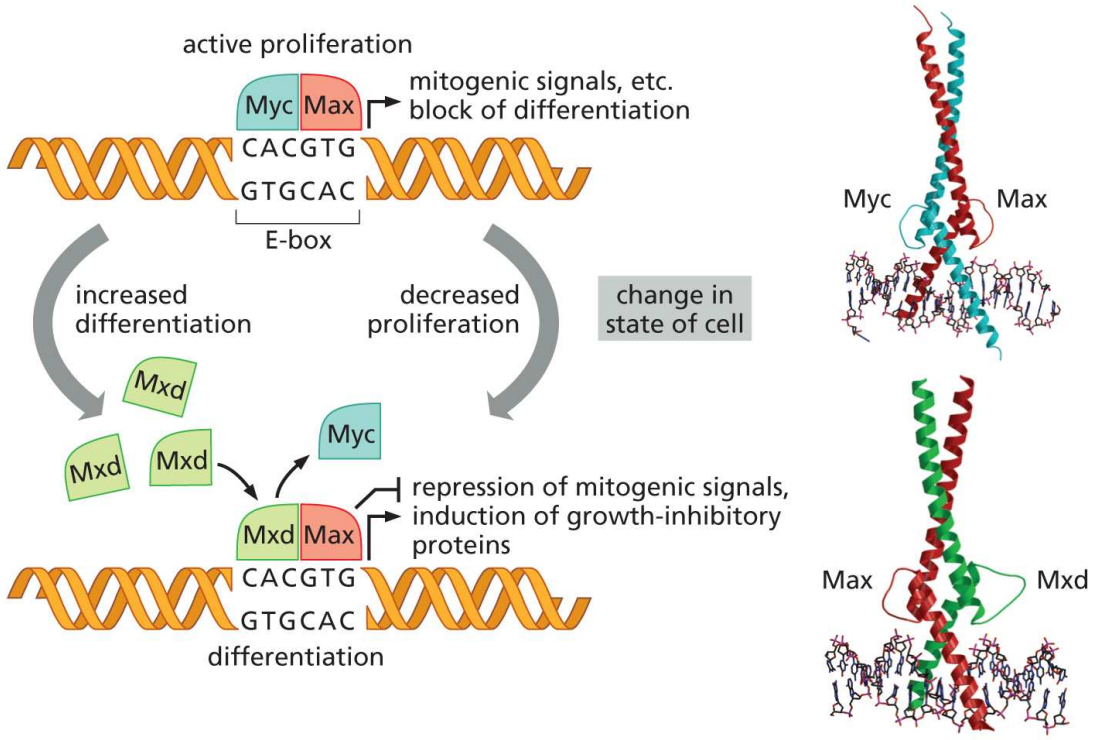
Table 8.1 Representatives of the classes of genes encoding TFs that act as oncoproteins[a]

Transcription factor	**Representative genes**
leucine zipper + basic DNA-binding domain	*fos* and *jun*
helix + loop + helix (bHLH)	*myc, N-myc, L-myc, tal,* and *sci*
zinc finger	*myl/RARa, erbA, evi-1,* and *gli-1*
homeobox	*pbx* and *Hoxb8*
others	*myb, rel, ets-1, ets-2, fli-1, spi-1, ski*

Adapted from T. Hunter, *Cell* 64:249–270, 1991. With permission from Elsevier.

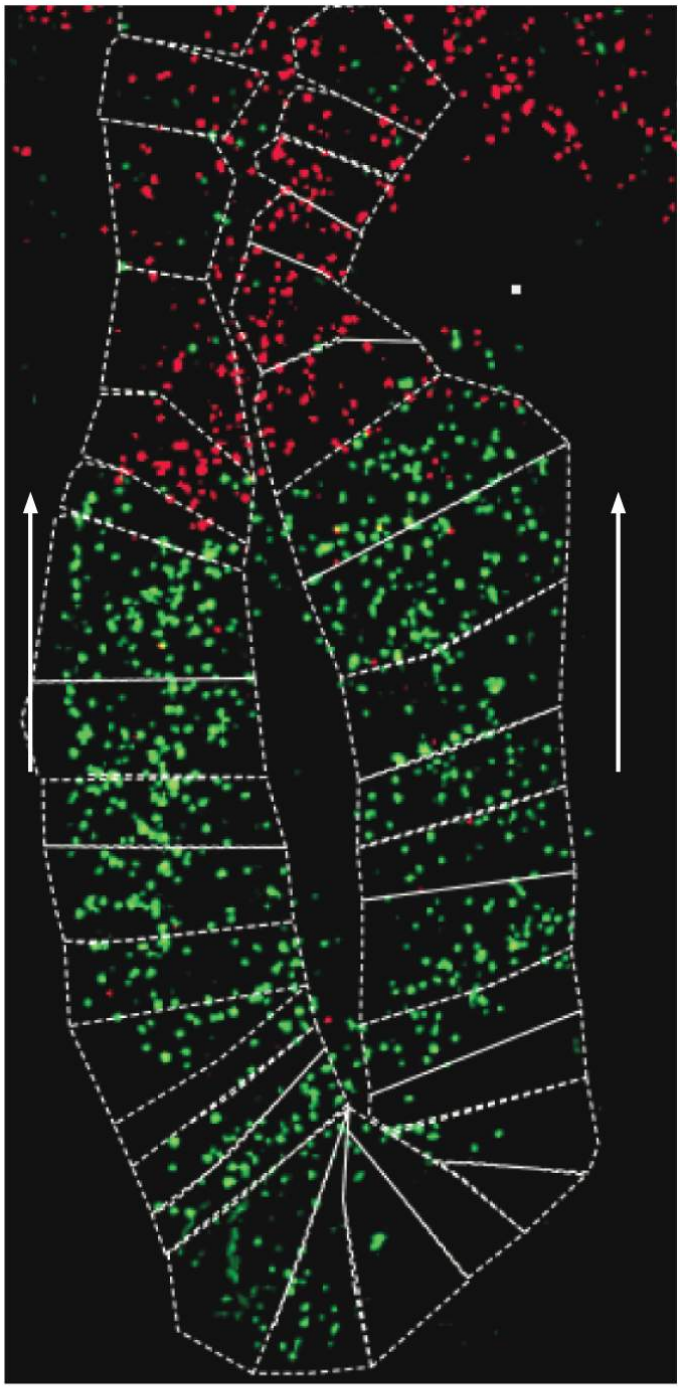
The constituency of target genes that are acted upon by each of these transcription factors (TFs) remains poorly defined. This lack of information is explained largely by the fact that at the experimental level, it has been challenging to determine the identities of the genes that are directly activated or repressed by various TFs. Even with the determination that various TFs bind to certain chromosomal segments does not, on its own, guarantee that the TF actually regulates the expression of a gene associated with this segment. Indeed, for many TFs, only a relatively small proportion (for example, 20% or 30%) of the binding sites can actually be validated as functionally important sites of TF action.

These three Myc family proteins are only three of a very large (>100 members) family of bHLH transcription factors. They were named after their shared three-dimensional structures, which include a **b**asic DNA-binding domain followed by amino acid sequences forming an α-**h**elix, a **l**oop, and a second α-**h**elix. Members of this transcription factor family form homo- and heterodimers with themselves and with other members of the family. Such dimeric complexes then associate with specific regulatory sequences, termed E-boxes (composed minimally of the consensus sequence CANNTG, where N can be any nucleotide), which are found in the promoters of target genes that they regulate (**Figure 8.21A**).



Active proliferation occurs when an M y c–Max complex, shown on the right as a ribbon diagram, binds to the E box sequence of a gene. This generates mitogenic signals, etc., and differentiation is blocked. When the cell changes state, differentiation increases, associated with the production of many M x dees. At the same time, proliferation decreases. One of the M x dees displaces the M y c to form an M x d-Max complex, also shown on the right as a ribbon diagram. Now repression of mitogenic signals occurs, along with induction of growth-inhibitory proteins.

(A)



A fluorescence microscopy image of a single crypt in the intestine of a mouse. The crypt is U shaped and the background is black. The bottom of the crypt features many green dots, revealing the presence of K i 67, associated with

proliferation. The upper, narrower part features many red dots, revealing the presence of Creb 3L3, associated with differentiation.
(B)

Figure 8.21 Proliferation vs. differentiation (A) Myc belongs to a family of bHLH (basic helix–loop–helix) transcription factors that act as heterodimers to modulate the transcription of a large cohort of target genes possessing E-box sequences (*left*). Myc–Max complexes act at enhancers like many other transcription factors and, in addition, promote elongation of nascent transcripts by releasing RNA polymerase II complexes from pause sites located immediately downstream of transcription start sites, allowing polymerase II to proceed with transcription and thus to the synthesis of full-length pre-mRNA transcripts; Mxd–Max complexes prevent this release. As cells differentiate, Mad levels increase progressively and Myc is displaced by Mxd, resulting in the disappearance of Myc–Max complexes, which otherwise would block differentiation (*left*). The actual molecular structures of these complexes sitting astride DNA (*right*) reveal why these proteins are termed basic helix–loop–helix transcription factors. (B) The opposition of proliferation vs. differentiation can be observed in various tissues. Here, a highly sensitive fluorescence *in situ* hybridization (FISH) technique has been used to detect individual mRNA molecules in the individual cells (*outlined in dashed lines*) lining a crypt in the mouse small intestine (see Figure 7.20. The *green dots* reveal mRNA molecules encoding Ki67 (indicating active proliferation), and the *red dots* reveal mRNA molecules encoding Creb3L3 (indicating enterocyte differentiation). The expression of these two mRNAs is mutually exclusive and the implied transition from one cell state to another occurs abruptly as cells migrate upward (*white arrows*) from one cell position to the next, apparently within an hour. (The involvement of Myc and its partners in this particular switch has not yet been demonstrated.) (A, right, from S.K. Nair and S.K. Burley, *Cell* 112:193–205, 2003. With permission from Elsevier. B, from S. Itzkovitz et al., *Nat. Cell Biol.* 14:106–114, 2011. With permission from Nature.)

In the particular case of Myc, its actions are determined by its own levels as well as by its associations with partner bHLH proteins that either enhance or suppress its function as a transcription-activating factor. Phosphorylation of the Myc protein also modulates its functioning and stability. When Myc associates with Max, one of its bHLH partners that enhance its transcription-activating powers, the resulting Myc–Max heterodimeric transcription factor drives the expression of a large cohort of target genes, possibly more than one thousand (**Sidebar 8.6**). The products of many of these genes, in turn, have potent effects on the cell cycle, favoring cell proliferation.

Sidebar 8.6 Myc can operate in a way that differs from that of most transcription factors

Recent research indicates that Myc can function quite differently than the other transcription factors discussed throughout this book. The others seem to be involved specifically in regulating transcriptional *initiation* (see Figure 1.18), that is, the formation of multiprotein complexes including RNA polymerase II at sites of initiation. In addition to initiating transcription, Myc has another role: in myriad genes, after RNA polymerase II (pol II) has initiated transcription, it halts at a pausing site ~50 bp downstream of the transcription start site. A Myc–Max heterodimer, bound to DNA, then interacts with the paused pol II complex and releases it from its pause site, allowing it to continue transcribing the bulk of the gene, that is, to *elongate* the RNA transcript; without this intervention by Myc–Max, the pol II that has begun the transcription of many genes is likely to sit at the pause site indefinitely. In one survey, 70% of actively transcribed genes were found to have Myc–Max heterodimers bound to these pause sites. (This number raises an interesting and unresolved paradox: in an actively growing cell, the number of genes found to bind Myc exceeds the absolute number of Myc molecules measured in such cells!) Stated differently, when acting as an anti-pausing factor, Myc serves to *amplify* the expression of genes that have already been activated, by other TFs. This, on its own, has important implications for Myc function: rather than having its own fixed constituency of responder genes that it regulates, many of Myc's targets are determined on a cell-type-specific basis, being governed by the actions of other TFs.

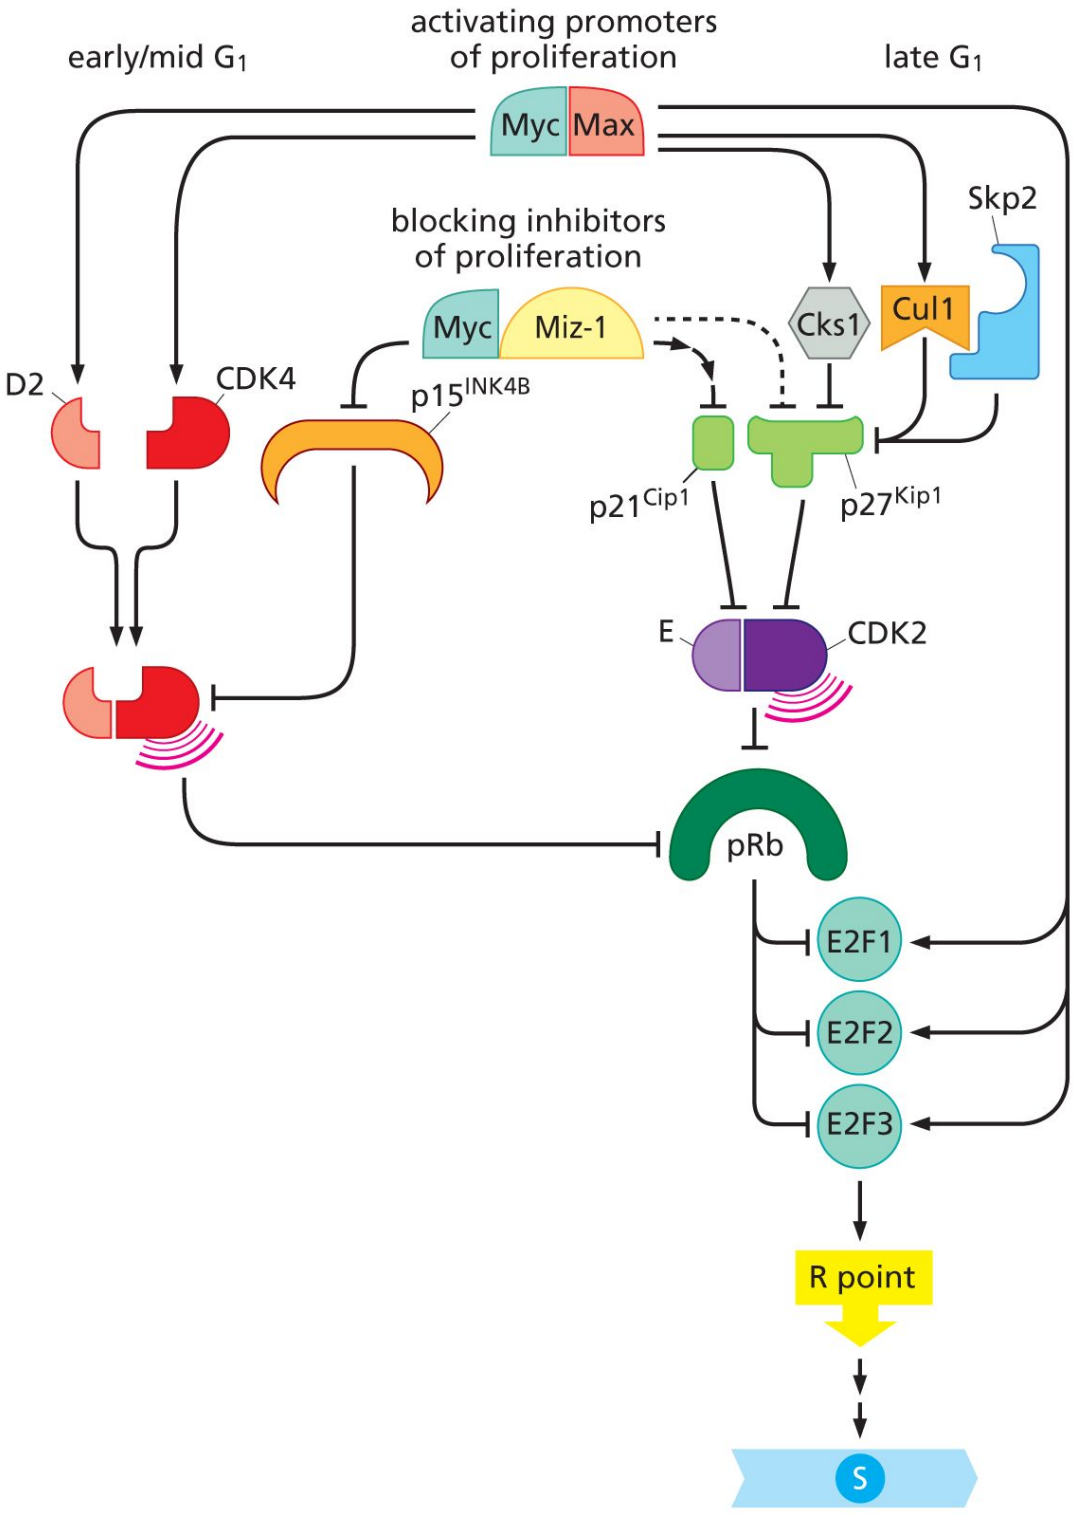
Whereas Myc levels are strongly influenced by mitogenic signals, the levels of Max are kept relatively constant within cells. Accordingly, when normal cells are cultured in the presence of serum mitogens, Myc accumulates to substantial levels; conversely, Myc levels collapse when serum mitogens are withdrawn. This means that the levels of the Myc–Max heterodimer are continuously controlled by the flux of mitogenic signals that normal cells are receiving.

A diverse array of transcription factors belonging to the same bHLH family as Myc are involved in orchestrating tissue-specific differentiation programs. Acting through intermediaries, Myc can prevent these other bHLH transcription factors from executing various differentiation programs. Consequently, Myc can simultaneously promote cell proliferation and block cell differentiation; this is precisely the biological behavior that is associated with actively growing cells that have not yet entered into post-mitotic, differentiated states (Figure 8.21B). However, as cells slow their proliferation and become differentiated, the Myc–Max complexes disappear, because increasing levels of Mxd protein (another bHLH partner formerly known as Mad) displace Myc from existing Myc–Max complexes (see Figure 8.21A). The resulting

Mxd–Max complexes then lose the ability to stimulate transcription, permitting cells in many human tissues to enter into post-mitotic differentiated states.

Myc interacts closely with the cell cycle machinery. Perhaps the first indication of this came from observations in which pairs of oncogenes were found to collaborate with one another in transforming rodent cells to a tumorigenic state. We will revisit oncogene collaboration later in Chapter 11. For the moment, suffice it to say that the *ras* and *myc* oncogenes were found to be highly effective collaborators in cell transformation, implying that each made its own unique contribution to this process. Similarly, a *ras* oncogene was found to collaborate with the adenovirus E1A oncogene in cell transformation. Together, these observations indicated that the *myc* and E1A oncogenes functioned analogously in this particular experimental setting. Precisely how they did so was a mystery.

The fact that the E1A oncoprotein binds and inactivates pRb and its p107 and p130 cousins (see Sidebar 8.4) suggested that the Myc protein could have similar effects on these vital cellular proteins, especially pRb. However, a direct association between Myc and pRb could not be established. Instead, we have come to realize that Myc induces the expression of other critical components of the cell cycle clock that operate to favor progression through the cell cycle (**Figure 8.22**). When expression of these components is driven by the abnormally high levels of Myc present in cells carrying *myc* oncogenes, the result is a physiological state similar to that seen in cells lacking pRb function. Both changes deprive a cell of the normal control of progression through the G_1 phase of its cell cycle and deregulate passage through the R point. This helps to explain the ostensibly analogous mechanisms-of-action of the adenovirus E1A oncoprotein and Myc, as mentioned above: both converge on incapacitating pRb, doing so in very different ways.



A diagram of the Actions of M y c on the cell cycle clock. During the early mid G 1 phase, M y c acts in conjunction with Max to activate promoters of proliferation by, for example, bringing D2 C D K4 together. At the same time, M y c acts in conjunction with M i z 1 to block inhibitors of proliferation such as p15 I N K4B,

which is an inhibitor of D2 C D K4. D2 C D K4 inhibits p R b, blocking it from inhibiting E2F 1, 2 and 3, thereby driving the cell cycle forward through the R point. During the late G1 phase, M y c Max directly activates the E 2 effs. It also, through intermediates C k s1 and C u l1 and with the help of S k p2, inhibits p27 Kip 1. M y c M i z 1 also inhibits p27 Kip 1, and p21 Cip1, as well. These inhibited proteins are thus prevented from blocking E C D K twos inhibition of p R b, which again promotes E2F 1, 2 and 3 driving the cell cycle forward through the R point.

Figure 8.22 Actions of Myc on the cell cycle clock The Myc protein, acting with its Max partner (*top*), induces expression of a number of positive regulators of cell cycle advance, thereby driving cells through the R-point transition. For example, the Myc–Max heterodimer is able to induce expression of the growth-promoting proteins cyclin D2 and CDK4 (*left*), which can promote advance through early G_1; it also contributes to the expression of cyclin E (*not shown*). At the same time, by increasing the expression of Cks1, Cul1, and Skp2 (which are responsible for degrading the $p27^{Kip1}$ CDK inhibitor, *upper right*; see Figure 8.20B) as well as E2Fs 1, 2, and 3 (*below right*), the Myc-Max complex favors advance into S phase. In addition, Myc, acting with its Miz-1 partner, represses directly or indirectly expression of the $p15^{INK4B}$, $p21^{Cip1}$, and $p27^{Kip1}$ CDK inhibitors; once again, effects are felt both in early/mid and in late G_1. Also not shown are the actions of active E-CDK2 complexes in phosphorylating $p27^{Kip1}$, leading to its degradation (see Figure 8.20B).

Among the many targets of Myc is the cyclin D2 gene (see Figure 8.22), whose elevated expression leads, in turn, to the monophosphorylation of pRb (see Figure 8.17). Myc also drives expression of the CDK4 gene; the resulting increased levels of CDK4 drive the formation of the cyclin D–CDK4 complexes that sequester the $p27^{Kip1}$ CDK inhibitor, thereby liberating cyclin E–CDK2 complexes from inhibition (see Figure 8.14B). Myc also drives expression of the Cul1 protein, which plays a central role in driving the degradation of the $p27^{Kip1}$ CDK inhibitor through ubiquitylation. In one way or another, these Myc-driven gene expression changes serve to push the cell through the G_1 phase of its cell cycle.

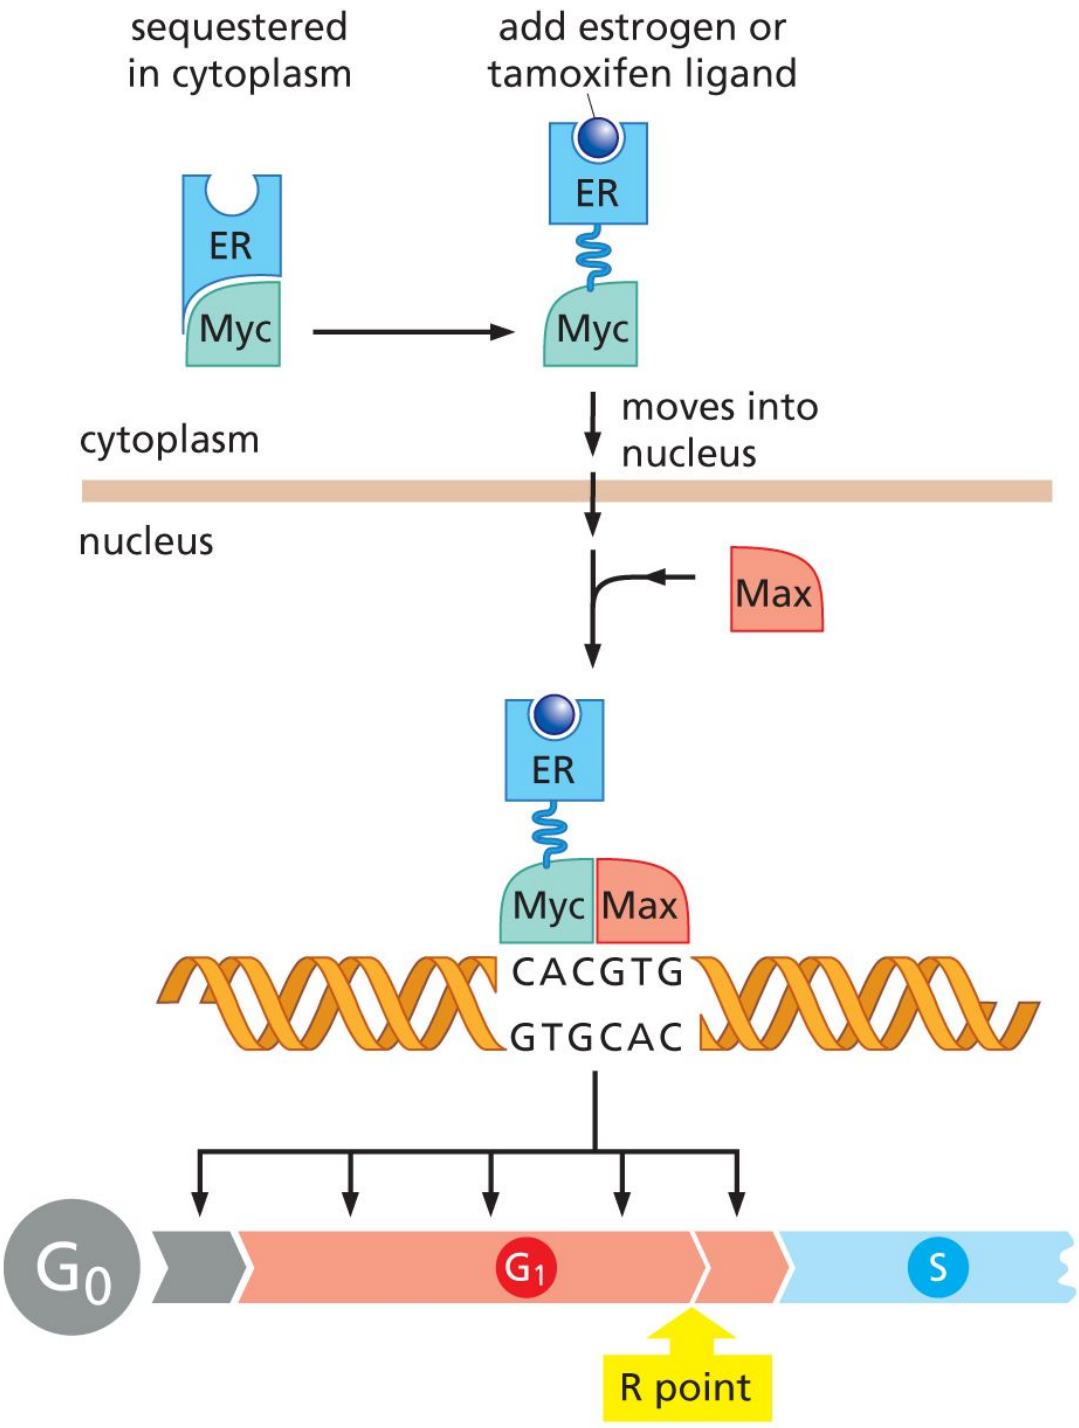
By associating with a second transcription factor named Miz-1, Myc can also function as a transcriptional repressor (see Figure 8.22). In this role, Myc can repress expression of the genes encoding the $p15^{INK4B}$ and $p21^{Cip1}$ CDK inhibitors, which shut down the actions of CDK4/6 and CDK2, respectively. In fact, as we will read later, TGF-β uses these two CDK inhibitors to block progression through the G_1 phase of the cell cycle. Hence, by preventing the expression of these two CDK inhibitors, Myc confers resistance to the growth-inhibitory actions of TGF-β. This represents an

important means by which cancer cells can continue to multiply under conditions (for example, the presence of TGF-β in their surroundings) that would normally preclude their proliferation.

Finally, Myc is able to induce the expression of the genes encoding the E2F1, E2F2, and E2F3 transcription factor proteins (see Figure 8.22). As we read earlier, pRb and its two cousins inhibit the transcription-activating powers of these transcription factors. By causing these growth-promoting transcription factors to accumulate to higher levels within a cell, Myc once again tips the balance in favor of cell proliferation.

Now, we begin to understand how the Myc oncoprotein can function so effectively to deregulate cell proliferation. It reaches in and pulls multiple regulatory levers within the cell cycle clock. The resulting changes in levels of key proteins shift the balance of proliferation-promoting versus -inhibiting mechanisms, strongly favoring pRb inactivation and cell growth.

Perhaps the most graphic demonstration of the potent mitogenic powers of Myc has come from an experiment in which Myc is engineered to be expressed at high, constant levels but as a protein that is fused with the estrogen receptor (ER). In the absence of an estrogen receptor ligand, such as estrogen or tamoxifen, the Myc–ER fusion protein is sequestered in a functionally inactive state in the cytoplasm (see Section 5.8). However, upon addition of ligand, this fusion protein is liberated from sequestration, rushes into the nucleus, and operates like the normal Myc transcription factor. When quiescent, serum-starved cells (in the G_0 state) expressing the Myc–ER fusion protein are treated with either estrogen or tamoxifen (but left in serum-deprived medium), these cells are induced to enter into the G_1 phase and progress to S phase (**Figure 8.23**). This illustrates that Myc, acting on its own and in the absence of serum-associated mitogens, is able to relieve all of the constraints on proliferation that have held these cells in G_0 and is able to shepherd them all the way through G_1—an advance that usually requires substantial, extended stimulation by growth factors. In addition to Myc, a number of other transcription factors display the wide-ranging powers of oncoproteins (see Table 8.1).



A diagram showing the action of the M y c oncoprotein in the cell nucleus. Initially, M y c is fused with E R, which has an open binding site, and the complex is sequestered in the cytoplasm. When the E R binding site is occupied by an estrogen or a tamoxifen ligand, the M y c E R complex elongates and moves into the nucleus, where Max joins to M y c. This complex can bind to M y c target

genes and drive the cell cycle forward at a number of points in the G zero and G1 phases, including after the R point.

Figure 8.23 Powers of the Myc oncoprotein The wide-ranging effects of the Myc protein are illustrated by an experiment in which the Myc protein has been fused to the estrogen receptor (ER) protein (*blue*), achieved by fusion of the two encoding genes. In the absence of ER ligands, such as estrogen or tamoxifen, the Myc–ER protein is trapped in the cytoplasm (through association with heat shock proteins, *not shown*). When estrogen or tamoxifen ligands are added to cells, the Myc–ER protein migrates into the nucleus, associates with Max, and activates Myc target genes within minutes. Such activation, when induced in serum-starved cells in the G_0 phase, enables them to enter the active cell cycle and advance all the way through G_1 into the S phase, indicating that Myc can act at multiple points in G_0 and G_1 to drive cell cycle progression.

In addition to promoting cell cycle progression, Myc is also able to positively regulate fundamental biosynthetic processes, such as ribosome biogenesis, general transcription, protein synthesis and, more generally, anabolism (the synthesis of complex biomolecules). Therefore, we can conclude that Myc acts as an important master regulator that operates to coordinate overall biosynthesis with a cell's advance through the cell cycle, thereby ensuring that a cell that is committed to pass through M phase has acquired the requisite biomass that is needed to generate two healthy daughter cells. Moreover, as might be expected from these multiple effects on the cell around it, a Myc oncoprotein can also perturb the interactions of this cell with others in its surroundings, that is, the neighboring cells that form its tissue microenvironment. Included here are, among other processes, neovascularization, the process of generating new blood vessels, a topic described in some detail in Chapter 13. Finally, elevated Myc expression can induce high levels of ID proteins (see Figure 8.85C), which are direct antagonists of many of the bHLH transcription factors that orchestrate differentiation programs in diverse tissues; indeed, one of these (ID2) is able to bind pRb directly and antagonize the proliferation-inhibiting powers of the latter (**Supplementary Sidebar 8.8**.)

8.10 TGF-β prevents phosphorylation of pRb and thereby blocks cell cycle progression

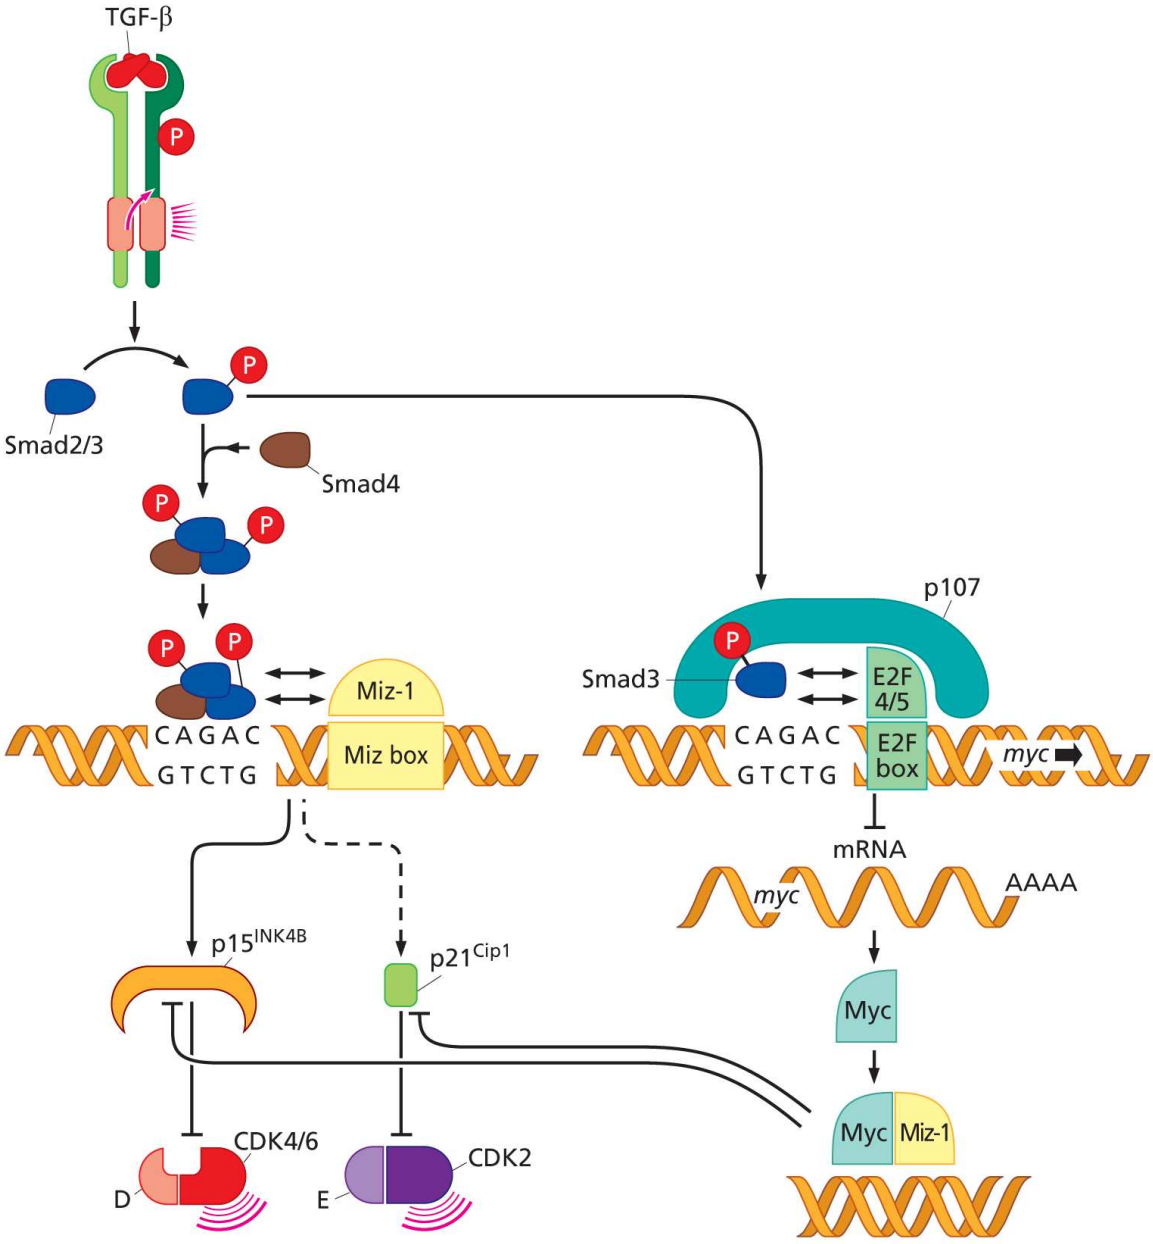
TGF-β represents a major growth-inhibitory signal that normal cells, especially epithelial cells, must learn to evade in order to become cancer cells. As we will learn later in Chapters 13 and 14, TGF-β also exerts other, quite distinct effects on cells, by forcing them to change their differentiation programs. Often the resulting changes in cell phenotype actually favor tumor progression, as some of these phenotypic changes enable cancer cells to become anchorage-independent, angiogenic, and even invasive.

These two major effects of TGF-β—one antagonizing, the other favoring tumor progression—are clearly in direct conflict with one another. Cancer cells often resolve this dilemma by learning how to evade the cytostatic effects of TGF-β while leaving intact other responses, such as those favoring tumor cell invasiveness. Not surprisingly, the cytostatic actions of TGF-β derive from its direct and indirect effects on pRb, the central controller that determines whether or not a cell will proliferate.

We previously learned that TGF-β has its own, quite unique cell surface receptor, which uses serine/threonine kinases in its cytoplasmic domains (rather than tyrosine kinases) to emit signals. The primary targets of these signals documented to date are proteins of the Smad transcription factor family. Once phosphorylated in the cytoplasm by a TGF-β receptor, a pair of Smad2 (or Smad3) protein molecules associates with a Smad4 protein (which is not a substrate for phosphorylation by the receptor), and the resulting heterotrimeric protein complexes migrate to the nucleus, where they function as transcription factors (see Figure 6.22D).

As we read earlier (Section 8.4), in the context of cell cycle control, the most important targets of action by TGF-β are the genes encoding the two CDK inhibitors $p15^{INK4B}$ and, to a lesser extent, $p21^{Cip1}$ (see Figures 8.12 and 8.13).

Each has a CAGAC sequence in its promoter that attracts a heterotrimeric Smad3–Smad4 transcription factor complex. On its own, such a Smad complex cannot activate transcription of these genes because of its intrinsically weak binding to DNA. Instead, it collaborates with yet another transcription factor—the Miz-1 factor mentioned in the last section—that binds to adjacent DNA sequences, allowing side-to-side association of these two transcription factors, cooperative stable binding of this complex to the promoters of target genes, and activation of transcription of such genes, in this case those encoding $p15^{INK4B}$ and $p21^{Cip1}$ (**Figure 8.24**, *left*).



A diagram illustrating how T G F-beta slows progress through the G1 phase of the cell cycle. There are two paths by which T G F-beta promotes the production of p15 I N K 4B, which inhibits D-C D K 4 slash 6, and the production of p21 Cip1, which inhibits E-C D K 2. Both paths begin with T G F-beta binding to a receptor that transphosphorylates and then phosphorylates S m a d 2 slash 3. In one path, two phosphorylated S m a d 2 slash threes combine with an S m a d 4. The resulting complex binds to a C A G A C sequence on a gene, immediately beside a Miz-1 bound to a Miz box. The result of this action is production of p15 I N K 4B which can inhibit D C D K 4 and 6 complex signalling and production of p21 Cip1 which can inhibit E C D K 2 complex signalling. In the other path, a phosphorylated S m a d 3 forms a complex with p107 and E2F 4 or 5. This complex binds to a C A G A C sequence and an immediately adjacent E2F box. This suppresses transcription of the m y c gene and thereby limits the formation of M y c Miz 1 protein complexes that would inhibit the production of p15 I N K 4B and p21 Cip1.

Figure 8.24 Antagonistic effects of TGF-b and Myc on cell cycle progression As shown here, TGF-β and Myc oppose one another in regulating advance through the G_1 phase of the cell cycle. TGF-β induces expression of the $p15^{INK4B}$ CKI and, to a lesser extent, the $p21^{Cip1}$ CKI, by causing TGF-β-activated phospho-Smads to bind to the CAGAC canonical Smad-binding sequence in promoters adjacent to the binding of Miz-1 transcription factor to its own, quite extended sequence binding site, termed here a Miz box (*left*). Together this complex of physically associated TFs causes expression of the genes encoding the two CKIs, thereby slowing or preventing advance through the G_1 phase up to the R point. At the same time, TGF-β-activated phospho-Smad3 associates physically with E2F4 or E2F5. (The *double-headed arrows* indicate physical interaction.) The E2F box represents the sequence TTTCCCGC. The resulting complexes of p107, E2F4/5, and Smad3 repress transcription of the *myc* gene. The resulting decrease of Myc-Miz-1 complexes (*lower right*) leads to less repression of the genes encoding the $p15^{INK4B}$ and $p21^{Cip1}$ CKIs and a slowdown of advance through G_1.

We also noted earlier that the Myc oncoprotein, acting in the opposite direction, can block the induction of these two CDK inhibitors, doing so through its ability to associate with Miz-1. By repressing expression of the genes encoding $p15^{INK4B}$

and $p21^{Cip1}$, Myc removes two major obstacles standing in the way of cell cycle progression (see Figure 8.22). Stated differently, the constitutively high levels of Myc protein made by *myc* oncogenes ensure that expression of these two CDK inhibitors is strongly repressed, thereby paving the way for vigorous cell cycle advance.

In contrast to its powers in cancer cells, TGF-β needs to have the last word in determining whether or not normal cells proliferate. In order to do so, TGF-β must overrule any conflicting signals that Myc might be releasing. To guarantee success in this endeavor, TGF-β must ensure that Myc does not thwart its scheme to activate expression of the $p15^{INK4B}$ and $p21^{Cip1}$ CDK inhibitors. So, in normal cells, TGF-β keeps Myc away from the promoters of these genes by shutting down expression of the *myc* proto-oncogene (see Figure 8.24, *right*). By forming a tripartite complex with E2F4/5 plus p107, Smad3 ensures the shutdown of *myc* transcription, thereby eliminating the growth-promoting effects of the Myc protein from the cell's regulatory circuitry. Once TGF-β has succeeded in removing Myc from the scene—from the promoters of the $p15^{INK4B}$ and $p21^{Cip1}$ CDK inhibitors—TGF-β can then deploy its Smad3–Smad4 complexes, working together with Miz-1, to activate the promoters of these two CDK inhibitors, thereby erecting major obstacles to the advance of a cell through the G_1 phase of the cell cycle (see Figure 8.24, *left*).

Many types of incipient cancer cells must evade TGF-β–imposed growth inhibition if they are to thrive. More specifically, such cancer cells depend on high levels of the Myc transcription factor to drive their proliferation and therefore must liberate *myc* transcription from the repressive actions of TGF-β. This explains why, for example, in a series of 12 human breast carcinomas, *myc* expression in all 12 of these tumors was no longer responsive to TGF-β–imposed shutdown even though many other TGF-β–induced responses were found to be intact in 11 of these tumors. (Because the *myc* gene itself was apparently in a wild-type configuration in these tumors, deregulation of some of the transcription factors controlling its transcription appeared to be responsible for the observed vigorous expression of this gene.) Once protected from the threat of this TGF-β–mediated repression, the *myc* oncogene, more specifically, its Myc product, proceeds to hold expression of the two CDK inhibitors (that is, $p15^{INK4B}$ and $p21^{Cip1}$) at a very low level and does so indefinitely. This helps, in turn, to create a condition in the cell permitting rapid, unimpeded proliferation.

In a more general sense, cancer cells place a high premium on escaping the growth-inhibitory influences of TGF-β while leaving other, potentially useful

TGF-β responses intact. Often this evasion of TGF-β–mediated growth inhibition is achieved through inactivation of the pRb signaling pathway. In effect, in normal cells pRb operates as the brake lining that calls a halt to cell proliferation in response to TGF-β–initiated signals. Accordingly, if the pRb protein is eliminated from the regulatory circuitry through one of the various mechanisms described earlier, then the ability of TGF-β to impose growth arrest is greatly compromised because the $p15^{INK4B}$ induced by TGF-β now fails to effectively block cell cycle advance.

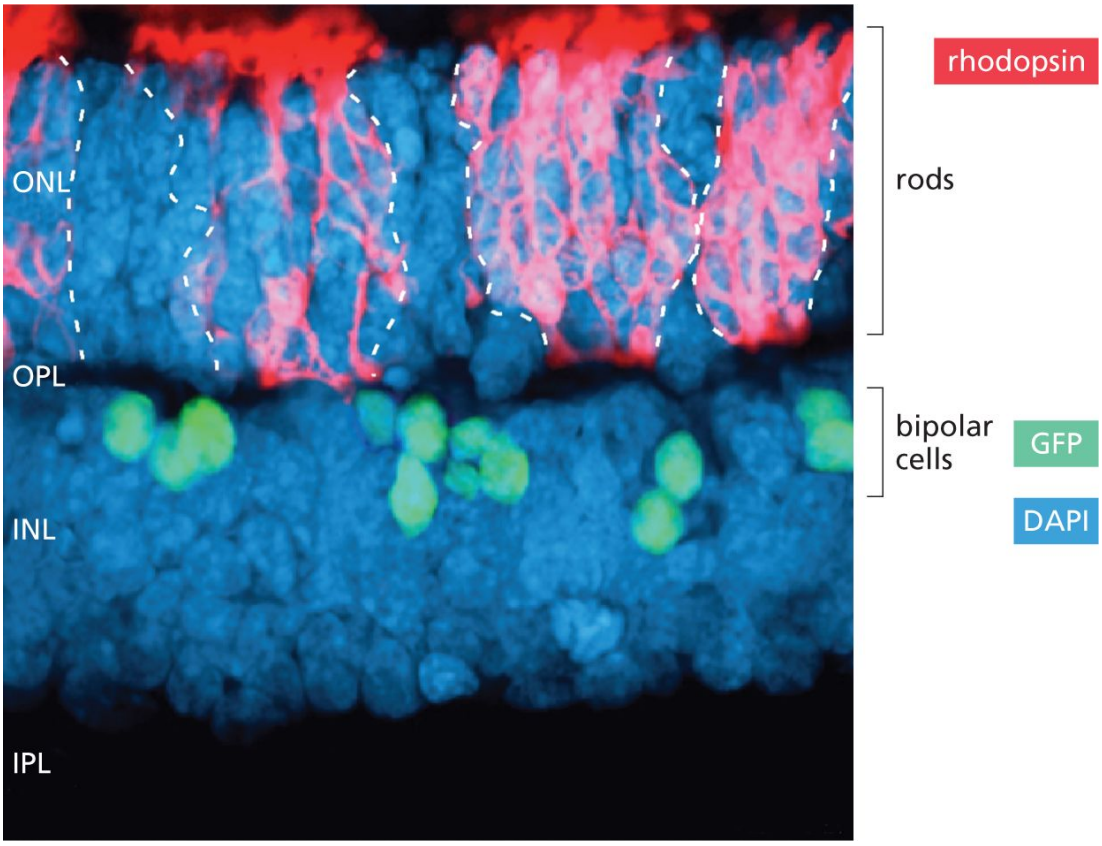
8.11 pRb function and the controls of differentiation are closely linked

Cell differentiation is a process of crucial importance to cancer pathogenesis and, as such, is mentioned repeatedly in this text. For the moment, we can imagine—a bit simplistically— that cells throughout the body can exist in either of two alternative growth states. They may be found in a relatively undifferentiated state in which they retain the option to divide in the event that mitogenic signals call for their proliferation; this is essentially the behavior of stem cells. Alternatively, cells leave this state and enter into a more differentiated state, whereupon they give up the option of ever proliferating again and thus become post-mitotic. The decisions that govern these fundamental changes in cell biology must be explainable in terms of the molecular controls that determine whether a cell remains in the active growth-and-division cycle, exits reversibly into G_0, or exits irreversibly from this cycle into a post-mitotic, differentiated state.

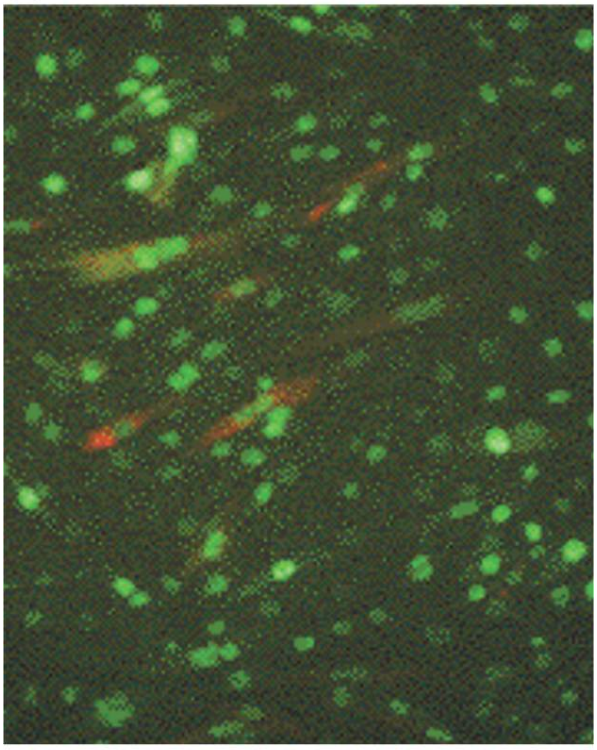
The opposition between cell proliferation and differentiation is seen most clearly in the formation of most types of cancer cells in which differentiation is partially or, more rarely, completely blocked. Knowing this, we might ask whether two independent changes in the cellular control circuitry must be made during the formation of a cancer cell—one that deregulates control of proliferation and another that blocks differentiation. The alternative is simpler: might certain alterations, in a single stroke, deregulate proliferation and prevent differentiation?

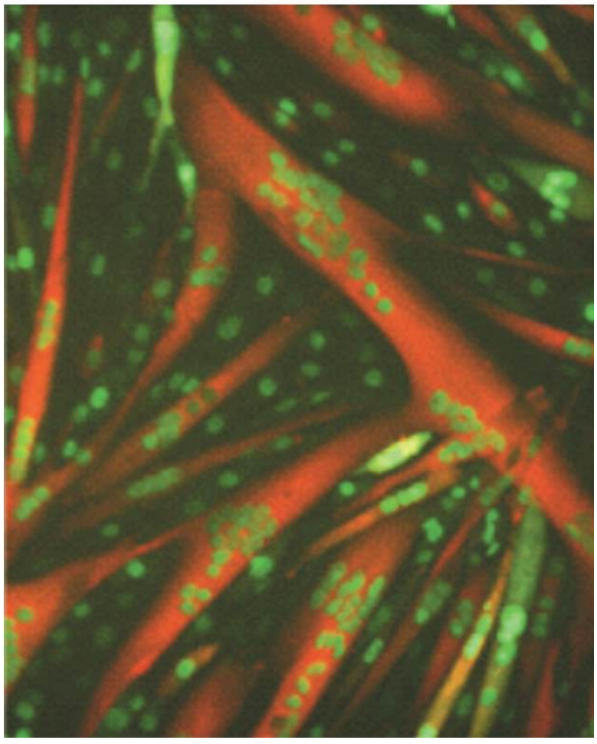
Evidence supporting the latter idea, which implies a close coupling between the mechanisms controlling these two processes, has been forthcoming from studies of retinal development *in vivo* and muscle cell differentiation *in vitro*. In the case of the retina, the absence of pRb function in retinal precursor cells prevents the proper differentiation of the rod photoreceptor cells (**Figure 8.25A**). In this micrograph, the *Rb* gene was inactivated sporadically in retinal precursor cells, resulting in patches of cells where subsequent rod development was defective (in which negative regulation of cell proliferation was also presumably lost).



A close-up of cell layers in a mouse retina. In the layer associated with rod cells, Rhodopsin glows red, contrasting dramatically with surrounding tissue stained dark blue by D A P I. Directly below in the next layer are bipolar cells that glow green due to the presence of G F P. There is no rhodopsin in this section.

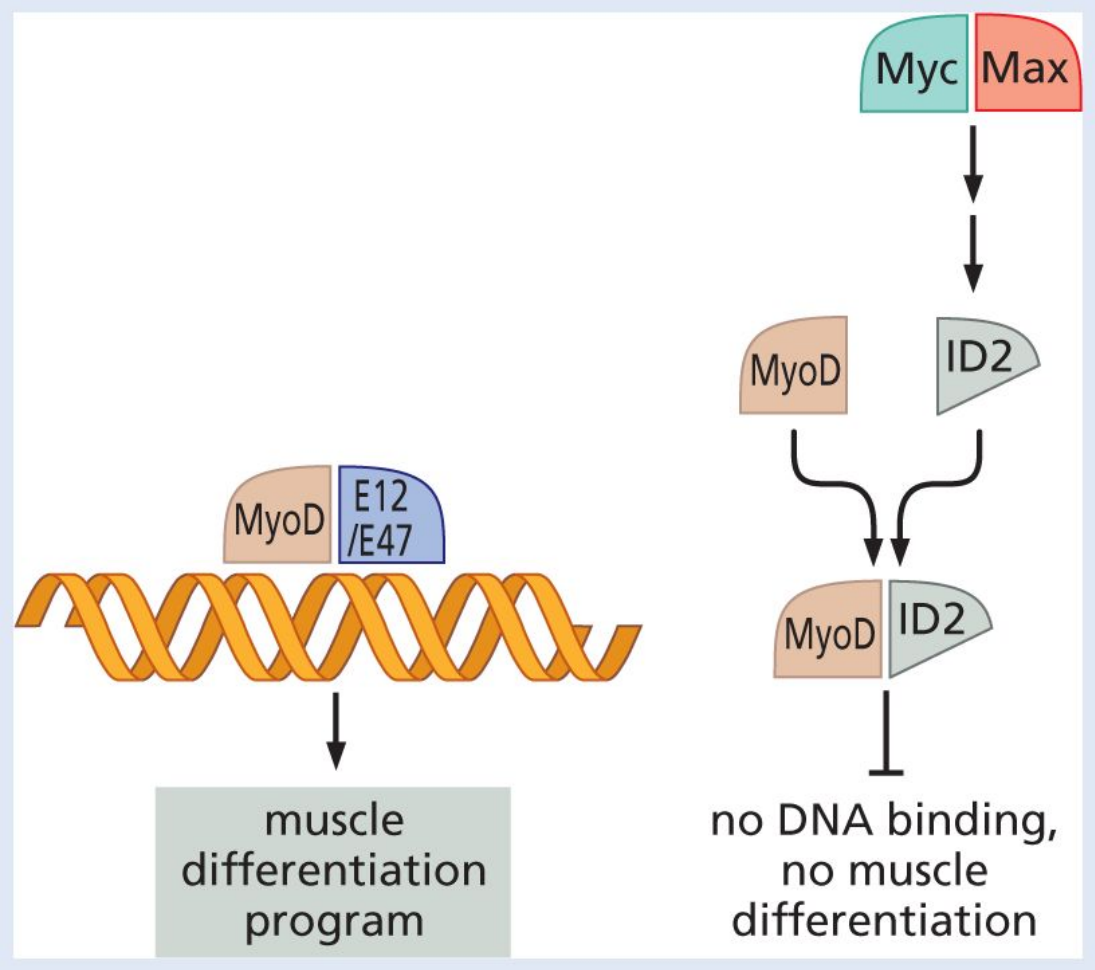
(A)





Two fluorescent color images. The upper one features many scattered green dots and a few faint reddish fibers. The bottom images features many thick, crisscrossing red fibers. There are also still quite a few green dots, scattered and also gathered in clumps on the red fibers.

(B)



A Myo D and E12 or 47 complex attached to a gene segment. This begins the complex muscle differentiation program. Also shown is an M y c Max complex that leads to production of I D 2, which forms a complex with Myo D whose presence inhibits muscle differentiation due to the absence of D N A binding.

(C)

Figure 8.25 Differentiation of retinal cells, and muscle cells (A) The proper differentiation of retinal cells (see Figure 7.2A) depends on the presence of pRb. During normal development, retinal progenitor cells move upward and differentiate into various specialized cell types. In the eyes of 2-week-old mice in an engineered transgenic mouse model, rod cells that successfully differentiated express the rhodopsin photoreceptor protein (*red*), whereas those that failed to do so (*between dashed white lines*) are represented only by the DAPI stain that marks their DNA (*blue*). The latter cells sit directly above GFP-labeled bipolar cells

(*green*) that mark the locations where progenitor cells had previously been forced to excise their only copy of their *Rb* gene (through the actions of a tissue-specific Cre-Lox system, see Sidebar 7.2) prior to migrating upward, showing directly that in the absence of pRb, progenitor cells differentiate incompletely and spawn rhodopsin-negative rod cells. (B) Myoblasts, the less differentiated precursors of muscle cells (myocytes), can be cultured *in vitro* and remain in the undifferentiated state (*upper panel*). However, various types of physiologic signals can induce them to differentiate into myocytes, whereupon they fuse to form muscle fibers (*red, lower panel*). For example, removal of serum (and its associated growth factors) from the culture medium leads to such differentiation. Numerous experiments have shown that differentiation can be prevented by forcing pRb phosphorylation and inactivation. Conversely, signals that prevent pRb phosphorylation favor and often induce differentiation. (C) MyoD is a bHLH transcription factor that serves as the master regulator, together with its E12/E47 partner, of the muscle differentiation program. Myc, for its part, acts to antagonize differentiation, in part through its ability to induce synthesis of ID2, an ID protein that has the bHLH structure but lacks DNA-binding ability; by forming heterodimers with MyoD, ID2 can act as a dominant-negative inhibitor of MyoD, because the heterodimer between MyoD and ID2 cannot bind DNA properly. (A, from S.L. Donovan and M.A. Dyer, *Vision Res.* 44:3323–3333, 2004. With permission from Elsevier. B, from E.M. Wilson et al., *Mol. Biol. Cell* 15:497–505, 2004. With permission from American Society for Cell Biology.)

Yet another line of evidence indicating a coupling between differentiation and the cell cycle machinery comes from research on the biochemistry of the Myc protein. As mentioned earlier (see Section 8.9), the Myc protein shifts the balance between proliferation and post-mitotic differentiation in favor of proliferation. A dramatic demonstration of the opposition between the Myc oncoprotein and cell differentiation has come from a mouse model of liver cancer pathogenesis, which depends on the targeted expression of a *myc* transgene in hepatocytes. Large hepatocellular carcinomas form, and these will regress whenever the *myc* transgene is shut down subsequently. At the same time, many of the carcinoma cells, which previously lacked most of the traits of normal hepatocytes, rapidly differentiate into liver cells that appear normal and assemble to reconstruct many of the histological features of the normal liver. Simi-lar dynamics operate during muscle differentiation (see Figure 8.25B and C). Moreover, the differentiation of a variety of cell types is favored by the G_1 CDK inhibitors, notably $p27^{Kip1}$. Finally, tissue-specific, differentiation-inducing transcription factors often antagonize cyclin:CDK function and, conversely, cyclin:CDK complexes can antagonize these transcription factors; the resulting double-negative feedback loops create bi-stable controls, in which cells either proliferate or enter into nonproliferative, differentiated states. These various controls

on cell differentiation, involving pRb, Myc, and other regulatory proteins, clearly have effects on the formation and development of various types of cancer, because tumors formed by more differentiated cells are usually less aggressive, whereas those composed of poorly differentiated cells tend to be far more aggressive and carry a worse prognosis for the patient. These observations are only a small part of a growing body of work demonstrating the opposition between active cell cycle progression and entrance into differentiated growth states (**Sidebar 8.7** and **Supplementary Sidebar 8.9**).

Sidebar 8.7 Blocked differentiation can accompany the advance of tumor progression

Some hematopoietic malignancies, specifically, leukemias, come in two forms—chronic and acute. The chronic diseases, such as chronic myelogenous leukemia (CML), are typified by more mature, differentiated cells and can proceed for years without becoming life-threatening. In the case of CML, after a period of 3 to 5 years, suddenly there is an eruption of a more malignant, aggressive form of the disease that is termed "blast crisis." The cells present in blast crisis clearly originate from the same cell clone that initiated the chronic phase of the disease. However, they are less differentiated and multiply ceaselessly, creating a life-threatening disease that is difficult to treat. It seems that the cells in the chronic phase are derived from a mutant self-renewing stem cell, but this disease remains relatively benign, because the differentiation of these mutant cells into post-mitotic neutrophils proceeds quite normally. The moment that such differentiation is blocked (by some still-poorly understood genetic changes), cells in this population are trapped in a less differentiated stem cell compartment (of either erythroid or myeloid type) and proliferate without a compensating exit of their progeny into more differentiated, post-mitotic compartments.

8.12 Control of pRb function is perturbed in most if not all human cancers

Deregulation of the pRb pathway yields an outcome that is an integral part of the cancer cell phenotype—unconstrained proliferation. This explains why normal regulation of the R-point transition, as embodied in pRb phosphorylation, is likely to be disrupted in most if not all types of human tumor cells (**Table 8.2** and **Table 8.3**). These disruptive mechanisms are summarized in **Figure 8.26**. We are already familiar with the most direct mechanism for deregulating advance through the R point—inactivation of the *Rb* gene through mutation. In some tumors, an equivalent outcome is achieved through methylation of the *Rb* gene promoter. In others, pRb, though synthesized in normal amounts, may be functionally inactivated by viral oncoproteins, such as the HPV E7 protein, which prevent pRb from binding and regulating E2Fs.

Table 8.2 Molecular changes in human cancers leading to deregulation of the cell cycle clock

Specific alteration	**Clinical result**
Alterations of pRb	
Inactivation of the *Rb* gene by mutation	retinoblastoma, osteosarcoma, small-cell lung carcinoma
Methylation of *Rb* gene promoter	brain tumors, diverse others

Specific alteration	**Clinical result**
Sequestration of pRb by ID1, ID2	diverse carcinomas, neuroblastoma, melanoma
Sequestration of pRb by the HPV E7 viral oncoprotein	cervical carcinoma
Alteration of cyclins	
Cyclin D1 overexpression through amplification of *cyclin D1* gene	breast carcinoma, leukemias
Cyclin D1 overexpression caused by hyperactivity of *cyclin D1* gene promoter driven by upstream mitogenic pathways	diverse tumors
Cyclin D1 overexpression caused by reduced degradation of cyclin D1 because of depressed activity of GSK-3β	diverse tumors
Cyclin D3 overexpression caused by hyperactivity of *cyclin D3* gene	hematopoietic malignancies
Cyclin E overexpression	breast carcinoma
Defective degradation of cyclin E protein from loss of hCDC4	endometrial, breast, and ovarian carcinomas

Specific alteration	**Clinical result**
Alteration of cyclin-dependent kinases	
CDC25A overexpression	breast cancers
CDK4 structural mutation	melanoma
Alteration of CDK inhibitors	
Deletion of *p15*^{INK4B} gene	diverse tumors
Deletion of *p16*^{INK4A} gene	diverse tumors
Methylation of *p16*^{INK4A} gene promoter	melanoma, diverse tumors
Decreased transcription of *p27*^{Kip1} gene because of action of Akt/PKB on Forkhead transcription factor	diverse tumors
Increased degradation of p27^{Kip1} protein because of Skp2 overexpression	breast, colorectal, and lung carcinomas, and lymphomas
Cytoplasmic localization of p27^{Kip1} protein due to Akt/PKB action	breast, esophagus, colon, thyroid carcinomas

Specific alteration	**Clinical result**
Cytoplasmic localization of $p21^{Cip1}$ protein due to Akt/PKB action	diverse tumors
Multiple concomitant alterations by Myc, N-myc, or L-myc	
Increased expression of ID1, ID2 leading to pRb sequestration	diverse tumors
Increased expression of cyclin D2 leading to pRb phosphorylation	diverse tumors
Increased expression of E2F1, E2F2, E2F3 leading to expression of cyclin E	diverse tumors
Increased expression of CDK4 leading to pRb phosphorylation	diverse tumors
Increased expression of Cul1 leading to $p27^{Kip1}$ degradation	diverse tumors
Repression of $p15^{INK4B}$ and $p21^{Cip1}$ expression allowing pRb phosphorylation	diverse tumors

Table 8.3 Alteration of the cell cycle clock in human tumors A plus sign indicates that this gene or gene product is altered in at least 10% of tumors analyzed. Alteration of gene product can include abnormal absence or overexpression. Alteration of gene can include mutation and promoter

methylation. More than one of the indicated alterations may be found in a given tumor.

Gene product or gene							
Tumor type	**Rb**	**Cyclin E1**	**Cyclin D1**	**$p16^{INK4A}$**	**$p27^{Kip1}$**	**CDK4/6**	**% of tumors with 1 or more changes**
glioblastoma	+	+		+	+	+/+	>80
mammary carcinoma	+	+	+	+	+	+/	>80
lung carcinoma	+	+	+	+	+	+/	>90
pancreatic carcinoma			[a]		+		>80
gastrointestinal carcinoma	+	+	+ [b]	+	+	+/ [c]	>80
endometrial carcinoma	+	+	+	+	+	+/	>80
bladder carcinoma	+	+	+	+	+		>70

Gene product or gene							
Tumor type	**Rb**	**Cyclin E1**	**Cyclin D1**	**p16^{INK4A}**	**p27^{Kip1}**	**CDK4/6**	**% of tumors with 1 or more changes**
leukemia	+	+	+	+ [d]	+	+/	>90
head-and-neck carcinomas	+		+	+	+	+/	>90

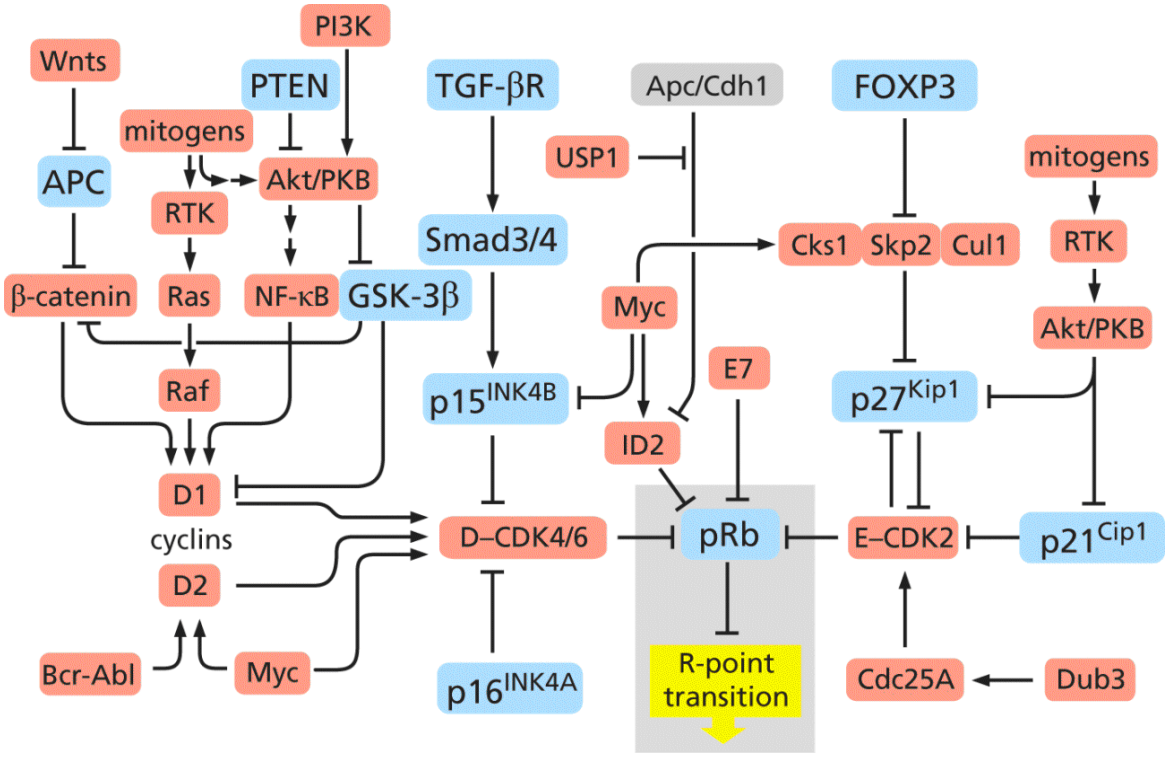
other sarcomas		+	+	+	+	/+	>90

Adapted from M. Malumbres and M. Barbacid, *Nat. Rev. Cancer* 1:222–231, 2001.

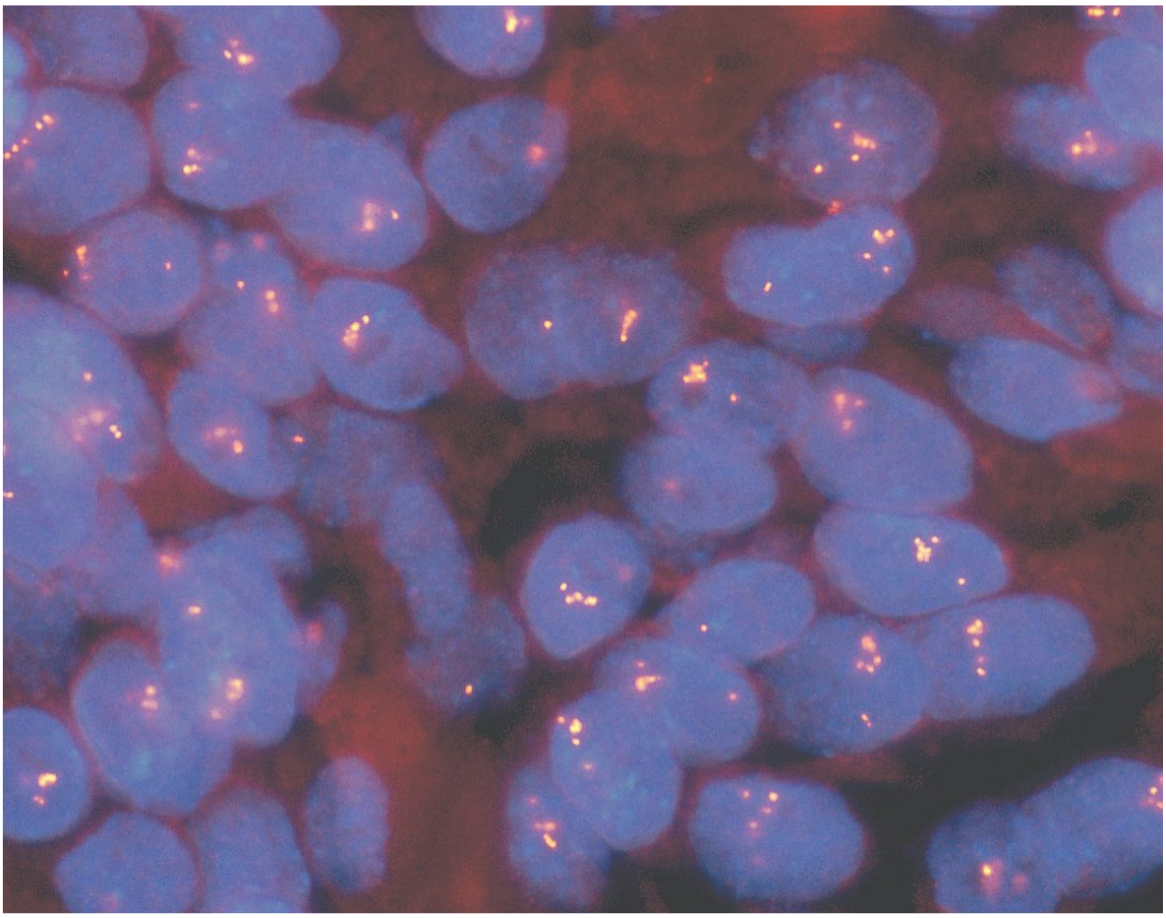


A complex network of activation and inhibition relationships among over three dozen genes and proteins. The many chains of interaction converge on D–C D K 4 slash 6, E–C D K2, and other inhibitors of p R b, which inhibits the R-point transition.

Figure 8.26 Perturbation of the R-point transition in human tumors The decision to advance through the R-point transition (*yellow, middle, bottom*) can be perturbed in a variety of ways in human tumors. Elements that favor advance through the R point are drawn in *red*, whereas those that block this advance are shown in *blue*. Almost all human tumors show either a hyperactivity of one or more of the agents favoring this advance (*red*) or an inactivation of the agents blocking this advance (*blue*). Proteins whose expression levels or activities are not known to change during the process of tumor formation are shown in *gray*.

Yet another strategy used by cancer cells to inactivate pRb function is indicated by the presence of very high levels of cyclin D1 in a variety of human tumor cells; the resulting D1–CDK4/6 complexes sequester $p27^{Kip1}$ molecules (see

Figure 8.14B), freeing E–CDK2 complexes to drive hyperphosphorylation and inactivation of pRb. This dynamic is most widely documented in breast cancer cells, in which as many as half of the tumors have been reported to show elevated levels of this G_1 cyclin. In these and other carcinomas, the overexpression is sometimes achieved by increases in the copy number of the cyclin D1 genes (that is, gene amplification; **Figure 8.27**). More frequently, however, breast cancer cells acquire excessive cyclin D1 by altering the upstream signaling pathways (see Section 8.8) that are normally responsible for controlling expression of the cyclin D1 gene.



A microscopy image showing many stained nuclei, looking like dark violet fish eggs. Within each nucleus there are clumps of bright spots, like tiny electric lights. Not all nuclei have the same number of bright spots.

Figure 8.27 Amplification of the cyclin D1 gene The use of fluorescent *in situ* hybridization (FISH) makes it possible to detect the copy number of specific genes in histological sections. Here is the result of using a probe for *CCND1*, the human gene encoding cyclin D1, to determine the copy number

of this gene in the cells of a head-and-neck squamous cell carcinoma (HNSCC). Each bright spot represents a single copy of this gene. Individual HNSCC nuclei are stained *purple*. Hence, *CCND1* is amplified to various extents here, being present in three to five copies per cell in this tumor. More generally, *CCND1* is found to be amplified in about one-third of HNSCC tumors, leading to corresponding increases in cyclin D1 expression and resulting loss of proper control of pRb phosphorylation. Similar observations (*not shown*) can be made with human breast cancer cells. (From K. Freier et al., *Cancer Res*. 61:1179–1182, 2003. With permission from American Association for Cancer Research.)

A more devious ploy is frequently exploited by cancer cells to disable the pRb machinery: they shut down expression of their $p16^{INK4A}$ tumor suppressor protein. Recall that the $p16^{INK4A}$ protein, like its $p15^{INK4B}$ cousin, inhibits the cyclin D–CDK4/6 responsible for initiating pRb phosphorylation. In the absence of the $p16^{INK4A}$ protein, pRb phosphorylation operates without an important braking mechanism, resulting in excessive cyclin D–CDK4/6 kinase activity, $p27^{Kip1}$ sequestration, pRb hyperphosphorylation, and associated inappropriate inactivation of pRb (see Figure 8.26). Individuals suffering from one form of familial melanoma inherit defective versions of the $p16^{INK4A}$ gene. It is unclear why loss of this particular CDK inhibitor, which seems to operate in all cell types throughout the body, should affect specifically the melanocytes in the skin that are the normal precursors of melanoma cells. In sporadic (that is, nonfamilial) tumors arising in various tissues, cancer cells resort far more frequently to another strategy to shed $p16^{INK4A}$ function—they methylate the CpG sequences present in the promoter of the $p16^{INK4A}$ gene (see Section 7.7), thereby shutting down transcription of this gene

Evidence of an even more cunning strategy for destabilizing this control circuit has been found in the genomes of a small number of both sporadic and familial melanomas. In these cancers, a point mutation in the CDK4 gene (the R24C mutation) creates CDK4 molecules that are no longer susceptible to inhibition by the family of INK4 molecules (that is, p15, p16, p18, and p19). Although these various CDK inhibitors may be perfectly intact and functional in such tumor cells, their normally responsive CDK4 target now eludes them. Once again, this permits CDK4, together with its cyclin D partners, to drive the initial steps of pRb phosphorylation and sequestration of $p27^{Kip1}$ (see Figure 8.14B) in a deregulated fashion, driving cells through the R point in the late G_1 phase of the cell cycle.

[Because the R24C mutation creates a dominant allele of CDK4 (at the cellular level), only one of the two copies of the gene encoding this CDK needs to be mutated in order for a cancer cell to derive proliferative benefit. Mice carrying one or two copies of this R24C allele develop a diverse variety of tumors, including those affecting mesenchymal, epithelial, and hematopoietic cell types.]

The most critical CDK inhibitor involved in cancer pathogenesis may well be $p27^{Kip1}$. As mentioned earlier, $p27^{Kip1}$ is involved largely in inhibiting the activity of cyclin E–CDK2 complexes (for example, see Figure 8.14B). As cells exit the cell cycle into the G_0 quiescent state, $p27^{Kip1}$ levels rise (see **Supplementary Sidebar 8.8**). Conversely, as cells re-enter the cell cycle and advance through its G_1 phase, the levels of free $p27^{Kip1}$ are reduced progressively throughout early and mid-G_1 through cyclin D:CDK4/6 sequestration. Beginning at the R point, $p27^{Kip1}$ levels fall precipitously by the actions of cyclin E–CDK2 complexes. In more detail, during progressive sequestration of $p27^{Kip1}$ protein by cyclin D:CDK4/6, a small number of E–CDK2 molecules are freed from the inhibitory effects of bound $p27^{Kip1}$ protein. The now-active E–CDK2 molecules can phosphorylate $p27^{Kip1}$ molecules (on their threonine 187 residue) that are still bound to E–CDK2 complexes, causing the resulting phosphoproteins to be recognized and bound by Skp2, which directs them to ubiquitylation and rapid degradation in the proteasomes. This rapidly self-amplifying regulatory loop (see Figure 8.20) results in the explosive elimination of the remaining $p27^{Kip1}$ molecules and the rapid activation of E–CDK2 complexes and pRb hyperphosphorylation. Indeed, the declining levels of Skp2 explain the observed increases in $p27^{Kip1}$ as cells enter into G_0. Interestingly, a very similarly structured complex is involved in the programmed degradation of cyclin E later on as cells pass through the G_1/S transition (see Figures 8.8 and 8.10).

The inverse relationship between $p27^{Kip1}$ levels and those of Skp2 is especially apparent in various human cancers such as mammary and oral carcinomas, as well as lymphomas (see, for example, **Supplementary Sidebar 8.8**), with higher levels of Skp2 portending shorter patient survival. Moreover, when the levels of $p27^{Kip1}$ are measured in the cells of human esophageal, breast, colorectal, and lung carcinomas, poor patient survival is correlated with low levels of this CDK inhibitor. In all of these tumors, Skp2 seems to act as a proliferation-promoting oncoprotein by forcing the degradation of the critical $p27^{Kip1}$ CDK inhibitor. One clue to the ultimate source of elevated Skp2 levels comes from research

indicating that the Notch protein (see Section 6.12), which is hyperactive in many types of human cancer, increases transcription of the gene encoding Skp2.

We have read repeatedly about the hyperactive state of the Akt/PKB kinase in many human tumors, which is caused by a variety of molecular defects, including hyperactive growth factor receptors, loss of the PTEN tumor suppressor protein, and mutations in the PI3K gene (see Section 6.6). It, too, has effects on the cell cycle clock in cancer cells by reducing the effective levels of important CDK inhibitors (see Figure 8.13). By phosphorylating $p21^{Cip1}$ and $p27^{Kip1}$, Akt/PKB ensures the cytoplasmic localization of these two critical antagonists of cell cycle advance, thereby marginalizing them. At the same time, Akt/PKB can suppress expression of the gene encoding $p27^{Kip1}$ by phosphorylating a transcription factor of the Forkhead family, which serves to further reduce the overall concentrations of $p27^{Kip1}$ in the cell. As if this were not enough, Akt/PKB ambushes $p27^{Kip1}$ in a third way: by phosphorylating Skp2, Akt/PKB activates the latter, enhancing its ability to bind $p27^{Kip1}$, resulting thereafter in the increased ubiquitylation and degradation of $p27^{Kip1}$ (see **Supplementary Sidebar 8.8**).

The diverse genetic and biochemical strategies shown in Figure 8.26 are all focused on one common goal—that of overwhelming and deregulating pRb function, thereby destroying the tight control that it normally imposes on the R-point transition. Darwinian selection, occurring in the microcosm of living tissues, favors the outgrowth of cells that, by hook or by crook, have succeeded in inactivating the critical pRb braking system and thus deregulating the R-point transition.

8.13 Synopsis and prospects

All of the physiological signals and signaling pathways affecting cell proliferation must, sooner or later, be connected in some fashion to the operations of the cell cycle clock. It represents the brain of the cell—the central signal processor that receives afferent signals from diverse sources, integrates them, and makes the final decisions concerning growth versus quiescence, and in the case of the growth-versus-quiescence decision, whether or not the exit from the active cell cycle will be reversible. Connected with the latter decision are the mechanisms governing entrance into tissue-specific differentiation programs.

The core components of the cell cycle clock are already present in clearly recognizable form in single-cell eukaryotes, including the much-studied baker's yeast, *Saccharomyces cerevisiae*. Single-cell organisms such as this one respond to a far smaller range of external signals than do metazoan cells residing within complex tissues. These simple organisms lack the hundred and more distinct types of growth factor receptors that vertebrate cells display on their surfaces, as well as other receptors, such as integrins, that our cells use to sense and control attachment to the extracellular matrix. Yeast cells also lack the growth-inhibitory receptors, such as the TGF-β receptors, that play such a critical role in the economy of mammalian tissues.

All this explains why the peripheral wiring that regulates the core cell cycle machinery of animal cells has been added relatively recently in the history of life on this planet—perhaps 600 million years ago when metazoa may first have appeared. The need to respond to a wide variety of afferent signals explains why so many distinct layers of regulation have been imposed on the core machinery. Without these additional regulators, notably the CDK inhibitors, the core machinery could not be made responsive to the diverse array of signals that impinge on individual metazoan cells and modulate their proliferation within complex tissues.

While these connections between the cell exterior and the cell cycle clock were being forged, other critical regulators became integrated into this complex circuitry. As might be anticipated, similarly constructed pRb- and E2F-like proteins are present in worms and flies, indicating their presence in early metazoans. Actually, the invention of the key governors of G_1 progression—pRb and its two cousins, p107 and p130—seems to have occurred well before the rise of metazoa: a pRb–E2F signaling pathway involved in cell cycle control is already present in flowering plants and, indeed, orthologs of these proteins can be found in *Chlamydomonas reinhardtii*, a single-cell alga that is related to the ancestors of land plants.

pRb may not have been the first of these three pocket proteins to have evolved, but during the ascendance of mammals, it surpassed the others in its ability to govern the critical decision made at the R point. These three proteins preside over various aspects of the growth-versus-quiescence decision of the cell and in this sense lie *upstream* of the cell cycle clock. At the same time, by affecting gene transcription, these proteins create a coupling between the cell cycle clock and the *downstream* circuits that must be activated in order for cells to execute the complex biochemical changes that enable them to enter into S phase. A partially unresolved question is: if pRb controls cell proliferation in many cell types throughout the body, why does germline heterozygosity at the RB locus predispose humans specifically to develop retinal tumors and osteosarcomas (**Supplementary Sidebar 8.10**)?

Some aspects of the neoplastic growth state can be explained by the workings of the cell cycle clock. We can explain the deregulated proliferation of cancer cells in terms of the operations of pRb and the molecules that control its state of phosphorylation. Without pRb at the helm, the requirement for the growth-promoting actions of oncoproteins such as Ras is greatly reduced, and cells advance through G_1 without fulfilling many of the prerequisites that normally determine whether or not passage through the R-point transition will proceed. The coupling between proliferation and blocked differentiation, still incompletely understood, seems to be traceable to the operations of pRb and to proteins such as Myc, which simultaneously drives the cell cycle clock forward through G_1 and antagonizes some of the master regulators of differentiation programs.

Perhaps surprisingly, one important aspect of the proliferative control of cells operates independently of the cell cycle clock. As we will learn in detail in Chapter 10, normal cells can replicate only a limited number of times before they lose the ability to proliferate further; cancer cells have an unlimited proliferative capacity—the phenotype of replicative immortality. The molecular devices within cells that tally the number of successive replicative generations through which a cell lineage has passed are embedded in the chromosomal DNA, and these devices do not seem to be controlled by the cyclin–CDK complexes regulating cell cycle advance.

Yet other aspects of the malignant growth program are not controlled by the cell cycle clock. Cells respond to severe, essentially irreparable genomic damage by activating their cell suicide program—apoptosis; this response does not seem to be connected directly to the cell cycle machinery. This program will be the subject of much of our discussions in the next chapter.

Many other peculiarities of the cancer cell phenotype are largely the purview of cytoplasmic oncoproteins such as Ras. Included here are phenotypes of cell motility, changes in cell shape, anchorage independence, alterations in energy metabolism, and

invasiveness. These behaviors are also not controlled by the cell cycle clock, which does its work in the nucleus.

In spite of significant alterations that the cell cycle clock suffers in cancer cells, we recognize that the effects of these changes are felt largely during the G_1 phase of the cell cycle. We can understand this by noting that the R-point transition occurring toward the end of G_1 represents a critical decision point in the life of a cell; this decision must be deregulated if cancer cells are to gain proliferative advantage. However, once a cell has moved past the R point and reached the G_1/S transition, the remaining steps of the cell cycle proceed in an essentially automatic, pre-programmed fashion. Accordingly, the S, G_2, and M phases of cancer cells, which together represent an extraordinarily complex program of biochemical and cell-biological steps, closely resemble the comparable cell cycle phases of normal cells. This similarity helps to explain an often-noted aspect of cancer cells: their growth-and-division cycles are not necessarily shorter than those of many normal cells in the body. Instead, cancer cells continue to enter into these cycles and thus continue to proliferate under conditions that would force normal cells to halt proliferation. The importance of the G_1 machinery in cancer cell proliferation is highlighted by clinical work reported in 2016 in which the Progression-Free Survival (PFS) of a class of breast cancer patients was increased from 14.5 months to 24.8 months by the addition of a CDK4/6 inhibitor to their treatment protocol.

Although the effects of deregulating the cell cycle clock are felt largely in late G_1, there are more subtle changes that extend into later phases of the cell cycle. For example, pRb–E2F1 complexes also seem to regulate the expression of genes that play key roles in organizing the complex steps of mitosis; the products of these genes contribute to chromosome condensation (during metaphase), centromere function, and general chromosomal stability. These more recent discoveries now indicate that cells that have lost pRb function suffer from chromosome instability (CIN) in addition to deregulation of the R-point transition, suggesting that in pRb-negative cells, CIN conspires with deregulation of the G_1/S transition to accelerate multi-step tumor progression. Finally, scattered research reports describe effects of TGF-β on the advance of cells through the G_2 phase of the cell cycle, indicating that, contrary to a depiction earlier in this chapter, this cytokine does not entirely lose its effects on a cell after its passage through the R point.

In addition to the critical regulators of G_1 progression and chromosomal stability, the only other components of the cell cycle clock that seem to be affected in the malignant growth state are the small cohort of proteins that serve as checkpoint controls during the G_1/S transition, during S phase, and during M phase. Their inactivation, which occurs in some cancers, is not directed toward the immediate goal of deregulating

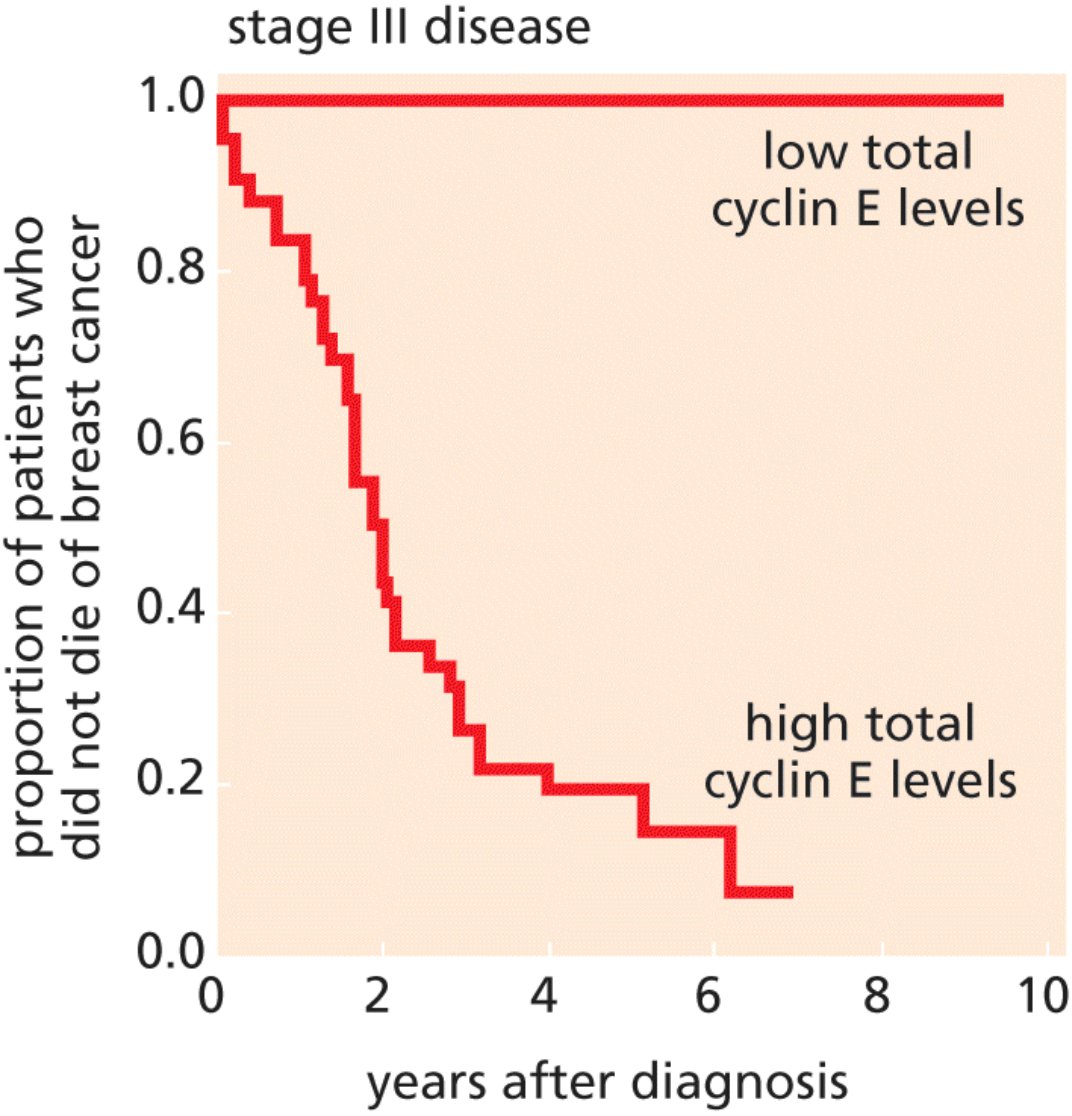
proliferation. Rather, the inactivation of these checkpoint controls serves to destabilize the cellular genome, enabling incipient cancer cells to generate a wide variety of permutations of the normal human genome. These cells and their descendants then test the resulting novel genetic configurations, searching for those that are particularly advantageous for neoplastic growth. We will return to the theme of genomic destabilization in Chapter 12.

Large gaps in this scenario remain to be filled in. We do not understand how the proliferation-versus-differentiation decision is made in most of the body's cell types. Moreover, many of the currently embraced models about the operations of the cell cycle clock, as described in this chapter, may one day require substantial revision.

For example, mutant mouse embryos that have been deprived of both copies of each of the three D-type cyclin genes (that is, with a $D1^{-/-}$ $D2^{-/-}$ $D3^{-/-}$ genotype) are able to pass through most stages of embryonic development, some dying as late as embryonic day 16 (out of the ~20 days of full-term gestation). How do the cells of these embryos succeed in advancing through many cycles of growth and division without D-type cyclins driving their advance through the G_1 phase of the cell cycle? Similarly, mouse embryos lacking both copies of each of the two cyclin E genes (that is, with an $E1^{-/-}$ $E2^{-/-}$ genotype) develop until mid-gestation, at which point they die because of placental defects; if these are circumvented, then the embryos can develop to term, whereupon they die. The existing models provide no insight into how the cells of these embryos are able to complete the last steps of the G_1 phase and initiate the S phase of the cell cycle. These startling results might suggest the operations of a normally latent cell cycle clock, possibly inherited from our protozoan ancestors, that is able to assume control when the more modern, metazoan cell cycle machinery fails to do its job.

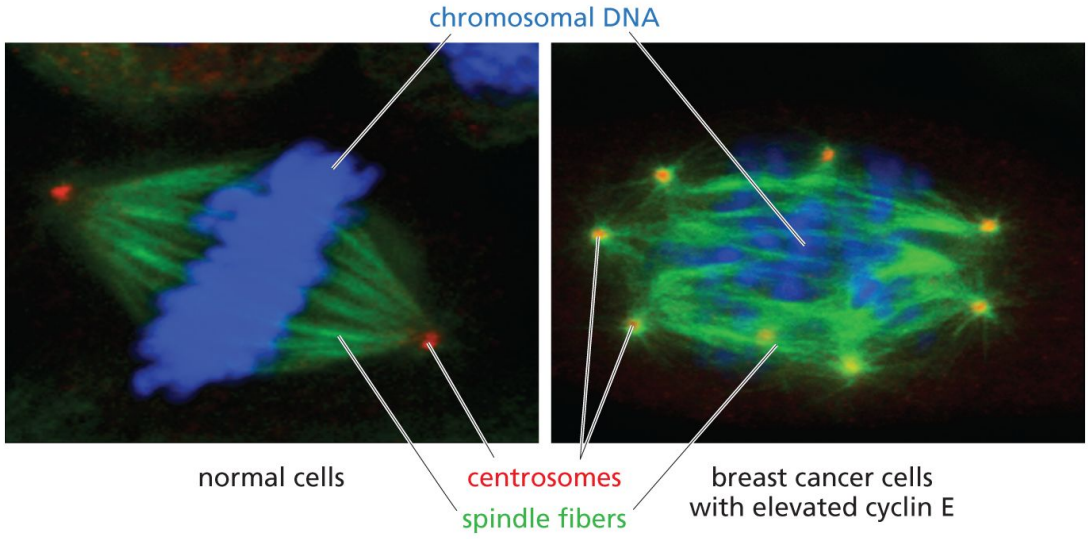
We have read about the details of cell cycle control and the various ways by which it is disrupted in many types of cancer cells, but the ultimate motivation behind these discussions is a need to understand clinical disease: How do these changes actually affect tumor progression and patient outcome? In fact, losses of pRb function can have particularly striking effects on the behavior of cancer cells and thus tumors. For example, as indicated in **Figure 8.28A**, abnormally high levels of cyclin E in the cancer cells of breast carcinoma patients are strongly predictive of aggressive malignancy and poor patient outcome, whereas low levels indicate long-term, disease-free survival. In this case, expression of the cyclin E mRNA may be elevated, and the degradative mechanisms that are normally responsible for reducing cyclin E levels are likely to be compromised. The resulting excessively high levels of cyclin E drive deregulated pRb phosphorylation and inactivation. Observations like these provide compelling indications that the cell cycle clock is, in its normal state, an important

deterrent to cancer development and, when deranged by various lesions, a potent agent for promoting cancer progression.



A graph showing the proportion, as time goes on, of Stage 3 breast-cancer patients who have not died of the disease. Low total cyclin E levels are associated with 100 percent non-mortality even out to ten years. With high total cyclin E levels, the outcomes are much worse. Half of the patients have died of the disease by the 2-year mark, and over 90 percent have died by the 6-year mark.

(A)



The effects of breast cancer on cell mitosis, seen in two contrasting fluorescence microscopy images. On the left, normal mitosis shows a band of D N A in blue with two red centromeres and two sets of green spindle fibers on either side in the usual orderly arrangement. On the right, green spindle fibers surround the blue D N A, and eight centromeres encircle the spindle fibers.

(B)

Figure 8.28 Cyclin E and breast cancer progression (A) This Kaplan–Meier plot presents the clinical progression of disease in women with stage III breast cancer, that is, those having relatively large primary tumors and cancer cells in regional lymph nodes but lacking observable metastases at distant anatomical sites. Plotted is the fraction of patients (*ordinate*) who had not died from their disease at the indicated times after initial diagnosis (*abscissa*). Total cyclin E includes both the high– and low–molecular-weight forms of this cyclin. (B) During normal mitosis, bipolar spindles are observed (*left*). However, in aggressive breast cancers, low–molecular-weight forms of cyclin E accumulate in the cytoplasm of the associated carcinoma cells, where they drive the formation of multiple extra centrosomes and resulting multipolar spindles; eight are visible here (*right*). These changes lead, in turn, to karyotypic chaos and the acceleration of tumor progression. (A, adapted from K. Keyomarsi et al., *N. Engl. J. Med.* 347:1566–1575, 2002. B, from R. Bagheri-Yarmand et al., *Cancer Res.* 70:5074–5084, 2010. With permission from American Association for Cancer Research.)

Our discussions of pRb and cell cycle control would suggest the preeminent importance of this protein among all the many products of tumor suppressor genes. In

fact, pRb shares this position with a second protein, p53, which plays an equally important role in normal cell physiology and in cancer development. In essence, the pRb circuitry deals with the relations between the cell and the outside world. The p53 circuitry has a very different function, because it monitors the *internal well-being* of the cell and permits cell proliferation and cell survival only if all the vital operating systems within the cell are functioning properly. As we will see in the next chapter, the inactivation of this p53 signaling pathway is as important to developing cancer cells as the deregulation of the controls governing pRb and the R-point transition.

Glossary

replicative immortality
: Trait of a cell or population of cells that reflects the ability of these cells and their descendants to proliferate indefinitely, usually observed in cell culture.

OceanofPDF.com

Key concepts

- The cell cycle is a precisely programmed series of events that enables a cell to duplicate its contents and to divide into two daughter cells. This series of events is controlled by the machinery that is often termed the cell cycle clock.
- Specific steps of the cell cycle are controlled by changing the levels and availability of cyclins. Cyclins function by activating the catalytic function of their partners—the cyclin-dependent kinases (CDKs), a family of serine/threonine protein kinases. Additional control of the cell cycle is provided by CDK inhibitors, which antagonize the activities of cyclin-CDK complexes.
- Although the levels of the D cyclins are controlled primarily through extracellular signals, the remaining cyclins operate on a preordained schedule, once the decision to advance into the late G_1 phase has been made; the gradual accumulation of these other cyclins followed by their rapid destruction ensures that the cell cycle clock can move in only one direction.
- Checkpoint controls operating throughout the cell cycle ensure that a new step in cell cycle progression is not undertaken before the preceding step is properly completed and that cell cycle progression cannot proceed if a cell's genome is damaged. Many types of cancer cells have inactivated one or more of these checkpoint controls, thereby allowing them to more rapidly accumulate the mutant genes and altered karyotypes that propel their neoplastic growth.
- The critical decisions concerning growth versus quiescence and entrance into post-mitotic differentiated states are made in the G_1 phase of the cell cycle. In normal cells, the decision to grow and replicate requires signals from the external environment (hence the dependence of D-cyclin levels on mitogenic signals). Thereafter, advance through the other phases of the cell cycle is relatively independent of external signals.
- The restriction point (R point) represents a point at which the cell commits itself, essentially irrevocably, to complete the remainder of

the cell cycle or, alternatively, to remain in G_1 and possibly retreat from the active cell cycle into the G_0, quiescent state. Deregulation of the R-point decision-making machinery accompanies the formation of most types of cancer cells, because it leads to unconstrained cell proliferation.

- Decisions concerning growth versus quiescence are governed by the state of phosphorylation of the three pocket proteins—pRb, p107, and p130—which in turn is controlled by the D cyclins and cyclin E. pRb, the retinoblastoma protein, controls passage through the R point. Hypophosphorylated pRb blocks passage through the R point, whereas hyperphosphorylated pRb permits this passage.
- pRb's phosphorylation is carefully controlled. Growth factors induce expression of D-type cyclins, which initiate pRb inactivation by monophosphorylating it. The resulting hypophosphorylation of pRb leaves it in a growth-inhibitory state, which appears to be a prerequisite for its hyperphosphorylation (and consequent inactivation) by cyclin E–CDK2 complexes.
- pRb acts by binding or releasing E2F transcription factors associated with promoters of genes that usher the cell from late G_1 into S phase. Hypophosphorylated pRb binds E2Fs, whereas hyperphosphorylated pRb releases them. When viral oncoproteins are present, they mimic pRb hyperphosphorylation by preventing pRB from binding and inactivating E2Fs.
- In cancer cells, a number of alternative mechanisms operate to ensure that cell proliferation is not constrained by pRb. Many of these cause pRb hyperphosphorylation and result in its functional inactivation.
- pRb function can be lost in a variety of ways, including excessive mitogenic signals (because these lead to elevated levels of D cyclins); mutation of the *Rb* gene; binding of pRb by a viral oncoprotein (for example, HPV E7); and the actions of cellular oncoproteins (for example, Myc) that deregulate pRb phosphorylation or directly affect pRb activity.
- The control of cell differentiation is coupled to the regulation of cell cycle progression. Hypophosphorylated pRB is needed to halt the proliferation of cells and to facilitate their differentiation. Conversely, other regulatory proteins, such as Myc and the IDs, work to inhibit cell differentiation.

- In most types of cancer, differentiation is partially or completely blocked. In general, the more differentiated the cells are that form a tumor, the less aggressive is the disease of cancer.

Thought questions

1. Why is pRb function compromised in human tumors through mutations of its encoding gene, whereas the genes encoding its two cousins, p107 and p130, have virtually never been found to suffer mutations in the genomes of cancer cells?
2. Why have DNA tumor viruses evolved the ability to inactivate pRb function?
3. How might loss of a CDK inhibitor's function affect the control of cell cycle advance?
4. What molecular mechanisms operate to ensure that once the decision to advance through the restriction point has been made, this leads to an essentially irreversible commitment to complete the remaining phases of the cell cycle through M phase?
5. How are the decisions of cell growth versus quiescence coupled mechanistically with the decisions governing cell differentiation? Why must these two processes be tightly coupled?
6. How do cells ensure that the transcription-activating functions of the E2F transcription factors are limited to a narrow window of time in the cell cycle? What might occur if E2F function were allowed to continue throughout the cell cycle?
7. In what ways does the Myc oncoprotein deregulate cell proliferation and differentiation?
8. Why is it important that the cell cycle clock never runs backward?
9. What kinds of experiments suggest that the cell cycle clock may be organized differently in certain cell types or stages of embryonic development?

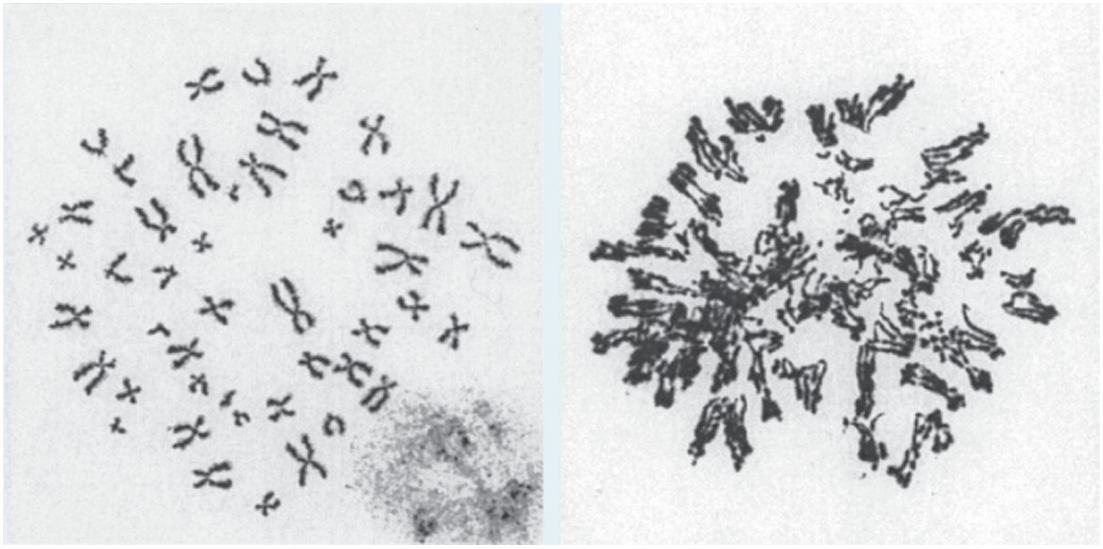
Supplementary Sidebars

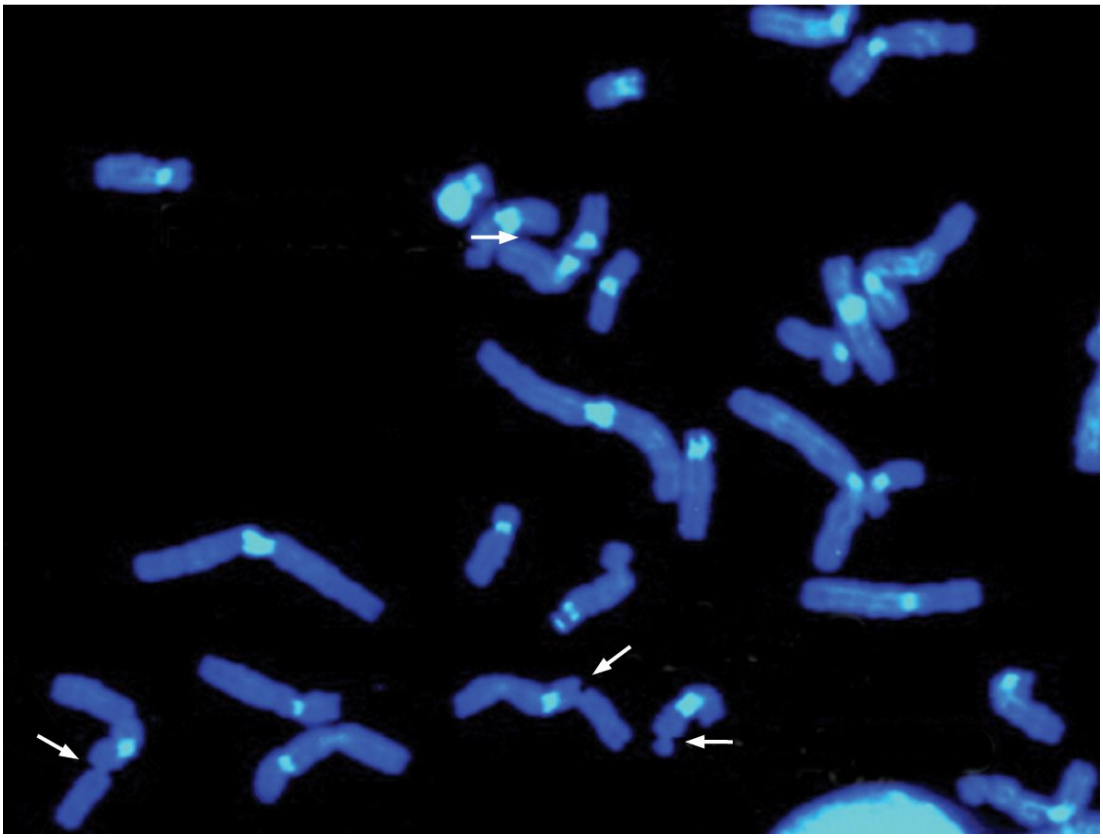
Supplementary Sidebar 8.1 Effects of breakdown of mitotic checkpoints

The checkpoint controls are imposed to ensure that (1) chromosomes replicate and segregate properly, (2) individual chromosomes remain intact, and (3) inadvertent re-replication of already-replicated DNA does not occur. These controls are often defective in cancer cells, leading to karyotypes that deviate from that seen in normal cells (**Figure S8.1**).



(A)

(B)

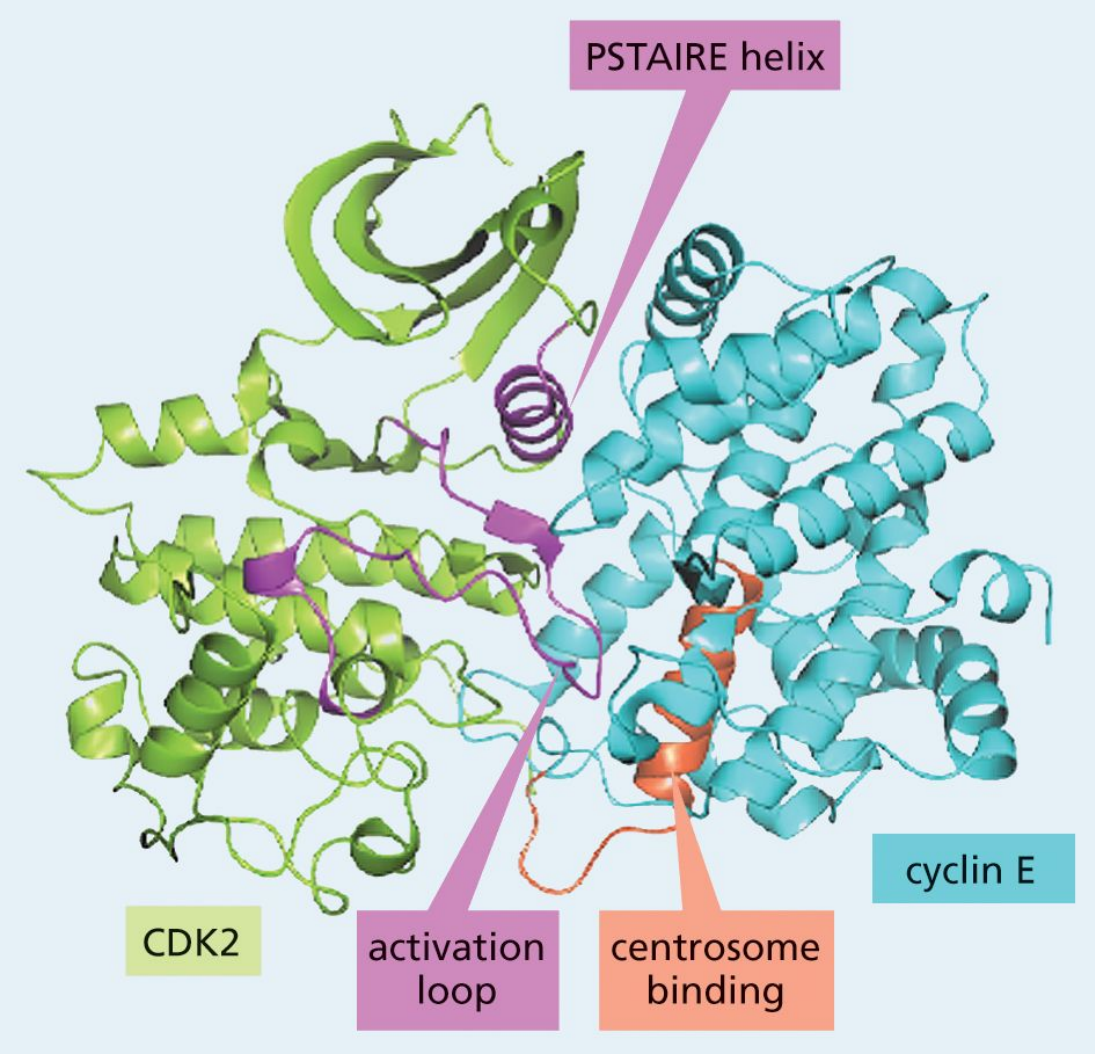


(C)

Figure S8.1 Consequences of loss of checkpoint controls Loss of critical cell cycle checkpoint control mechanisms is often manifested as an altered karyotype. (A) The normal human karyotype (*left*) is contrasted with that of a cell that has been deprived of the Rad17 checkpoint protein (*right*), which is responsible for preventing inadvertent re-replication of already-replicated chromosomal DNA, resulting in *endoreduplication* and increases in the *ploidy* of the cell. (B) The Bub1 protein normally prevents segregation of chromosomes in the event that one or more chromosomal pairs are not properly aligned on the metaphase plate. In its absence, cells gain or lose chromosomes, as seen in this spectral karyotyping (SKY) analysis, which indicates that this human cell has only one Chromosome 1 (*yellow, arrow, right*) and one Chromosome 6 (*red, arrow, left*). (Several other red-colored chromosomes are evident but can be identified as belonging to other chromosome pairs by their size and shading.) (C) The ATR (ataxia telangiectasia and Rad3 related) protein kinase is responsible for, among other functions, halting further DNA replication until stalled replication forks are repaired. In its absence, *fragile sites*—sites in the chromosome prone to breakage—become visible upon karyotypic analysis. Here, fragile sites on human Chromosomes 3 and 16 (*white arrows*) are apparent in cells lacking ATR function. (A, from X. Wang et al., *Genes Dev.* 17:965–970, 2003. Casper et al., *Am. J. Hum. Genet.* 75:654–660, 2004. With permission from Elsevier.)

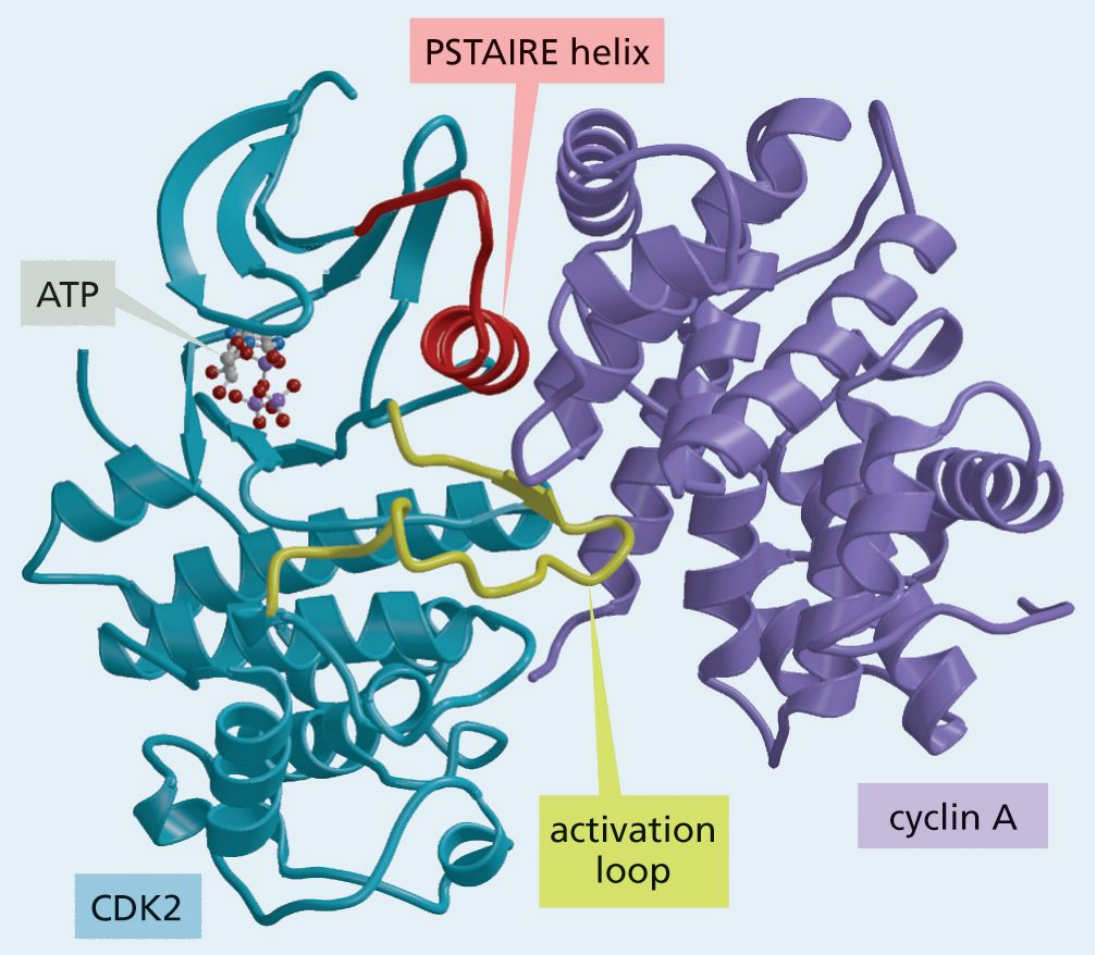
Supplementary Sidebar 8.2 Structures of cyclin:CDK complexes

The structures of cyclin-CDK complexes provides some insights into how the cyclins control the catalytic activity and substrate specificity of these complexes (**Figure S8.2**). Not shown here are corresponding complexes of D-CDK4/6 complexes that play key roles in G_1 phase progression. In fact, there is a large cohort of distinct cyclin-CDK complexes that are involved in various processes not directly connected with cell cycle control and are not described in this book because of their apparent lack of direct involvement in cancer pathogenesis.



PSTAIRE helix
cyclin E
CDK2
activation loop
centrosome binding

(A)



(B)

Figure S8.2Cyclin–CDK complexes X-ray crystallographic analyses have revealed the structures of cyclin–cyclin-dependent kinase (CDK) complexes, such as these formed by CDK2 with two of its alternative partners, cyclins A and E. In each case, the cyclin activates the CDK molecule through stereochemical shifts of the CDK catalytic site and directs the resulting activated complex to appropriate substrates for phosphorylation. (A) During the late G_1 phase of the cell cycle, cyclin E directs CDK2 to substrate proteins that must be phosphorylated in preparation for entrance into S phase. Another segment (*orange*) is involved with cyclin E's association with centrosomes. The PSTAIRE α-helix is present in all CDKs and is essential for the binding of cyclins and contributes to the catalytic site of the CDK. The activation loop, sometimes termed a T-loop, must be phosphorylated on a threonine residue by a CDK-activating kinase (CAK) in order for the catalytic function of a CDK to become activated (see also Figures S5.7B and 6.6B and C). (B) During the course of S phase, cyclin A replaces cyclin E and directs CDK2 to substrates that must be phosphorylated in order for S phase to

proceed. (A, from R. Honda et al., *EMBO J.* 24:452–463, 2005. With permission from John Wiley & Sons. B, from P.D. Jeffrey et al., *Nature* 376:313–320, 1995. With permission from Nature.)

Supplementary Sidebar 8.3 Why do mammalian cells employ three D-type cyclins?

The three D-type cyclins seem to have very similar functional powers in forming complexes with CDKs 4 and 6 in driving the monophosphorylation of pRB (see Section 8.6) and in driving the progressive sequestration of $p27^{Kip1}$ (see Figure 8.14B); the latter process appears to be the most important mechanism for determining the timing of the activation of the R point transition in late G_1. These similarities provoke the question of why mammalian cells express three apparently redundant cyclins.

One major clue comes from a description provided in Section 8.3 of their unique role: unlike all of the other cyclins associated with the cell cycle clock, the expression of D-type cyclins is controlled in large part by extracellular signals, specifically those triggering the firing of cell-surface receptors such as the tyrosine kinase-bearing growth factor receptors. The expression of the remaining cyclins is governed by intracellular signals that are intrinsic components of the cell cycle machinery and are not responsive to extracellular signals. This unique functional role positions D-type cyclins as molecular messengers that inform the cell cycle machinery about the extracellular signaling environment of the cell, specifically the incoming signals that determine whether or not a cell should proliferate in a specific tissue microenvironment.

These extracellular mitogenic signals impinge on the transcriptional promoters of the three genes encoding D-type cyclins. In fact, a diverse array of signals is experienced in various combinations by the hundreds of distinct differentiated cell types during embryonic development and adult tissue homeostasis. This demanded the development during metazoan evolution of D-type cyclins that could respond to a diversity of afferent signals impinging on a cell. What appears to be a redundancy actually offers the cell refined sensory input and enhanced flexibility of response. The promoter of each of the three encoding genes is under the control of a different set of signaling pathways and thus under the control of a different set of cell-surface receptors (**Table S8.1**). For example, the promoter of the *cyclin D1* gene (properly termed, in humans, as *CCND1*) carries sites for binding by at least six distinct transcription factors (see Figure 8.9B), which in turn are activated by a variety of growth factor receptors. In contrast, the *cyclin D2* promoter is responsive to activation by the Myc transcription factor and to extracellular signals that stimulate increases in the concentration of intracellular cyclic adenosine monophosphate (cAMP). The *cyclin D3* gene has been

found to be responsive to STAT3 and STAT5 transcription factors, and these in turn often respond to interleukin receptors active in various types of hematopoietic cells; the E2A transcription factor, which is active in programming the differentiation of lymphocytes, also controls *cyclin D3* expression. These arrangements enable a diverse set of extracellular signals to influence, often in combination, the levels of its various D-type cyclins, the activities of CDK4/6, and thus the advance of the cell cycle clock through the G_1 phase of the cell cycle.

Table S8.1 Induction of D-type cyclin expression by extracellular signals

Source of signal	**Signaling intermediaries**	**Type of cyclin**
RANK receptor	NF-κB pathway	D1
prolactin receptor	Jak/STAT	D1
estrogen receptor	AP-1 TF	D1
focal adhesion kinase		D1
HER2/Neu receptor	E2F and Sp1 TFs	D1
Wnts–Frizzled receptor	β-catenin and *TCF/LEF*	D1
Bcr/Abl		D2
FSH receptor	cyclic AMP	D2
various mitogens	Myc	D2
interleukin-4, 7 receptor		D2

Source of signal	Signaling intermediaries	Type of cyclin
interleukin-5 receptor	STAT3/5	D3
mitogens	E2A TF	D3

Abbreviations: RANK, receptor activator of NF-κB; FSH, follicle-stimulating hormone.

Supplementary Sidebar 8.4 Mitogenic signals affect cyclin D1 levels in complex ways

The mitogenic signals flowing through the Ras proteins affect cyclin D1 levels in conflicting ways. Thus, the signaling pathways operating downstream of Ras proteins (see Figure 6.9) act in countervailing ways to regulate cyclin D1 protein levels (**Figure S8.3**). The best studied of these signals flow via the Ras → Raf → MAPK pathway (see Section 6.5). For example, members of the Fos family of transcription factors, which lie at the bottom of this signaling cascade (see Table 6.1), create the heterodimeric AP-1 transcription factors by forming complexes with Jun proteins. (Individual members of both sets of proteins are capable of functioning on their own as oncoproteins.) These AP-1 complexes are known to be powerful activators of cyclin D1 gene transcription. In addition, a variety of cytoplasmic signal-transducing proteins impinge on the cyclin D1 promoter in ways that are poorly understood.

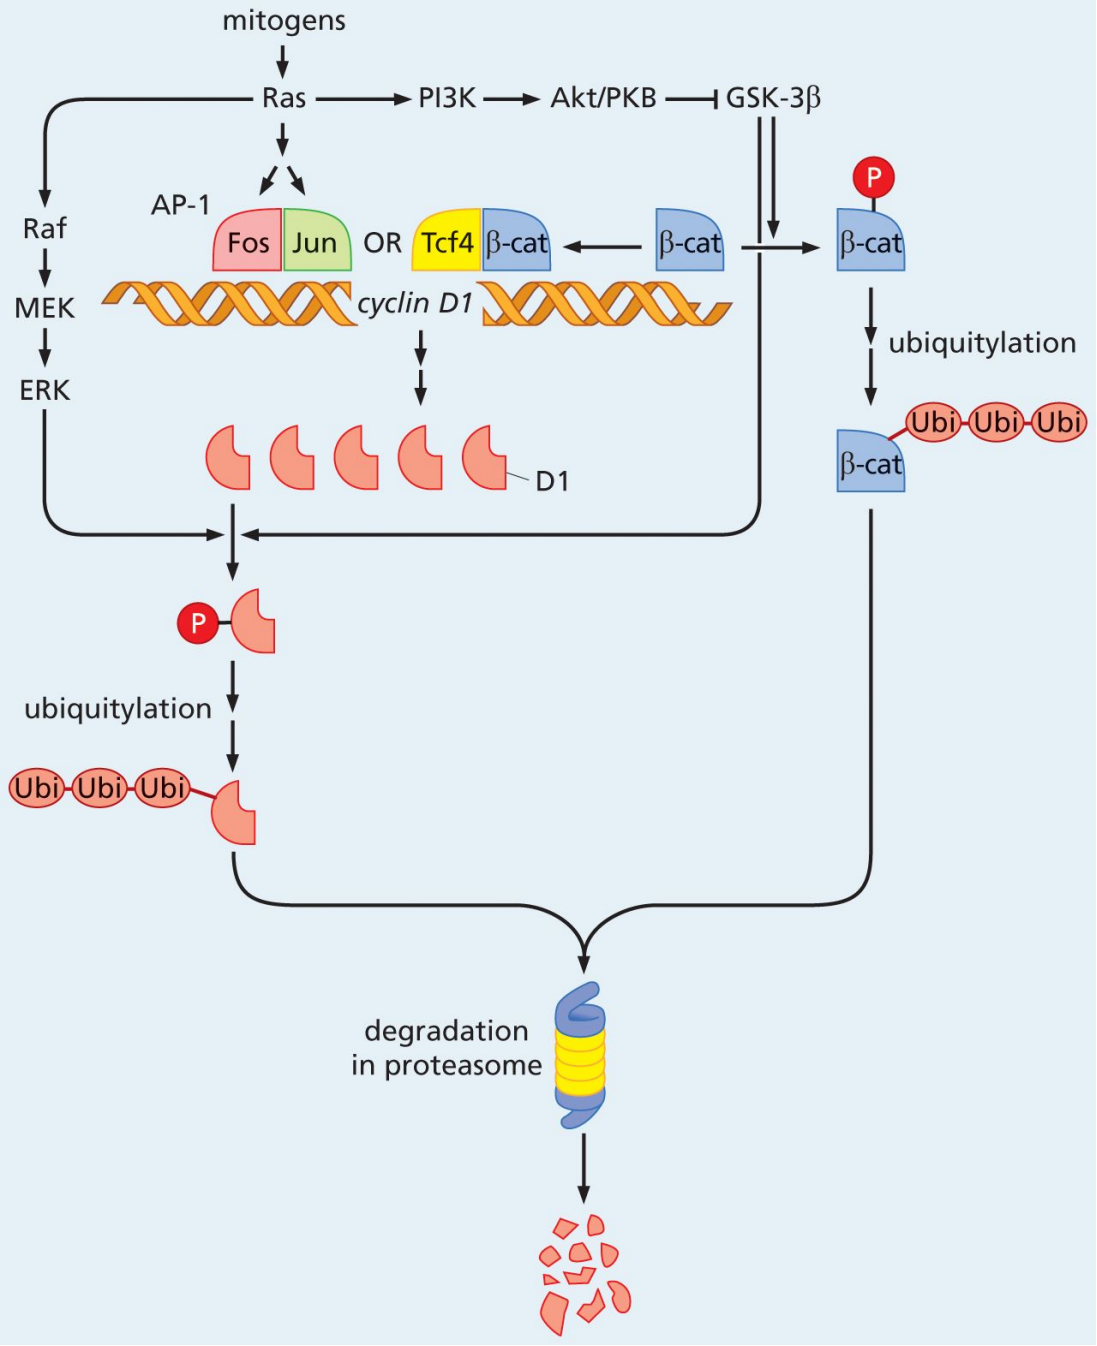


Figure S8.3 Countervailing controls on cyclin D1 levels A variety of intracellular signaling pathways transducing mitogenic signals modulate the levels of cyclin D1, doing so in at least four ways that operate downstream of the Ras proteins. First, the AP-1 transcription factor acts on the *cyclin D1* promoter, yielding increased levels of the cyclin D1 mRNA; AP-1 is composed of Fos–Jun heterodimers, both of which are increased in amount or functionally activated by mitogenic signals flowing through Ras (see Figure 8.9B). Second, by activating PI3 kinase and thus Akt/PKB, Ras proteins are able to inhibit the actions of GSK-

3β (glycogen synthase kinase-3β). This, in turn, spares β-catenin (β-cat) from phosphorylation by GSK-3β, ubiquitylation, and degradation, allowing it to partner with the Tcf4 transcription factor to induce *cyclin D1* transcription. Third, such inhibition of GSK-3β also spares the cyclin D1 protein from phosphorylation by this GSK-3β kinase and subsequent degradation following ubiquitylation. Fourth, operating in the opposing direction is ERK, which lies at the bottom of the Ras → Raf → MEK → ERK kinase cascade (see Section 6.5). Cyclin D1 is phosphorylated by ERK and thereby marked for ubiquitylation and degradation in proteasomes. Overall, Ras favors cyclin D1 accumulation, because the powers of the Ras pathway to increase cyclin D1 levels seem to greatly exceed its effects in causing cyclin D1 degradation.

Activation of the Ras signaling pathway also leads, via phosphatidylinositol 3-kinase (PI3K), to activation of the Akt/PKB kinase; the latter proceeds to phosphorylate and inactivate glycogen synthase kinase-3β (GSK-3β; see Section 6.10). This inactivation has several benefits for growth promotion. Normally, GSK-3β targets β-catenin molecules for destruction by phosphorylating them; this phosphorylation then results in the ubiquitylation of β-catenin molecules and their destruction in proteasomes. However, when GSK-3β is inactivated by PKB/Akt phosphorylation, β-catenin can accumulate and migrate to the nucleus, where it forms transcription factor complexes with TCF/LEF that stimulate production of the cyclin D1 mRNA. Because GSK-3β phosphorylation also targets the cyclin D1 protein for destruction, its inactivation further increases cyclin D1 levels. It is also possible that the Wnt growth factors (see Section 6.10), by suppressing GSK-3β activity, have similar effects on the cell cycle clock.

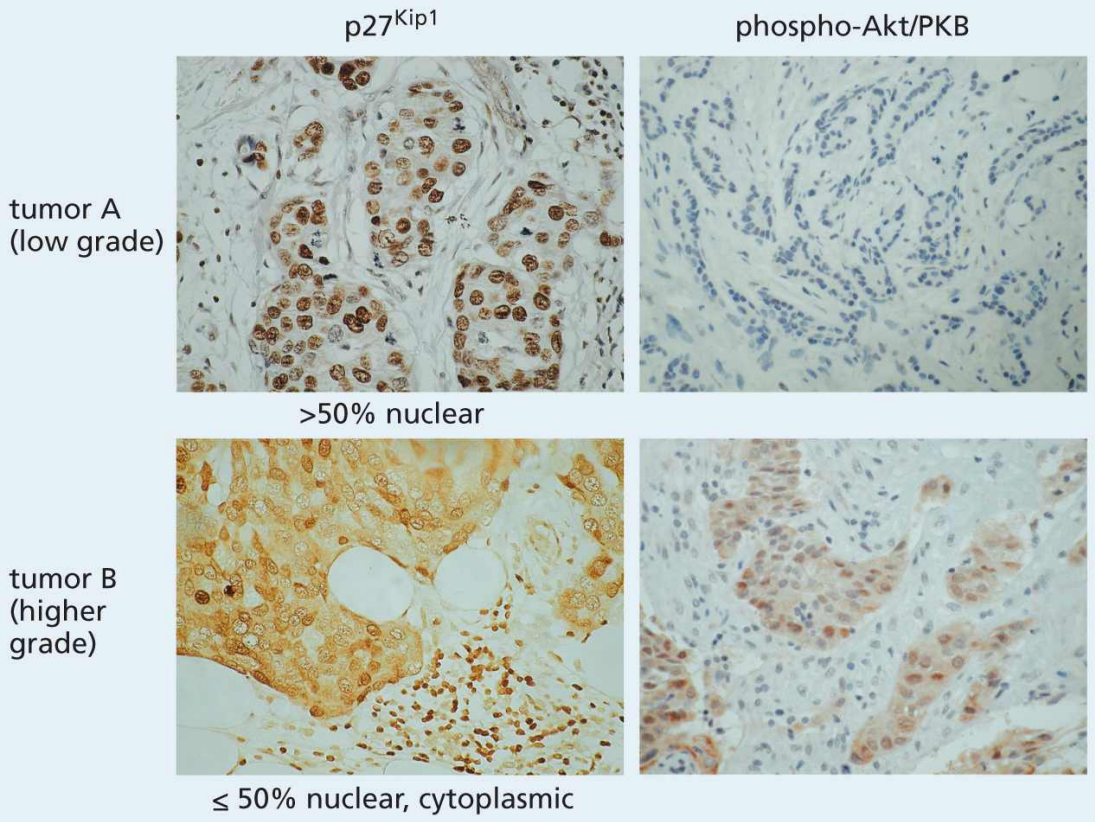
Supplementary Sidebar 8.5 Plasticity of the cell cycle clock

Although the portrayal in Section 8.3 of the normal workings of the cell cycle clock is reasonably accurate, the functions of the clock and its various cyclin–CDK complexes can be reconfigured in major ways, as indicated by experiments in which the genes encoding various component parts are inactivated, that is, knocked out, in the mouse germ-line; see Figure 7.17). For example, mice lacking either CDK 4, 6, or 2 are viable. When the genes encoding CDK4 and CDK6 are both knocked out, D-type cyclins can associate with and activate CDK2, allowing cultured cells to proliferate; mouse embryos lacking these two CDKs are viable through mid-gestation. Mice lacking CDK2 survive for two years—an essentially normal life span—but are sterile, whereas those lacking both CDK2 and CDK4 complete embryonic development but die at full term. The extreme case has come from study of embryonic stem (ES) cells; as a 2017 report demonstrated, these cells can advance through G_1 phase without any

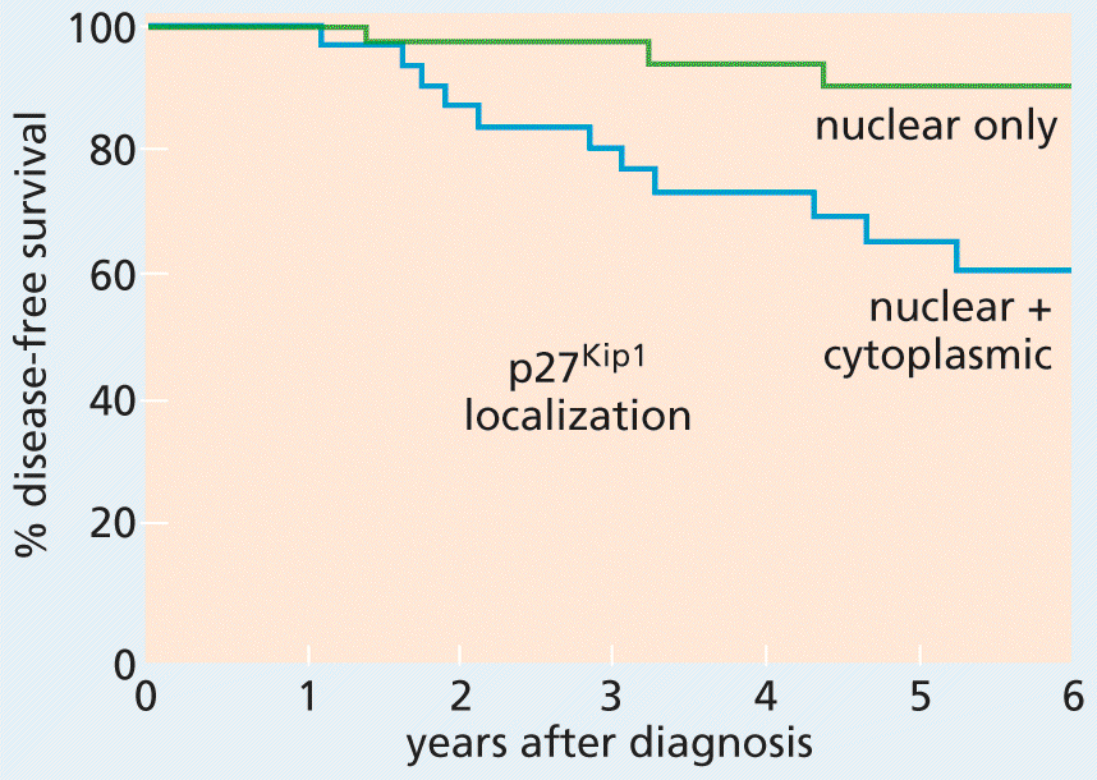
of the three D-type cyclins and two E-type (E1 and E2) cyclins. However, the moment these cells undergo differentiation into a specific adult cell type, such as fibroblasts, they require at least a single G_1 cyclin, in this case cyclin E1, in order to proliferate. Experiments like these indicate great functional redundancy and plasticity in the cell cycle machinery. Moreover, they suggest that in certain cell types and at certain stages of embryonic development, the organization of this machinery may be quite different from that depicted in this chapter.

Supplementary Sidebar 8.6 Cytoplasmic versus nuclear localization of p27

Akt/PKB (see Section 6.6) is a strongly anti-apoptotic, cell growth-promoting and proliferative agent. It favors proliferation in various ways. Thus, it can phosphorylate and inactivate GSK-3β, which in its unphosphorylated state is strongly anti-proliferative because when active it phosphorylates cyclin D1 and b-catenin, leading to the degradation of both (see Figure S8.3). At the same time, Akt/PKB reaches into the cell cycle machinery by phosphorylating $p27^{Kip1}$, which drives this key CDK inhibitor into the cytoplasm, where it can no longer exert its function in blocking G_1 phase cell cycle advance (**Figure S8.4**).



(A)



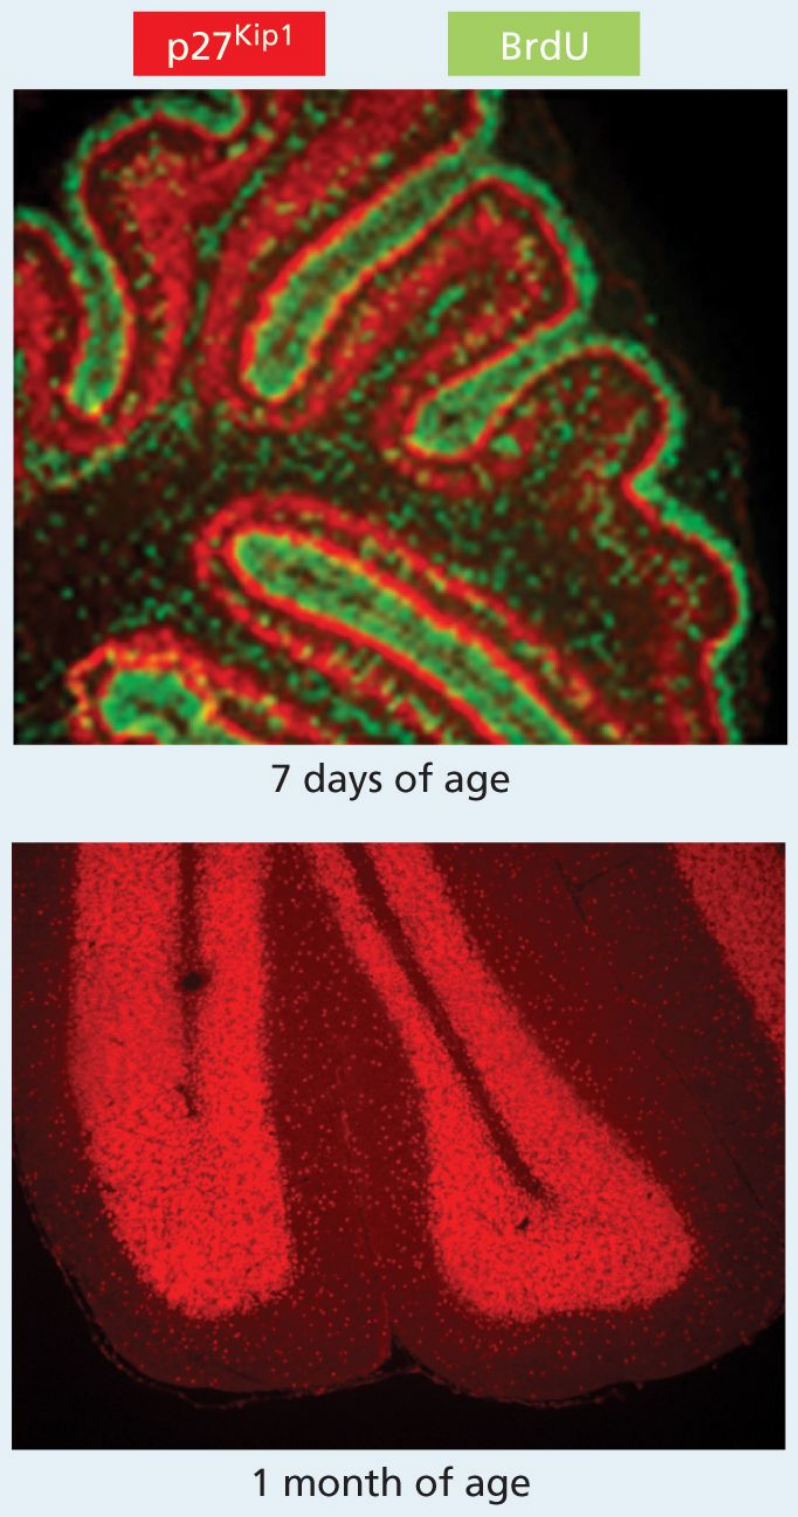
(B)

Figure S8.4 Suppression of $p27^{Kip1}$ function by Akt/PKB in human breast cancers Various breast cancers show differing intracellular locations of $p27^{Kip1}$ that reflect the activation state of Akt/PKB; the latter can be gauged by using an antibody that specifically recognizes the phosphorylated, functionally activated form of this kinase. (A) In some low-grade primary breast cancers (e.g., tumor A), $p27^{Kip1}$ is exclusively nuclear and is clearly present in more than 50% of nuclei (*brown staining, upper left*); functionally activated phospho-Akt/PKB cannot, however, be detected in these cells (*upper right*). Conversely, in higher-grade tumors (e.g., tumor B, *lower left*), $p27^{Kip1}$ is found (*yellow brown staining*) in less than 50% of the nuclei but is also found in significant quantities throughout the cytoplasm, where it cannot block cell proliferation; in these tumors, activated phospho-Akt/PKB can be readily detected (*light brown staining, lower right*). (B) This Kaplan–Meier graph indicates that those patients bearing primary breast tumors with largely nuclear $p27^{Kip1}$ (*green curve*) have a relatively good prospect of long-term, disease-free survival over a period of six years following initial diagnosis and treatment. In contrast, patients whose tumors show $p27^{Kip1}$ staining in both nuclei and cytoplasm (*blue curve*) suffer significant relapses over this time period, many of which lead to death. (Importantly, this correlation with clinical outcome does not prove causation, i.e., that $p27^{Kip1}$ mislocalization causes clinical

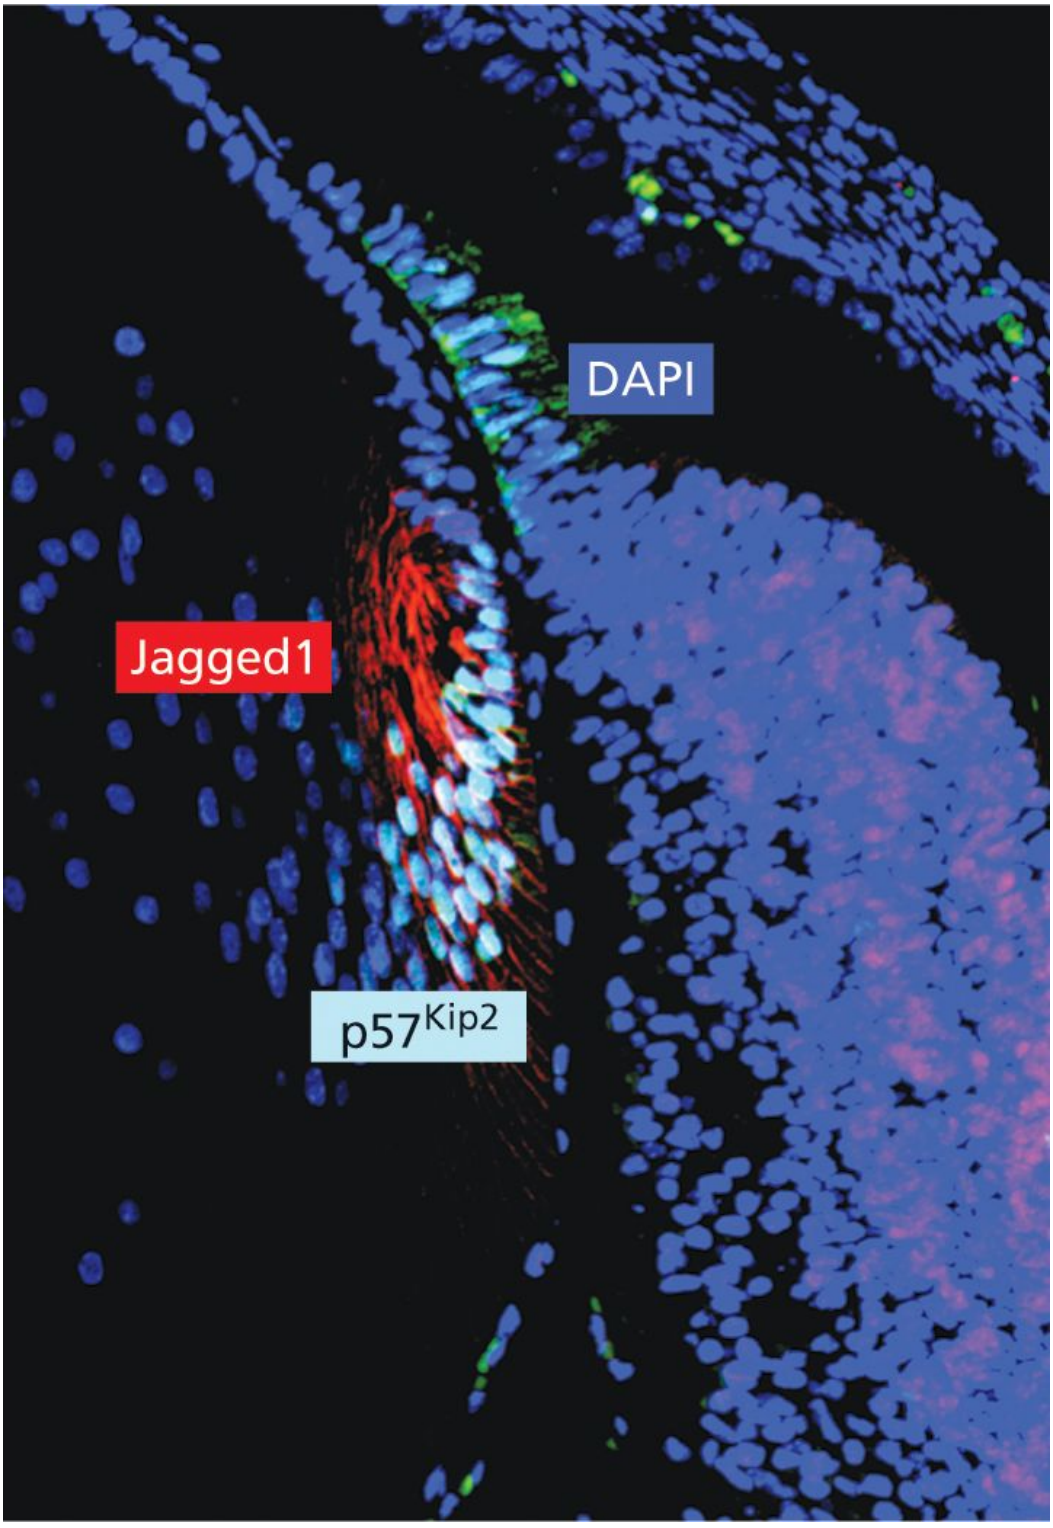
progression.) (A, courtesy of J. Zubovitz and J.M. Slingerland. B, from J. Liang et al., *Nat. Med.* 8:1153–1160, 2002. With permission from Nature.)

Supplementary Sidebar 8.7 CDK inhibitors (CKIs) help to maintain the post-mitotic states of differentiated cells

A diverse array of observations is revealing the key roles of CKIs in the differentiation process operating in various tissues, including the maintenance of the post-mitotic state of many differentiated cell types. For example, as shown in **Figure S8.5A**, in the developing cerebellum of a mouse, the cell layers that have become post-mitotic maintain high levels of $p27^{Kip1}$, whereas those that are still in active cycle lack this CDK inhibitor. Moreover, once this tissue is formed in the days after birth, the cells of this part of the brain are held in a post-mitotic state by the $p27^{Kip1}$, which they express at a high and constant level throughout adulthood. $p27^{Kip1}$ seems to play similar roles in curtailing proliferation in other tissues as well: mice deprived of both copies of its encoding gene show a ~30% increase in overall body size together with hyperplasia in multiple organs. During normal development, the expression of $p57^{Kip2}$, the cousin of $p27^{Kip1}$, is curtailed when cells need to continue proliferating for proper tissue formation to occur (Figure S8.5B).



(A)



(B)

Figure S8.5CKIs and the control of differentiation The development of tissues depends on the differentiation of embryonic cells and the imposition of post-

mitotic states by the $p27^{Kip1}$ and $p57^{Kip2}$ CKIs. (A) Much of cerebellar development in mammals occurs postnatally as cells differentiate and enter into a post-mitotic state. During the course of cerebellar development in the mouse, proliferating cells can be detected through their incorporation of bromodeoxyuridine (BrdU), a thymidine analog; they are revealed here at postnatal day 7 by immunofluorescence using an antibody that recognizes BrdU-containing DNA (*green*). The levels of $p27^{Kip1}$ have been gauged by use of a fluorescence-tagged antibody that recognizes it in the same section (*red*). As is apparent, $p27^{Kip1}$ accumulates in cells that have ceased proliferating (*above*). By one month of age, cerebellar development is complete (*below*), and the levels of $p27^{Kip1}$ (*red*) are maintained at high levels throughout adulthood, ostensibly to hold these cells in a post-mitotic state. (B) The Notch signaling pathway (see Figure 6.22B) is involved in many tissues in blocking the entrance of cells into post-mitotic differentiated states, thereby allowing such cells to continue active proliferation. In the developing ocular lens of the mouse (day 17.5 of gestation), the Notch ligand Jagged1 (*red*) induces expression of a transcriptional repressor, Herp2 (*not shown*), which in turn represses expression of $p57^{Kip2}$ (*light blue*). By suppressing $p57^{Kip2}$ expression, Jagged1, acting via a Notch receptor, can ensure that cells remain in an actively proliferating state until the developing lens grows to an appropriate size, after which $p57^{Kip2}$ expression is then permitted, allowing it to impose a post-mitotic state. Cell nuclei are revealed by the DAPI dye (*dark blue*). (A, above, from T. Uziel, F. Zindy, S. Xie et al., *Genes Dev.* 19:2656–2667, 2005; with permission from Cold Spring Harbor Laboratory Press. Below, courtesy of A. Forget, F. Zindy and M.F. Roussel, St. Jude Children's Research Hospital. B, from J. Jia et al., *Mol. Cell. Biol.* 27:7236–7247, 2007. With permission from American Society for Microbiology.)

An experimental model of muscle development is equally revealing about the connection between cell cycle progression and differentiation. Relatively undifferentiated myoblasts can be induced *in vitro* to differentiate into myocytes (muscle cells). An enforced block in the G_1 phase of the myoblast cell cycle, achieved experimentally by introducing genes encoding elevated levels of either the $p16^{INK4A}$ or the $p21^{Cip1}$ CDK inhibitor (CKI), causes the myoblasts to differentiate under conditions (for example, high levels of growth factors in the medium) in which such differentiation would otherwise not occur (see Figure 8.25B).

Supplementary Sidebar 8.8 Specific targeting of cell cycle and differentiation regulators by E3 ubiquitin ligases and de-ubiquitylating enzymes

Much of the regulation of protein function during cell cycle progression is dependent on controlling the levels of key regulatory proteins achieved by controlling their levels post-translationally; this control is achieved, in turn, by modulating the levels and activities of specific ubiquitin ligase complexes (see **Supplementary Sidebar 7.5**). The specific recognition of the protein substrate that is to be ubiquitylated is achieved by the E3 subunits of the multi-subunit ligase complex. In the case of cyclin E, its ubiquitylation and resulting degradation in proteasomes occurs at the G_1/S boundary and the beginning of S phase (see Figure 8.8). Earlier at the R point, the formation of small numbers of cyclin E–CDK2 complexes allows the phosphorylation of, among other substrates, $p27^{Kip1}$ (see Figure 8.20). This phosphorylation results in the recognition of the phosphorylated $p27^{Kip1}$ by a ubiquitin ligase complex involving the Skp2, Cks1, and Cul1 proteins (**Figure S8.6**). A very similar multi-subunit complex operates later at the G_1/S boundary (Figure S8.6D). In this case, however, the E3 subunit involved in the recognition of the cyclin E substrate contains an Fbw7 subunit.

(D)

Figure S8.6Suppression of $p27^{Kip1}$ and cyclin E levels by ubiquitin ligases
Levels of $p27^{Kip1}$and cyclin E are controlled by, among other factors, the activities of ubiquitin ligases. In the case of $p27^{Kip1}$, the Skp2 component of the ubiquitylating complex is responsible for directing the ubiquitylating machinery to $p27^{Kip1}$, thereby tagging it for degradation in proteasomes. (A) As normal human cells enter into the G_0 quiescent state, in this case because they are deprived of serum mitogens, Skp2 levels fall, allowing the accumulation of $p27^{Kip1}$; the latter, in turn, is responsible for blocking the actions of CDK2. The loss of cyclin A confirms that cells have retreated from the active cell cycle, because this cyclin is responsible for pushing cells through the late G_1 and S phases of the cell cycle. (B) After $p27^{Kip1}$ is phosphorylated by cyclin E–CDK2 (see Figure 8.20B), it is recognized and bound by a large multiprotein complex that ubiquitylates it, thereby targeting it for destruction in proteasomes. The phosphorylated domain of $p27^{Kip1}$ (*dark green*, *above*) associates with the Cks1 adaptor protein (*purple*) and the "palm" of Skp2 (*dark pink*). This complex is connected to the ubiquitylating complex via the Cul1 stalk (*green*), which holds the E2 enzyme (*right*, *light blue*) 100 angstroms away from its $p27^{Kip1}$ substrate. Covalent modifications of the Cul1 stock cause it to bend, allowing the E2 ubiquitin ligase to access its $p27^{Kip1}$ substrate. Myc fosters cell cycle progression, in part by inducing expression of Cul1, Csk1, and Skp2, which proceed to ubiquitylate $p27^{Kip1}$, thereby driving its degradation. (The UbcH7 E2 shown here is used to represent the structurally related E2 ubiquitin ligase that actually functions in this complex.) (C) The inverse relationship between Skp2 levels and those of $p27^{Kip1}$ is plotted here for a large number of oral epithelial dysplasias and carcinomas. (Similar relationships, *not shown*, are seen in lymphomas and colorectal carcinomas.) (D) A very similar multiprotein complex to the one that is assembled at the R point in order to ubiquitylate $p27^{Kip1}$ (see Panel B) operates soon thereafter at the G_1/S transition to trigger the degradation of cyclin E. As seen in the expanded image (*below*), the F-box protein Fbw7 (*red*) recognizes and binds a domain of cyclin E (*aquamarine*), driving its ubiquitylation and destruction. (The phosphorylated form of cyclin E that arises at the G_1/S boundary, *not shown*, is bound by this ubiquitylation complex.) The remainder of the Fbw7-associated complex (*lower magnification*, *above*) is composed of Skp1, Cul1, and Rbx1—precisely the same multi-subunit assembly that forms the complex driving $p27^{Kip1}$ ubiquitylation shown *above* and in Panel B. The complexes differ in their respective subunits involved in substrate recognition: the complex driving $p27^{Kip1}$ degradation contains Skp2 + Cks1 instead of the Fbw7 seen here. (A, from T. Bashir et al., *Nature* 428:190–193, 2004. B, from N. Zheng et al., *Nature* 416:703–709, 2002. Both with permission from Nature. C, from M. Gstaiger, *Proc. Natl. Acad. Sci. USA* 98:5043–5048, 2001. At the same time, the regulation of protein levels by de-ubiquitylating enzymes (DUBs) plays a critical role in key cell biological processes such as differentiation. For example, the ID proteins are known to block both differentiation and senescence, both of which are blocked when the IDs accumulate to high concentrations. The block of differentiation is achieved largely, and perhaps entirely, by their ability to associate with and inhibit various bHLH proteins that are important master regulators of specific differentiation programs (see Figure 8.25C). (The ID proteins are able to function as dominant-negative inhibitors of these bHLH TFs, because they form heterodimers with these TFs via their HLH domains. However, they lack a basic DNA-binding domain; such heterodimers block the ability of the bHLH master regulators to form stable, high-affinity associations with gene enhancers, which requires two DNA-binding bHLH TFs, usually as heterodimers, to recognize and stably bind cognate recognition sequences in the DNA.)

The ID1, ID2, and ID3 proteins are usually turned over rapidly, with half-lives estimated to be between 2 and 20 minutes, whereas the turnover of ID4 is slower, resulting in a half-life of more than an hour. Of note, the concentrations of the IDs are high in rapidly dividing tissues, and the concentrations of several of these (for example, ID2) are markedly elevated in a broad range of malignancies.

The modulation in steady-state levels of certain IDs suggests a finely tuned regulatory apparatus that governs the synthesis and degradation of the first three ID proteins. Indeed, soon after being synthesized, they usually are rapidly ubiquitylated by a complex involving an E3 ubiquitin ligase identified as APC (anaphase promoting complex)/Cdh1. Equally important are de-ubiquitylases (DUBs), which strip polyubiquitin chains from ubiquitylated proteins, such as the IDs, before these proteins are transported to proteasomes for degradation; removal of the polyubiquitin chains by DUBs spares these proteins, allowing their accumulation to higher steady-state levels. These dynamics suggest that the elevated levels of ID proteins found in many tumors may be consequences of a suppression of the ubiquitylase enzymes or an overexpression of the responsible DUB, which has been identified as USP1.

In fact, in a number of tumors, the expression of both ID2 and the USP1 DUB have been found to be coordinately up-regulated. This correlation supports the idea that the elevated levels of USP1 are responsible for the increased accumulation of ID2, a notion that has been supported by direct experimentation. This suggests that an important means of deregulating the Rb circuitry in human tumors depends on increasing levels of this DUB, which results in higher concentrations of IDs that can, in turn, antagonize Rb function.

The important role of ID proteins in blocking differentiation has been directly tested in an osteosarcoma cell line in which ID2 is overexpressed. Reducing the concentrations of the USP1 DUB (achieved through an introduced shRNA directed against its mRNA) resulted in marked reduction in ID2 levels, cessation of cell proliferation, and the osteogenic differentiation of the osteosarcoma cells into osteoblasts. This experiment reveals how critical this particular ID protein is in blocking differentiation, thereby holding the osteosarcoma cells in an actively proliferating, undifferentiated state. Moreover, one of the IDs (ID2) has been found to bind directly to pRb and antagonize its ability to halt proliferation, whereas two other IDs (ID1 and ID3) are unable to do so. This behavior suggests a scenario in which ID2 helps to block differentiation and at the same time encourages active cell proliferation.

Supplementary Sidebar 8.9 Other connections between cell cycle progression and entrance into a differentiated state

While CKIs such as $p27^{Kip1}$ and $p21^{Cip1}$ play an important role in differentiation (also see **Supplementary Sidebar 8.7**), that depends on the cellular context. For example, genetically altered mouse myoblasts that lack both *Rb* gene copies, and therefore express no pRb, are unresponsive to the differentiation-inducing influences of the introduced genes that encode $p16^{INK4A}$ and $p21^{Cip1}$. Additionally, overexpression of cyclin D1 in myoblasts (which drives pRb phosphorylation and inactivation) blocks the differentiation that is normally seen when growth factors are removed from their culture medium. These experiments indicate that hypophosphorylated pRb is needed for two ostensibly unrelated functions—halting the proliferation of myoblasts and facilitating the differentiation of these cells into myocytes.

The converging effects on differentiation of these various regulators is illustrated most dramatically by the behavior of granulocytes that have been deprived of both $p27^{Kip1}$ and Mxd: $p27^{Kip1}$ cannot be mustered to halt G_1 cell cycle progression, and the differentiation-blocking effects of Myc cannot be reversed by its prime antagonist, Mxd. The result is a profound failure of differentiation (see also Figure 8.21).

Yet other molecular connections between cell cycle control and differentiation have been uncovered. Thus, experimentally enforced expression of CDK inhibitors, such as $p21^{Cip1}$ or $p27^{Kip1}$, is able to induce differentiation of neuroblastoma cells, primary neurons (in frogs), and myelomonocytic leukemia cells, and enforced expression of E2F4 (a repressive E2F; see Section 8.7) induces the differentiation of neuronal precursor cells. Mice that are genetically deprived of this transcription factor (and thus have an $E2f4^{-/-}$ genotype) die in gestation because of defective differentiation of their erythrocytes. The C/EBPβ transcription factor associates with pRb to induce the differentiation of adipocytes (fat cells), and the CBFA1/Runx2 transcription factor has

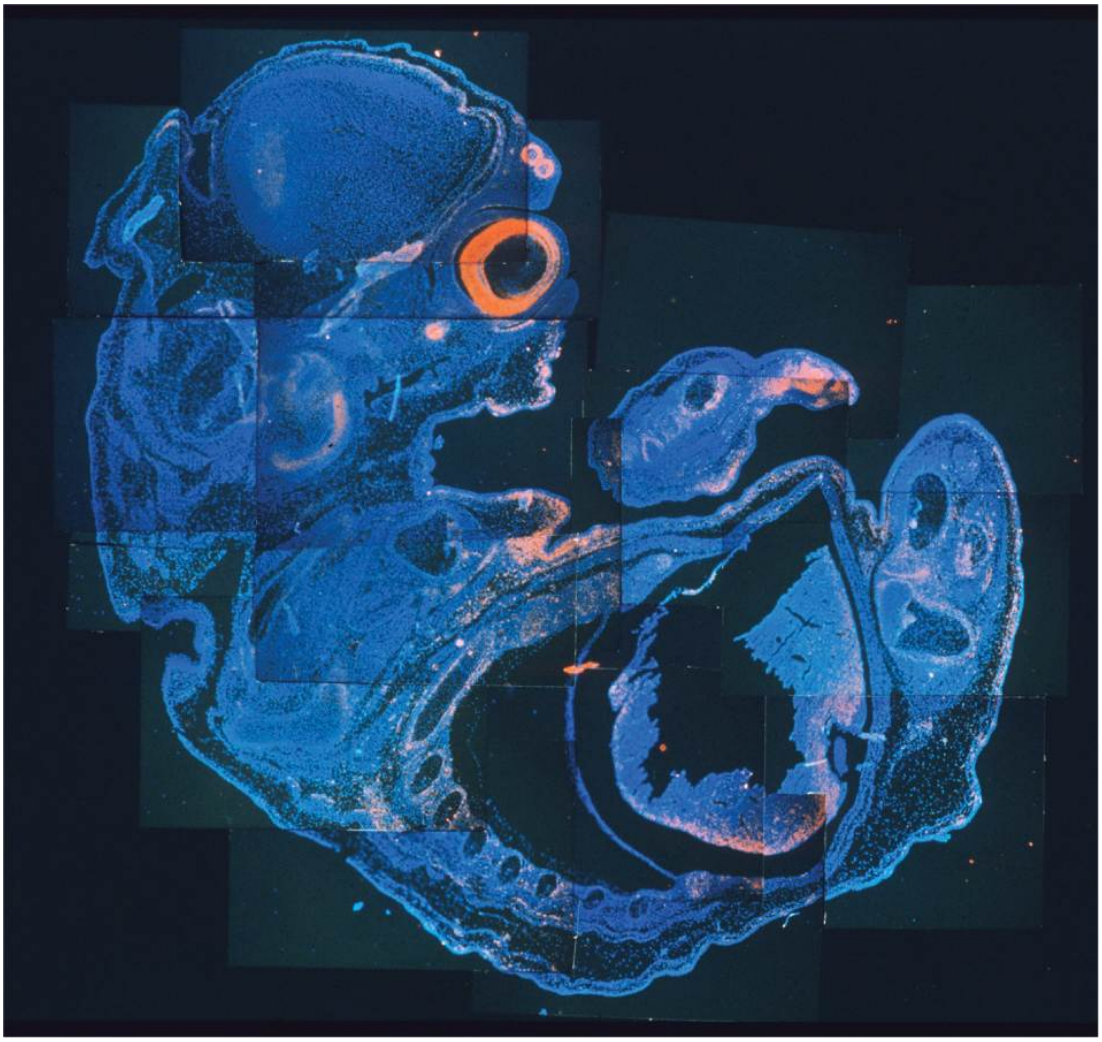
been found to bind pRb and collaborate with the latter to program osteoblast differentiation. Expression of $p27^{Kip1}$'s cousin, $p57^{Kip2}$, is important for stabilizing MyoD, a transcription factor that helps to program muscle differentiation. Finally, retinoic acid induces the differentiation of acute promyelocytic leukemia (APL) cells, in part through its ability to trigger degradation of cyclin D1.

These diverse experimental observations indicate that the machinery controlling the phosphorylation state of pRb and its cousins is also an active participant in the differentiation process, at least in the well-studied biological systems described above. More specifically, signals favoring the hyperphosphorylation (and thus functional inactivation) of the three pocket proteins (pRb, p107, and p130) operate to block differentiation, whereas those that prevent pRb hyperphosphorylation favor differentiation. This mechanistic linkage, still poorly documented for most cell types, suggests another idea that remains largely speculative: when a cell decides to leave the active cell cycle in order to differentiate, it exits the cycle sometime during the G_1 phase, precisely when pRb is active in controlling the fate of the cell.

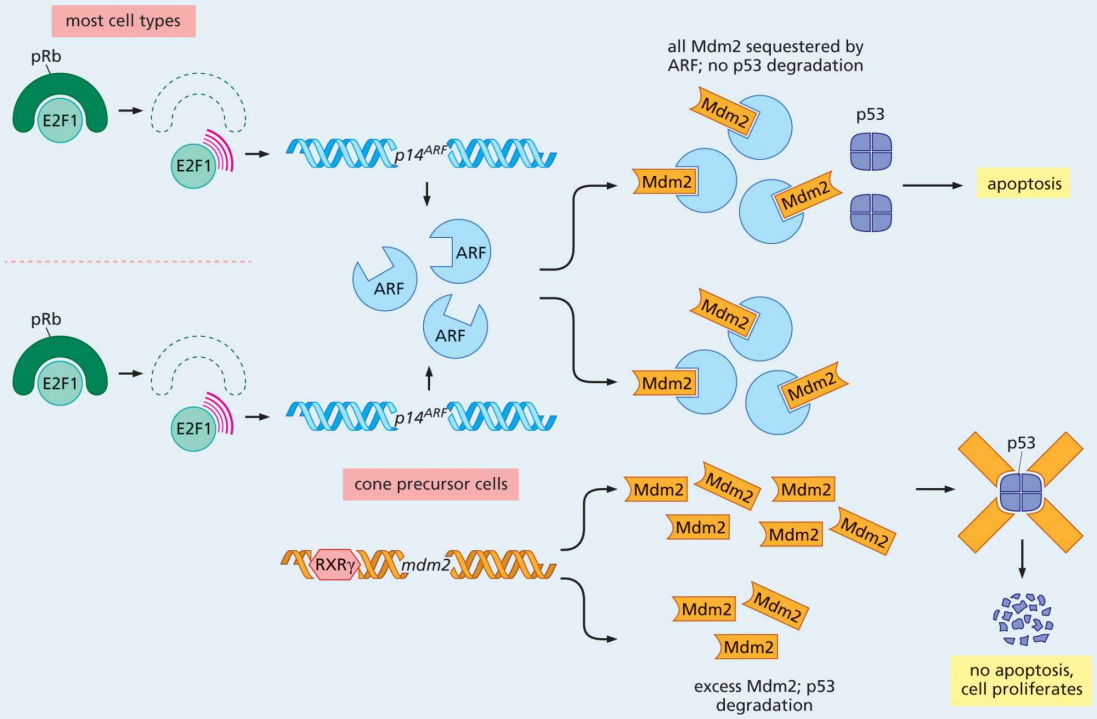
Supplementary Sidebar 8.10 The major puzzle surrounding the *RB* gene: retinoblastomas

pRb clearly plays a role in governing cell cycle progression in a wide array of cell types throughout the body, and its loss in cells early in life leads, peculiarly, to retinal tumors. The retina (see Figure 7.2A) is a relatively tiny organ compared with other tissues throughout the body. This only heightens the mystery, because the absolute numbers of cells in an organ should provide some indication of its intrinsic vulnerability to spawn tumors: tissues with large numbers of cells should be more susceptible to develop cancers, because they represent a far larger target size for the accidental triggering of a tumorigenic event. Some clues to the resolution of this puzzle have come to light in recent years, although a coherent mechanistic explanation is still lacking.

To begin, cyclin D1 is expressed at extraordinarily high levels in the developing mouse retina, as much as two orders of magnitude higher than in other organs at this stage of development (**Figure S8.7A**). Although not yet documented, it is presumed that comparable levels of high expression are present in other mammalian embryos, including those of humans. Cyclin D1 operates as a major antagonist to drive partial phosphorylation and functional inactivation of pRb (see Figure 8.17) and sequestration of the CDK2 antagonist $p27^{Kip1}$ (see Figure 8.14B); this would seem to make developing retinal cells especially dependent on the functioning of pRb in order to constrain their own proliferation.



(A)



(B)

Figure S8.7 Why does loss of pRb lead preferentially to retinal tumors? Retinoblastomas appear to arise from a cell type that is closely related to the precursors of the cone cells in the eye that give us color vision. The reason *Rb* gene inactivation leads specifically to retinal tumors in young children has been elusive, because this gene and its encoded protein are responsible for regulating cell cycle progression in many cell types throughout the body, possibly almost all of them. Multiple factors may contribute to the special sensitivity of the developing retina to pRb loss. (A) Use of *in situ* hybridization reveals that cyclin D1 mRNA (*red*) is expressed in the developing retina of a 14.5-day mouse embryo at levels that are as much as 100-fold higher than in most other organs of the embryo. (A series of *in situ* hybridizations of sections of the same embryo have been joined together to reveal the expression of the mRNA in the entire embryo.) Although not yet demonstrated directly, comparable elevated levels of expression are likely to be present in the developing retinas of other mammals, including humans. This high-level expression may, in ways that remain unclear, contribute to the special susceptibility of the retina to tumor formation in the absence of pRb function. (B) Another important contributing factor derives from the responses that many cell types throughout the body mount following inactivation of the *Rb* gene or its product, pRb. As described in Sections 9.8 and 9.9, the resulting deregulated activation of the E2F transcription factors (E2F1 is shown here) often leads to expression of $p14^{ARF}$ ($p19^{ARF}$ in mice). $p14^{ARF}$ then sequesters Mdm2,

allowing p53 to escape Mdm2-driven degradation and to accumulate to high levels and trigger apoptosis. In cone cell precursors, the first steps of this process proceed identically, i.e., *Rb* gene inactivation leads, as before, to loss of pRb and to the production of $p14^{ARF}$. However, in these cone precursor cells, a relative of the retinoic acid receptor, specifically another nuclear receptor (see Section 5.8) termed RXRγ, drives high levels of *Mdm2* transcription, leading to high concentrations of Mdm2 protein. These high levels of Mdm2 overwhelm the limited amount of available $p14^{ARF}$ in these cells, and thus succeed in triggering p53 degradation, allowing these retinal cells to evade p53-initiated apoptosis. As a consequence, *Rb* nullizygous retinal cells apparently can survive and proliferate under the influence of active E2F1, leading to retinal tumors. (A, from P. Sicinski et al., *Cell* 82:621–630, 1995. With permission from Elsevier.)

A second contributing factor appears to derive from the responses of many cells to loss of pRb function. The immediate effect is hyperactivity of the E2F1 transcription factor, which induces, in turn, expression of $p14^{ARF}$ ($p19^{ARF}$ in mice); the latter sequesters and thereby inhibits Mdm2, thus permitting high levels of p53 to accumulate (to be described in Chapter 9). Hence, loss of pRb results, through this chain of events, in increases in the pro-apoptotic p53 protein and the associated triggering of apoptosis. This response to pRb loss seems to represent a naturally implanted safeguard against cancer development, because it causes the elimination by apoptosis of cells that have, for one reason or another, been deprived of pRb function (see Figure S8.7B).

This safeguard mechanism is thwarted in retinal cells, specifically, cone precursor cells, in which Mdm2 levels are naturally very high. These Mdm2 proteins apparently succeed in suppressing p53 function, even when pRb is lost in these cells. Accordingly, such cone precursor cells, which appear to be closely related to the cells from which retinoblastomas arise, are particularly tolerant of pRb loss, because the apoptotic elimination process that operates in many cell types elsewhere in the body is rendered inoperative by the high Mdm2 levels. Following this logic, an $Rb^{+/-}$ heterozygous child may lose the remaining wild-type *Rb* gene copy in many cells throughout their body, but those cells will never spawn tumors because they are eliminated by apoptosis. Only nullizygous ($Rb^{-/-}$) retinal cells will therefore have a chance of surviving and generating tumors. (One clear exception to this rule is the bone-forming osteoblasts, which spawn the osteosarcomas that occur at greatly elevated rates in $Rb^{+/-}$ heterozygous children.)

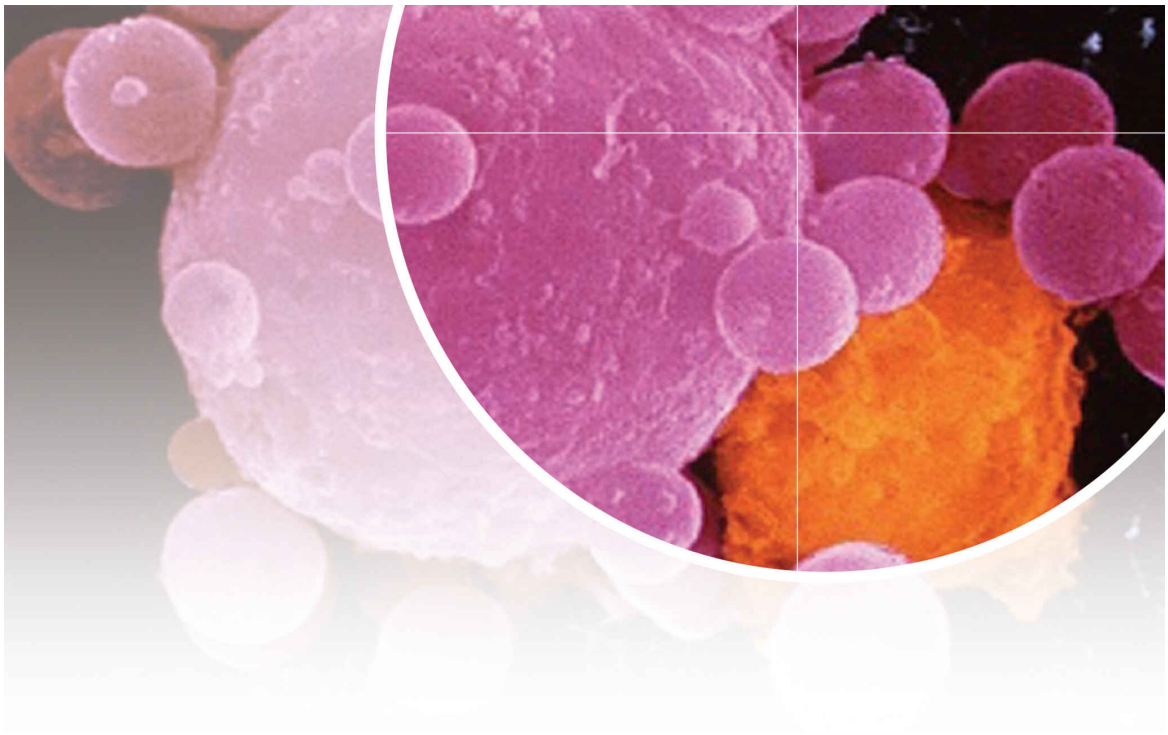
Chapter 9

p53: Master Guardian and Executioner



A scanning electron micrograph of a cytotoxic T lymphocyte attacking a cancer cell that is covered with spherical blisters.

There cannot however be the least doubt, that the higher organisms, as they are now constructed, contain within themselves the germs of death.

August Weissmann, philosopher of biology, 1889

To examine the causes of life, we must first have recourse to death.

Mary Shelley, *Frankenstein*, 1831

Multicellular animals have a vital interest in limiting the effects of defective or malfunctioning cells in their tissues. To accomplish this goal, organisms have within their cells the p53 protein. This loyal sentinel serves as a local representative of the organism's interests and is present on-site to ensure that every cell keeps its own household in order.

If p53 receives information indicating a cell is experiencing genetic corruption or metabolic disarray, the protein may arrest the progress through the cell's growth-and-division cycle and, at the same time, orchestrate localized responses to facilitate the repair of damage in that cell. In other circumstances, including situations in which damage is too extensive to be repaired, p53 can emit signals that awaken the cell's normally latent suicide program—apoptosis. The consequence of this summons is the rapid death of the cell. Such drastic measures eliminate cells whose continued growth and division might otherwise pose a threat to the overall health and viability of the organism.

The apoptotic program that can be activated by p53 is built into the control circuitry of most cells throughout the body. Apoptosis consists of a series of distinctive molecular changes that function to ensure the disappearance of all traces of a cell, often within an hour of its initial activation. The continued presence of this latent but intact suicide machinery represents an ongoing threat to incipient cancer cells, because this program is poised to eliminate cells that are en route to becoming neoplastic. The role of p53 in orchestrating cell cycle arrest, apoptosis, and a range of other functions, explains why this gene becomes disabled in a high percentage of human tumors. Without a clear description of the many functions of p53, we cannot fully appreciate the processes that limit the creation of virtually all types of human cancer.

9.1 DNA tumor viruses lead to the discovery of p53

When murine cells that have been transformed by the SV40 DNA tumor virus are injected into a mouse of identical genetic background (that is, a syngeneic host), the immune system of the host reacts by mounting a strong response. The antibodies produced react with a protein that is present in the virus-transformed cells but is otherwise undetectable in normal mouse cells. This protein, the large tumor (large T or LT) antigen, is encoded by a region of the viral genome that is also expressed when this virus infects and multiplies within monkey cells—the host cells that permit a full infectious cycle to proceed to completion, unlike infected murine cells, which do not permit this cycle to proceed but can be transformed by the virus (see Section 3.4).

Antisera collected from mice and hamsters bearing SV40-induced tumors were used in 1979 to analyze the proteins in SV40-transformed cells. The samples contained antibodies that recognized both large T and an associated protein that exhibited an apparent molecular weight of 53 to 54 kD (**Figure 9.1**). Antisera reactive with the latter, smaller protein could also detect that protein in mouse embryonal carcinoma cells and, later on, in a variety of human and rodent tumor cells—including those that had never been infected by SV40. Monoclonal antibodies directed specifically against large T could also immunoprecipitate the 53- to 54-kD protein—but only in SV40-infected cells.

An autoradiograph matrix of proteins run through a gel. On the left are four mouse fibroblast channels, namely a T and an N with S V 40 and a T and an N without S V 40. On the right are four mouse embryonal carcinoma cell channels, again a T and an N with S V 40 and a T and an N without S V 40. In the first channel, for S V 40 infected fibroblasts with T, there are visible markers at 94 k D and, more faintly, just below 54 k D. The same marker just below 54 k D is present, and more pronounced, in the two T channels for embryonal carcinoma cells.

Figure 9.1 The discovery of p53 and its association with SV40 large T Normal mouse fibroblasts (3T3 cells) and mouse embryonal carcinoma cells (F9 cells) were infected by SV40. Cell lysates prepared from both infected (SV40) and uninfected (−) cells were labeled with ^{35}S-methionine and incubated with either normal hamster serum (N) or with antiserum prepared against SV40-transformed hamster cells (T). In the virus-infected fibroblasts, the anti-tumor serum immunoprecipitated a protein of 94 kD (large T), as well as a second protein that runs slightly ahead of the 54-kD marker. This same smaller protein is immunoprecipitated from the embryonal carcinoma cells, whether or not they had been exposed to SV40 (*arrow*). Although these data, on their own, did not prove a physical association between large T and p53, they did show that p53 was present in elevated amounts in two types of transformed cells, one of which had no association with a tumor virus. (From D.I. Linzer and A.J. Levine, *Cell* 17:43–52, 1979. With permission from Elsevier.)

Taken together, these observations indicated that the large T protein expressed in SV40-transformed cells was tightly bound to a novel protein, which came to be called p53. The observation that p53 could also be detected in certain uninfected cells, such as the mouse embryonal carcinoma cells analyzed in Figure 9.1, indicated that p53 was of cellular rather than viral origin. This conclusion was reinforced by a report in the same year that mouse cells transformed by exposure to a chemical carcinogen also harbored detectable p53.

These various lines of evidence suggested that the viral large T oncoprotein functions, at least in part, by targeting host-cell proteins. (The discovery that large T antigen is also able to bind pRb would come seven years later.) In the years since these discoveries, a number of other DNA viruses and at least one RNA virus have been found to specify oncoproteins that associate with p53 or perturb its function (**Table 9.1**). As is apparent from this table, these viruses also target pRb and function to block apoptosis, an observation that we return to later in this chapter.

Table 9.1 Tumor viruses that perturb pRb, p53, and/or apoptotic function

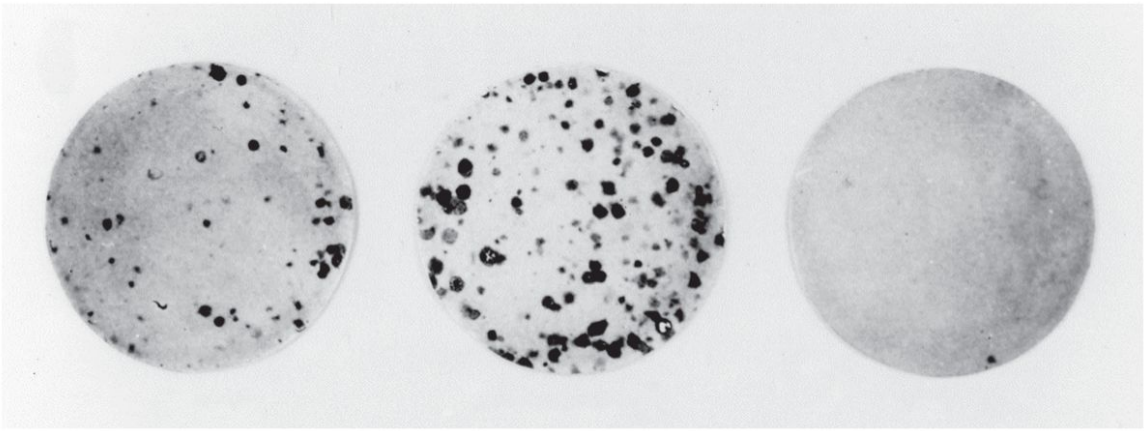
9.2*p53* is discovered to be a tumor suppressor gene

The path to our understanding of p53's function began with a substantial scientific detour: early studies in which a cDNA encoding p53 was transfected into rat embryo fibroblasts revealed that this cDNA, in collaboration with a co-introduced *ras* oncogene, could transform the rodent cells. Such activity suggested that the *p53* gene (which is sometimes termed *Trp53* in mice and *TP53* in humans) could operate as an oncogene—much like the *myc* oncogene, which had previously been shown to collaborate with the *ras* oncogene in rodent cell transformation (see Section 11.8). Like *myc*, the introduced *p53* cDNA seemed to contribute certain growth-inducing signals that resulted in cell transformation in the presence of a co-expressed *ras* oncogene.

But appearances turned out to be deceiving. As later became apparent, the *p53* cDNA used in these experiments had been synthesized from a template mRNA extracted from tumor cells (rather than normal cells). This mRNA was later shown to carry a mutant form of *p53*. Subsequent use of a *p53* cDNA cloned instead from the mRNA of normal cells revealed that this wild-type *p53* cDNA clone, rather than favoring cell transformation, actually *suppressed* it (**Figure 9.2**). Comparison of the sequences of the two cDNAs revealed that they differed by a single base substitution—a point mutation—that caused an amino acid substitution in the p53 protein.



deletion of *p53* at 37.5° + *myc* + *ras*

val-135 p53 at 37.5° (= point mutated *p53*) + *myc* + *ras*

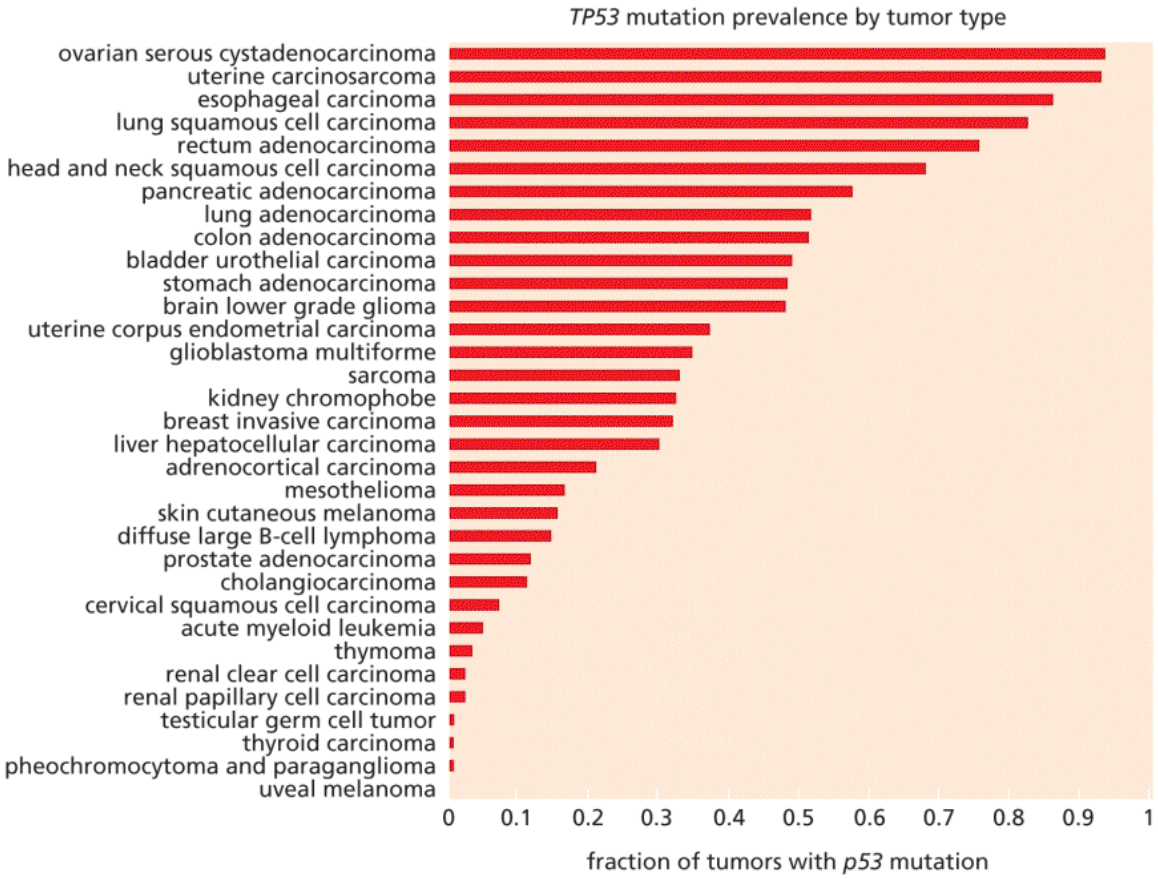
val-135 p53 at 32.5° (= wt *p53*) + *myc* + *ras*

Photos of three Petri dishes. In the first, labeled deletion of p53 at 3 7.5 degrees plus m y c plus r a s, there is a modest number of dark foci, mostly near the perimeter. In the second dish, labeled val-135 p53 at 37.5 degrees (= point mutated p53) plus m y c plus r a s, there are many dark foci. In the third dish, labeled val-135 p53 at 32.5 degrees (= w t p53) plus m y c plus r a s, there is only one dark focus, at the edge.

Figure 9.2 Effects of p53 on cell transformation A cDNA encoding a *ras* oncogene was co-transfected with several alternative forms of a *p53* cDNA into rat embryo fibroblasts. In the presence of a mutant vector that contains an almost complete deletion of the *p53* reading frame (*left*), a small number of transformed foci appeared. In the presence of a *p53* gene that carries a point mutation (*middle*), a large number of robust foci were formed, which is explained by the dominant-negative effects of the point mutant p53 protein (see Section 9.4). However, in the presence of a *p53* wild-type clone (*right*), almost no foci were formed. The experiment demonstrated that wild-type *p53* is effective at suppressing *ras*-induced transformation, whereas this mutant version appeared to facilitate transformation. (Courtesy of M. Oren; from D. Michalovitz et al., *Cell* 62:671–680, 1990. With permission from Elsevier.)

These results suggested that, in normal cells, the wild-type allele of *p53* functions to suppress cell proliferation, and that *p53* only acquires powers that promote growth when it sustains a mutation. Because of this discovery, the *p53* gene was eventually categorized as a tumor suppressor gene (TSG).

By 1987 it became apparent that *p53* alleles carrying a point mutation are common in the genomes of a wide variety of human tumor cells. Data accumulated from diverse studies indicate that the *p53* gene is mutated to varying degrees in human cancers, and may cause more than 90% of some types of cancer (**Figure 9.3**). Indeed, among all the genes examined to date in human cancer cell genomes, *p53* is the gene found to be most frequently mutated.



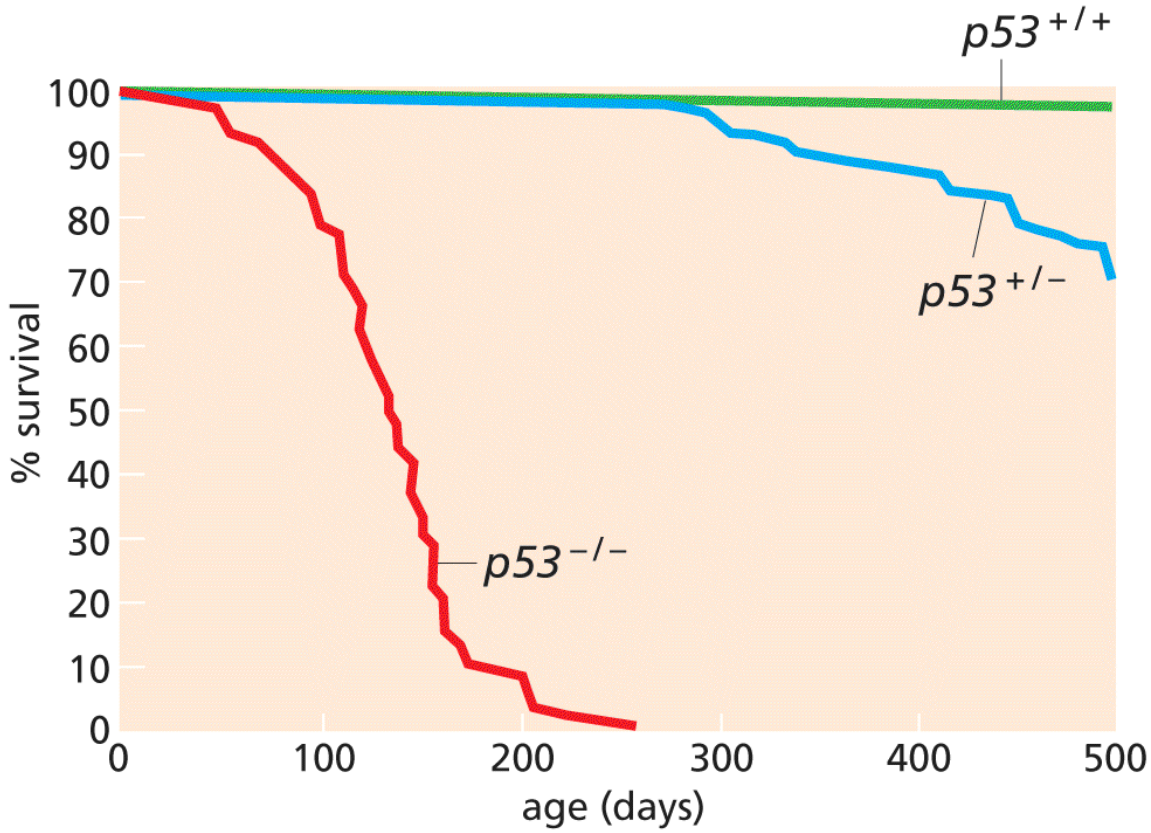
A horizontal bar graph showing the fraction of tumors with the T P 53 mutation, for different tumor types. At the upper extreme, the prevalence is above 90 percent for ovarian serous cystadenocarcinoma and uterine carcinosarcoma. At the lower extreme, the prevalence is at or near zero for testicular germ cell tumor, thyroid carcinoma, pheochromocytoma and paraganglioma, and uveal melanoma.

Figure 9.3 Frequency of mutant *p53* alleles in human tumor cell genomes As indicated in this bar graph, mutant alleles of *p53* are found frequently in human tumors. Sequences were obtained from more than 10,000 patients with 32 different cancer types. The bars indicate the percentage of each tumor type

found to carry a mutant *p53* allele. Note that greater than 90 percent of ovarian serous carcinomas and uterine carcinosarcomas carry mutant *p53* alleles. (Adapted from L. Donehower et al., *Cell Rep.* 28:1370–1384, 2019.)

Further functional analyses of *p53*, conducted much later, made it clear that *p53* is not a typical TSG. For most members of this class of cancer genes, homozygous inactivation in the mouse germ line (using the strategy of targeted gene "knockouts" described in Sidebar 7.2) causes a disruption of embryonic development caused by deregulated morphogenesis in one or more tissues. These TSGs appear to function as negative regulators of proliferation in a variety of cell types, and their removal from the regulatory circuitry of cells leads to disruption of normal development.

In stark contrast, deletion of both copies of *p53* from the mouse germ line has no significant effect on the development of the great majority of $p53^{-/-}$ embryos. Therefore, *p53* cannot be considered to be a simple negative regulator of cell proliferation during normal development. Still, *p53* is clearly a TSG, because mice lacking both germ-line copies of the *p53* gene have a short life span (about 5 months) and often die from lymphomas and sarcomas (**Figure 9.4**). This behavior provided the first hints that the p53 protein is not involved in the regulation of normal cell proliferation. Instead, p53 seemed to be specialized in preventing the appearance of abnormal cells, specifically, those that might be capable of spawning tumors.



A line graph shows the survival percentage over time of three different types of mice. Of mice with no functioning p 53 alleles, less than 30 percent remain alive after 150 days, and zero remain alive after 250 days. Of mice with one functioning p 53 allele, nearly all remain alive after 300 days and 70 percent remain alive after 500 days. Of mice with two functioning p 53 alleles, nearly all remain alive after 500 days.

Figure 9.4 Effects of mutant *p53* alleles in the mouse germ line This plot shows the survival of mice with or without functional *p53* alleles. Although the absence of p53 function in the mice carrying two *p53* null alleles ($p53^{-/-}$) had relatively little effect on their embryonic development and viability at birth, it resulted in a greatly increased mortality relatively early in life. This effect was caused by the development of cancer, particularly lymphoma. All $p53^{-/-}$ homozygotes succumbed to malignancies by about 250 days of age (*red line*), and even $p53^{+/-}$ heterozygotes (*blue line*) began to develop tumors at this time; wild-type ($p53^{+/+}$) mice (*green line*) showed virtually no mortality until almost 500 days of age. 9.3 Inherited mutations affecting *p53* predispose individuals to a variety of tumors

Inherited mutations in tumor suppressor genes underlie a number of human familial cancer syndromes (as we read in Chapter 7). And germ-line mutations in *p53* are likewise associated with significantly increased cancer risk. In 1982, a group of families was identified that displayed a greatly increased susceptibility to a variety of different tumors, including glioblastoma; leukemias; carcinomas of the breast, lung and pancreas; Wilms tumor; and soft-tissue sarcomas. In some families, as many as half of the members were afflicted with one or another of these cancers, and two-thirds developed some type of cancer by the time they reached age 22. Some family members were even afflicted with several types of cancer concurrently. This familial cancer syndrome, termed Li–Fraumeni after the two human geneticists who first identified and characterized it, was notable because of the wide range of tumor types involved (see Table 7.1).

Eight years after the Li–Fraumeni syndrome was first described, researchers discovered that many of the cases arose from a mutant allele at a locus on human Chromosome 17p13—precisely where the *p53* gene is located. In about 70% of these families, mutant alleles of *p53* were found to be transmitted in a Mendelian fashion. Individuals who inherited a single mutant *p53* allele had a high probability of developing some form of malignancy, often early in life, although the age of onset for these various malignancies was found to be quite variable: about 5 years of age for adrenocortical carcinomas, 16 years for sarcomas, 25 years for brain tumors, 37 years for breast cancer, and almost 50 years for lung cancer. In light of the multiple roles that *p53* would be discovered to play in suppressing cancer throughout the body, it seems reasonable that mutant

germ-line alleles of this gene should predispose a person to such a diverse group of malignancies.

We now know that the mutant *p53* alleles that are transmitted through the germ lines of Li–Fraumeni families carry a variety of point mutations that are scattered across the *p53* coding sequence. These germ-line mutations, which have been characterized in nearly 900 families, display a distribution reminiscent of that shown by the somatic mutations that have been documented in the genomes of more than 30,000 sporadic human tumors.

9.4 Mutant versions of *p53* interfere with normal p53 function

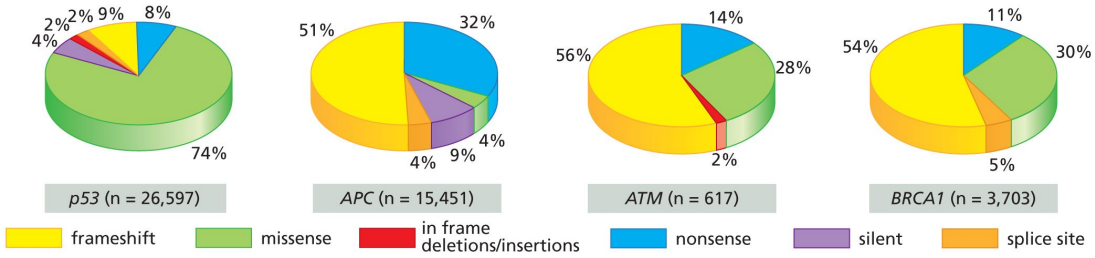
The observations of frequent mutations in the *p53* gene in familial cancer syndromes and in a large percentage of the genomes present in sporadic (nonfamilial) tumors suggested that, for many incipient cancer cells, perturbation or elimination of p53 function enhances their ability to survive. This notion raised the question of precisely how these cells succeed in shedding p53 function. Investigators researching this question encountered another puzzle: the *p53* gene did not seem to obey Knudson's hypothesis for the two-hit elimination of TSGs (see Section 7.3).

According to the Knudson scheme, an evolving premalignant cell can reap substantial benefit only after it has lost both functional copies of a TSG that has been holding back its proliferation. In the Knudson model, such loss of function is caused by mutations that create inactive—or null—alleles, which are therefore recessive. Hence, a premalignant cell that inactivates only one copy of a TSG will gain minimal benefit —due to the halving of effective gene function—or none at all, if the residual activity specified by the surviving wild-type gene copy is sufficient to mediate normal function. As we learned in Chapter 7, substantial change in cell phenotype usually occurs only when the function of a suppressor gene is eliminated through two successive inactivating mutations or through a combination of an inactivating mutation plus a loss-of-heterozygosity (LOH) event (see Section 7.4).

Knudson's model was hard to reconcile with the observed behavior of the mutant *p53* cDNA introduced into rat embryo fibroblasts (see Figure 9.2). The mutant *p53* cDNAs clearly altered cell phenotype, even though these embryo fibroblast cells continued to harbor their own pair of wild-type *p53* gene copies. This meant that the introduced mutant *p53* cDNA could not be functioning as an inactive, recessive allele. It seemed, instead, that the point-mutated *p53* allele was actively exerting some type of dominant function when introduced into these rat embryo cells.

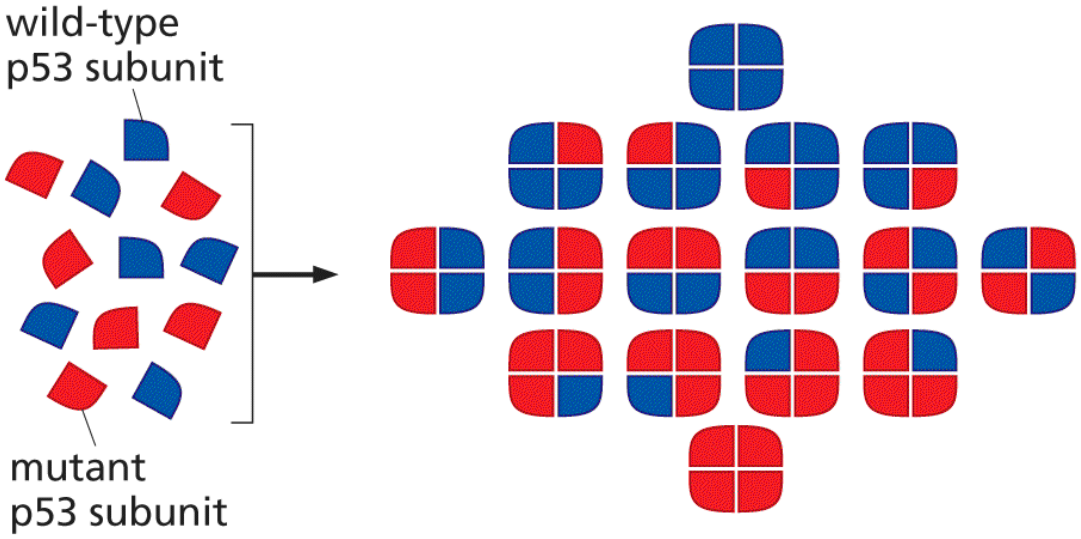
A solution to the genetic puzzle of how mutant *p53* alleles might foster tumor cell formation arose from three lines of research. First, studies in the area of yeast genetics indicated that, for certain genes, mutations can do more than compromise the normal functioning of the encoded gene product; they can confer on the mutant allele (and its protein product) the ability to interfere with or obstruct the ongoing activities of the surviving wild-type copy of the gene. Alleles that show this behavior are termed dominant-interfering or dominant-negative alleles.

A second telling clue came from analysis of the mutant alleles of the *p53* gene in cancer cells (**Figure 9.5A**). These analyses indicated that most tumor-associated, mutant *p53* alleles carry point mutations in their reading frames that create missense codons (resulting in amino acid substitutions) rather than nonsense codons (which cause premature termination of the growing polypeptide chain and, quite often, degradation of the resulting truncated protein). Furthermore, larger deletions within the coding sequence of the *p53* gene were found to be relatively uncommon. Consequently, researchers came to the inescapable conclusion that tumor cells can derive more benefit from the presence of a slightly altered p53 protein than from its complete elimination through the creation of null alleles by nonsense mutations or by the outright deletion of significant portions of the *p53* gene. These slightly altered p53 proteins—so the thinking went—could somehow function in a dominant-interfering manner to compromise the function of any wild-type p53 protein that might be present in a cell.



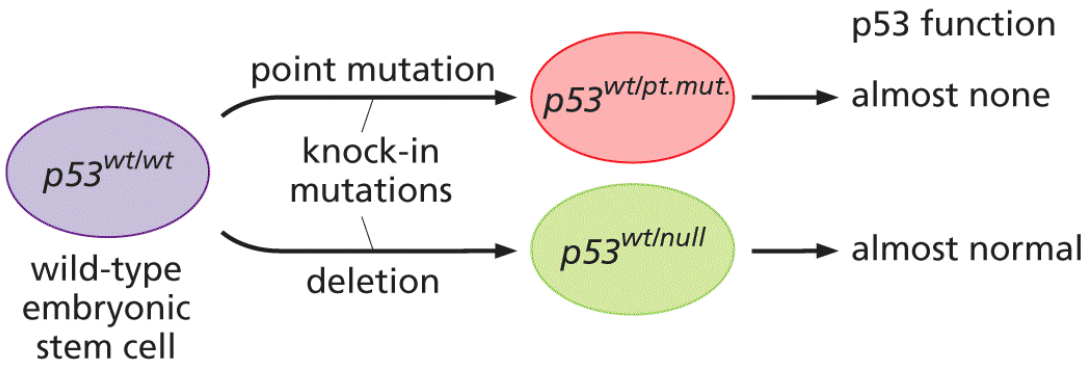
Four pie charts, each for a different gene, describing the relative frequencies of different types of mutation. Of 26,597 mutations in the p53 gene, 74 percent were found to be missense mutations. Of 15,451 mutations in the A P C gene, 51 percent were frameshift mutations and another 32 percent were nonsense mutations. Of 617 mutations in the A T M gene, 56 percent were frameshift mutations, 28 percent were missense mutations, and 14 percent were nonsense mutations. And of 3,703 mutations in the B R C A 1 gene, 54 percent were frameshift mutations, 30 percent were missense mutations, and 11 percent were nonsense mutations. In frame deletions and insertions, splice site mutations, and silent mutations each never accounted for more than 9 percent.

(A)



An illustration of the 16 different ways four p53 subunits can be assembled into a 2 by 2 block when choosing from a mix of wild-type and mutant subunits.

(B)



The effect of knock-in mutations on an embryonic stem cell that is wild-type respect to p53. When the mutation replaces one of the two wild-type gene copies with a point mutation, p53 function is almost completely lost. By contrast, when the mutation deletes one of the two wild-type gene copies, p53 function remains almost completely normal.

(C)

Figure 9.5 *p53* functions as a dominant-negative allele (A) As indicated in these pie charts, missense mutations that lead to amino acid substitutions (*green*) affect the great majority of the mutant *p53* alleles found in the 30,000 human tumor genomes analyzed here; other types of mutations are seen relatively infrequently

in *p53*. In contrast, the mutations striking other well-studied tumor suppressor genes (such as *APC*) or "caretaker" genes involved in maintenance of the genome (*ATM*, *BRCA1*) and described in Chapter 12 are more often frameshift mutations (*yellow*) or nonsense codons (*blue*); both of these types of mutation disrupt protein structure, usually by creating truncated versions of proteins that are often degraded rapidly in cells, and thus create effectively null alleles. (B) In cells bearing a single mutant *p53* and a single wild-type allele, the mutant protein usually retains its ability to form tetramers but loses its ability to function normally because of a defective DNA binding domain. Consequently, mixed tetramers composed of differing proportions of wild-type (*blue*) and mutant (*red*) p53 subunits may form, and the presence of even a single mutant protein subunit may compromise the functioning of the entire tetramer. Therefore, in a cell that is heterozygous at the *p53* locus, fifteen-sixteenths of the p53 tetramers may lack fully normal function. (C) Perhaps the most direct demonstration of the dominant-negative mode of *p53* action has come from "knocking in" (see Sidebar 7.5) mutant *p53* alleles into the genome of mouse embryonal stem (ES) cells. In cells in which a point mutation in the DNA-binding domain was knocked into one *p53* gene copy, almost all p53 function was lost. In contrast, when one *p53* gene copy was completely inactivated (yielding a null allele), p53 function was almost normal. (A, from International Agency for Research on Cancer, TP53 genetic variations in human cancer, IARC release R14, 2009; and A.I. Robles et al., *Oncogene* 21:6898–6907, 2002. With permission from Nature.)

The third and final clue to the p53 puzzle came from biochemical and structural analyses of its encoded protein, which revealed that p53 is a DNA-binding transcription factor that normally exists in the cell as a homotetramer, that is, an assembly of four identical polypeptide subunits. This observed tetrameric state suggested a plausible mechanism through which a dominant-negative mutant allele of *p53* could actively interfere with the continued functioning of a wild-type *p53* allele being expressed in the same cell.

Assume that a mutant *p53* allele found in a human cancer cell encodes a form of the p53 protein that has lost most of its normal function but has retained the ability to participate in tetramer formation (Figure 9.5B). If one such mutant allele were to coexist with a wild-type allele in this cell, the p53 tetramers assembled in such a cell would contain mixtures of mutant and wild-type proteins in various proportions. In fact, statistically speaking, if the mutant and wild-type proteins were expressed at equal levels, 15 out of the 16 equally possible combinations of mutant and wild-type p53 monomers would contain at least one mutant p53 subunit (Figure 9.5B). If the presence of even a single mutant p53 protein in a tetramer could interfere with the functioning of the complex as a whole, these mixed tetramers might therefore lack some or all of the activity associated with their fully wild-type counterpart.

Consequently, only one-sixteenth of the p53 tetramers assembled in a heterozygous cell (which carries one mutant and one wild-type *p53* gene copy) would be formed purely from wild-type p53 subunits and thus retain full wild-type function. This scheme would also explain why slightly altered versions of p53 were far more effective in driving cancer progression than the absence of p53 protein, that is, the state in which mutant null alleles of *p53* arose in the genome of an evolving, pre-neoplastic cell. Experiments in genetically altered embryonic stem (ES) cells have since provided direct evidence for p53's dominant-negative mode of action (Figure 9.5C).

In an experimental situation in which a mutant *p53* cDNA clone is introduced via an engineered expression vector into cells carrying a pair of wild-type *p53* alleles (see Figure 9.2), the expression of this introduced allele is usually greater than that of the native *p53* gene copies. As a consequence, in such transfected cells, the amount of mutant p53 protein present will be vastly higher than the amount of wild-type protein. Hence, far fewer than one-sixteenth of the p53 tetramers in such cells will be formed purely from wild-type p53 subunits. The relative abundance of the mutant p53 protein explains how introducing a mutant *p53* allele might compromise virtually all p53 function in such cells.

The above logic suggests that many incipient human tumor cells would benefit from carrying one wild-type and one co-existing mutant *p53* allele. However, in most human tumor cells that are mutant at the *p53* locus, a subsequent LOH event eliminates the wild-type allele, producing a cell with either two mutant *p53* alleles or only one allele that is mutant. Again, this observation at first seems puzzling. If a mutation that creates a dominant-negative allele can eliminate much of a cell's p53 function (see Figure 9.5B), why should the loss of the surviving wild-type *p53* allele be necessary? The answer, it seems, is that even a fraction of fully normal *p53* gene function is disadvantageous to a cancer cell. So, the most opportunistic cancers eventually evolve to shed the remaining wild-type *p53* allele.

In addition, many experiments demonstrate that point-mutant p53 proteins can also display a "gain-of-function" activity that contributes to tumorigenesis, doing so in the absence of wild-type p53 (**Sidebar 9.1**). This behavior, on its own, indicates that mutant p53 interacts with a variety of other nuclear proteins beyond wild-type p53 subunits and in various ways perturbs their function. Of additional interest are the sites of *p53*-associated point mutations. As seen in **Figure 9.6A**, almost all of them affect the DNA-binding site of p53, preventing this protein from participating in its normal function as a transcriptional regulator (Figure 9.6B), which in turn holds strong implications for how p53 functions in more than half of human cancers.

Sidebar 9.1 Missense mutant p53 proteins can display gain-of-function activities

As discussed in Section 9.4, most mutant *p53* alleles found in human cancers carry missense mutations that result in an amino acid substitution in the protein. These missense mutant p53 proteins act in a dominant-negative fashion by forming nonfunctional mixed tetramers with wild-type p53 (see Figure 9.5B). This association allows for the mutation of a single *p53* allele to largely abrogate cellular p53 function.

In addition to this dominant-negative activity, many missense p53 mutants have also been shown to actively *promote* cellular transformation in culture or tumor progression in mouse cancer models, even in the absence of wild-type p53. These so-called dominant gain-of-function (or neomorphic) activities cannot be ascribed to an inhibition of normal p53 function, because they can manifest their effects when the wild-type protein is absent. Instead, it is thought that missense mutant p53 proteins can interact with other cellular proteins and alter their function in a manner that promotes transformation and tumorigenesis. For example, point-mutant p53 proteins have been shown to selectively engage with, and inhibit the activities of, the p53-related proteins p63 and p73 (see Sidebar 9.5). A number of pathways involved in mitogenic signaling, transcription, and metabolism have also been shown to be affected by the expression of missense p53 proteins, and multiple additional cellular proteins have been implicated as specific binding partners of mutant p53 to mediate these effects.

Making matters more complex is that it is likely that different missense mutations in p53 affect the formation of these aberrant protein–protein interactions differently and thus have distinct gain-of-function activities. Moreover, different tumor types may be more or less sensitive to these effects: for some cancers, the dominant-negative activity may be the *raison d'etre* behind the selection for the missense mutant *p53* allele, whereas for other cancers, a combination of dominant-negative and gain-of-function activities might be more advantageous. Ironically, as discussed early in this chapter, *p53* was initially classified as an oncogene rather than a TSG based on the inadvertent use of a point-mutant *p53* allele in early co-transfection assays (see Section 9.2). Given that these missense alleles can also have gain-of-function activity, perhaps the proper classification of *p53* should be that it is both an oncogene and a TSG!

OceanofPDF.com

Glossary

sporadic
: Describing a disease or condition that appears to occur randomly in a large population without any apparent inborn predisposition.

dominant-interfering
: Referring to a mutant allele of a gene that, when co-expressed with the wild-type allele of the gene, is able to interfere with the functioning of the latter. *Also termed* **dominant-negative**.

dominant-negative
: Referring to a mutant allele of a gene that, when co-expressed with the wild-type allele of the gene, is able to interfere with the functioning of the latter. *Also termed* **dominant-interfering**.

null allele
: An allele of a gene that lacks all normal functions of the gene. *See also* **hypomorphic**.

homotetramer
: An assembly of four identical subunits, usually referring to proteins.

neomorphic
: Referring to a mutation that confers a novel function on a gene and encoded protein.

missense codon
: A triplet codon in the genetic code, often created by a point mutation, that specifies an amino acid residue different from that specified by the codon that it replaces. *See also* **nonsense codon**.

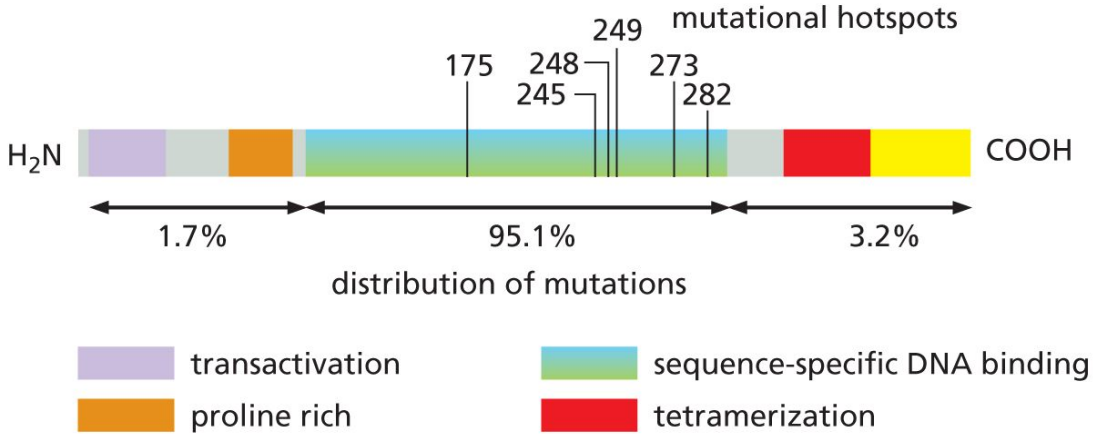
nonsense codon
: A triplet codon in the genetic code that specifies termination of the growing polypeptide chain; nonsense codons generated by point mutations within reading frames cause premature termination of translation and resulting formation of truncated proteins. *See also* **missense codon**.

OceanofPDF.com

9.5 p53 protein molecules usually have short lifetimes

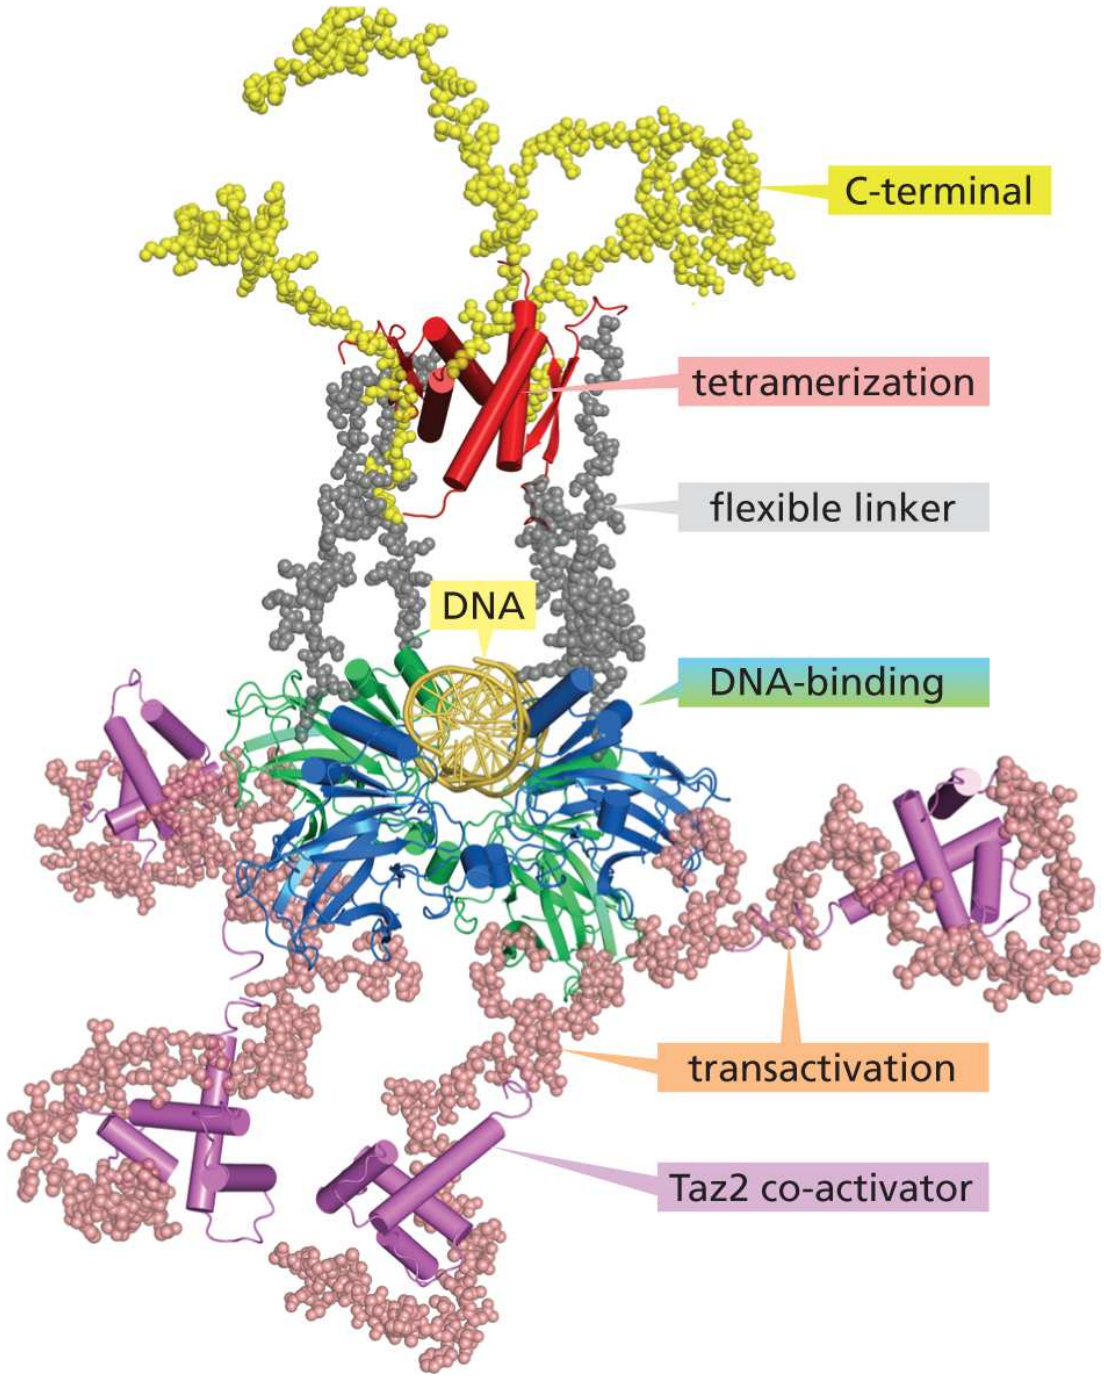
Long before p53 was discovered to bind to DNA, the nuclear localization of this protein in many normal and neoplastic cells suggested that it might function as a transcription factor. In general, there are at least three mechanisms that can regulate the activity of transcription factors: (1) modulation of their nuclear concentrations; (2) alteration of their intrinsic activity by covalent modification; (3) variation in the concentrations of transcription factors with which they collaborate. In some instances, all three mechanisms cooperate. For *p53*, the first mechanism—changes in the concentration of the p53 protein—was initially implicated. Measurement of p53 protein levels indicated that they could vary drastically from one cell type to another and, provocatively, would increase rapidly when cells were exposed to certain types of physiological stress.

These observations raised the question of how cells control the concentration of p53. Many protein molecules, once synthesized, persist for tens or even hundreds of hours. Yet other proteins are highly unstable and are degraded almost as soon as they are assembled. One way to measure the half-life of proteins is to treat cells with cycloheximide, a drug that blocks ongoing protein synthesis. When such an experiment was performed in cells with wild-type *p53* alleles, the p53 protein disappeared with a half-life of only 20 minutes, leading to the conclusion that p53 is usually a highly unstable protein and one that is broken down by proteolysis soon after it is synthesized.



The locations of the point mutations that cause amino acid substitutions in p53. 1.7 percent of mutations occur in a short section at the H2N end of the

gene, where the transactivation and proline-rich domains are located. 3.2 percent of mutations occur in another short section, at the C O O H end of the gene, where the tetramerization domain is located. 95.1 percent of mutations occur in the long middle section that consists mostly of the sequence-specific D N A binding domain. Mutational hotspots in this domain are labeled with protein residue numbers 175, 245, 248, 249, 273, and 282.
(A)



A model of tetramerized p53, with four C domains, four tightly joined tetramerization domains, flexible linkers, four D N A binding domains, four transactivation domains, and four Taz2 co-activators. A D N A shaped into a ball sits in the middle of the D N A binding domains.

(B)

Figure 9.6 Nature of *p53* mutations (A) The locations of the point mutations that cause amino acid substitutions in the p53 protein are shown. Most *p53* mutations (95.1%) affect the DNA-binding domain of the p53 protein. The numbers above the structure indicate the residue numbers of the amino acids that are subject to frequent substitution in human tumors. The transactivation domain enables p53 to interact physically with a number of alternative nuclear partner proteins, including the transcriptional co-activator p300/CBP and the p53 antagonist Mdm2. (B) The overall structure of the DNA-bound p53 tetramer. The four DNA-binding domains are shown in *green* and *blue*, and the four tetramerization domains are seen as *red* and *dark red* α-helices. The DNA double helix (*center*) is shown in *yellow.* Each of the four DNA-binding domains associates with half of a binding site in the DNA; two copies of the binding site are present in the DNA with a small number of base pairs separating them (see Figure 9.15). Each of the four transactivating domains (*dark pink)* is shown interacting with the Taz2 domain of the p300 co-activator (*light purple*), which functions to stimulate transcription through its ability to acetylate histones and p53 itself. The C-terminal domain (*yellow*) plays important roles in regulating transcription. (A, from K.H. Vousden and X. Lu, *Nat. Rev. Cancer* 2:594–604, 2002; and A.C. Joerger and A.R. Fersht, *Annu. Rev. Biochem.* 77:557–582, 2008. With permission from Nature. B, from A.C. Joerger and A.R. Fersht, *Cold Spring Harb. Perspect. Biol.* 2:000919, 2010. With permission from Cold Spring Harbor Laboratory Press.)

Such rapid degradation might seem highly wasteful. Why should a cell invest substantial energy and synthetic capacity in making a protein molecule, only to destroy it almost as soon as it has been created? Similar behaviors have been associated with other cellular proteins such as Myc (see Section 6.1).

The rationale underlying this ostensibly “futile cycle” of rapid protein turnover is a simple one: a cell may need to rapidly increase or decrease the concentration of a protein in response to certain physiological signals. In principle, such modulation could be achieved by regulating the level of its encoding mRNA or the rate with which this mRNA is translated. However, far more rapid changes in the levels of a critical protein can be achieved simply by stabilizing or destabilizing the protein itself. In the case of p53, a cell can double the concentration of p53 protein in 20 minutes simply by blocking its degradation.

Under normal conditions, a cell will continuously synthesize p53 molecules at a high rate and subsequently degrade them at an equally high rate. The net result of this rapid turnover is a very low “steady-state” level of the protein within this cell. In response to certain physiological signals, however, the degradation of p53 is inhibited, resulting in a rapid increase of p53 levels in the cell. Why would a normal cell need to rapidly modulate p53 levels, and what types of signals would cause a cell to halt p53 degradation and instead allow the protein to accumulate?

OceanofPDF.com

9.6 Various signals cause p53 induction

In the early 1990s, a variety of agents were found to induce rapid increases in p53 protein levels. These inducers included X-rays, ultraviolet (UV) radiation, certain chemotherapeutic drugs that damage DNA, and inhibitors of DNA synthesis. Within minutes of exposing cells to some of these agents, p53 levels rapidly increased. This rapid induction occurred in the absence of any marked changes in *p53* mRNA levels and hence did not result from increased transcription of the *p53* gene. Instead, it soon became apparent that this collection of agents boosts the concentration of p53 by stabilizing post-translationally the otherwise labile p53 protein.

In the years that followed, an even greater diversity of physiological signals were found capable of triggering increases in p53 levels. Among these were low oxygen tension (hypoxia), which is experienced by cells—both normal and malignant—that lack adequate access to the circulation and thus to oxygen borne by the blood. Still later, introduction of the adenovirus *E1A* or the cellular *Myc* oncogene (see Sections 8.5 and 8.9) into cells was also found to be capable of causing increases in p53 levels.

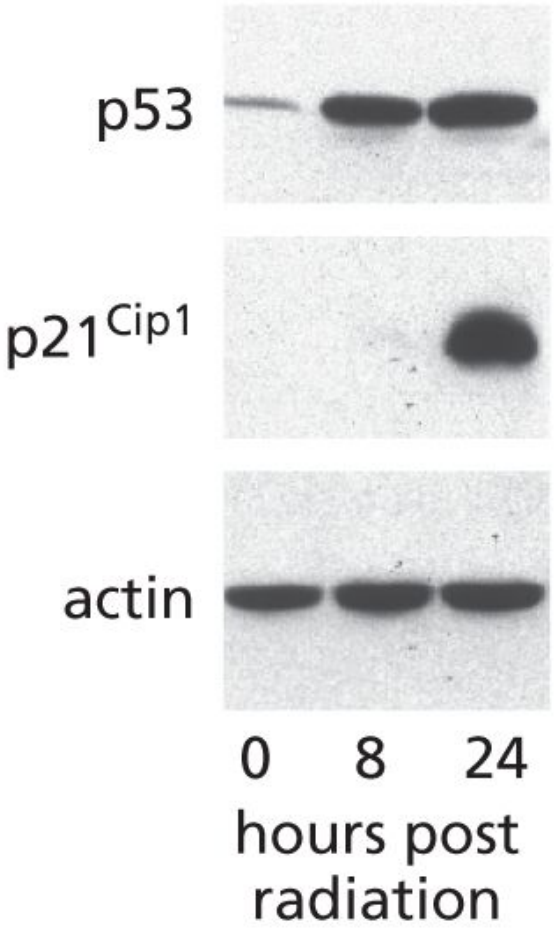
By now, the list of stimuli that elevate p53 levels has grown even longer. Expression of higher-than-normal concentrations of active E2F1 transcription factor (see Figure 8.18), widespread demethylation of chromosomal DNA (see Section 7.7), deficits in the nucleotide precursors of DNA, and increases in intracellular reactive oxygen species (ROS) all elicit p53 accumulation. Exposure of cells to nitrous oxide or to an acidified growth medium, depletion of the intracellular pool of ribonucleotides, and blockage of either RNA or DNA synthesis drive increases of p53 levels as well.

This extensive list of triggers made it clear that a diverse array of sensors is responsible for monitoring the integrity and functioning of various cellular systems. When these sensors detect damage or aberrant functioning, they send signals to p53 and its regulators, resulting in a rapid increase in p53 levels within a cell and the subsequent induction of a variety of downstream responses.

The same physiological signals and DNA-damaging—or genotoxic—agents that provoke p53 increases were already known from other work to trigger cell cycle arrest (sometimes referred to as “growth arrest”). In some cases, these stresses could even induce a more permanent form of arrest known as cellular senescence (see Section 9.11). In yet other situations, some of these stressful signals might trigger activation of the apoptotic cell suicide program (see Section 9.13). These observations, when taken

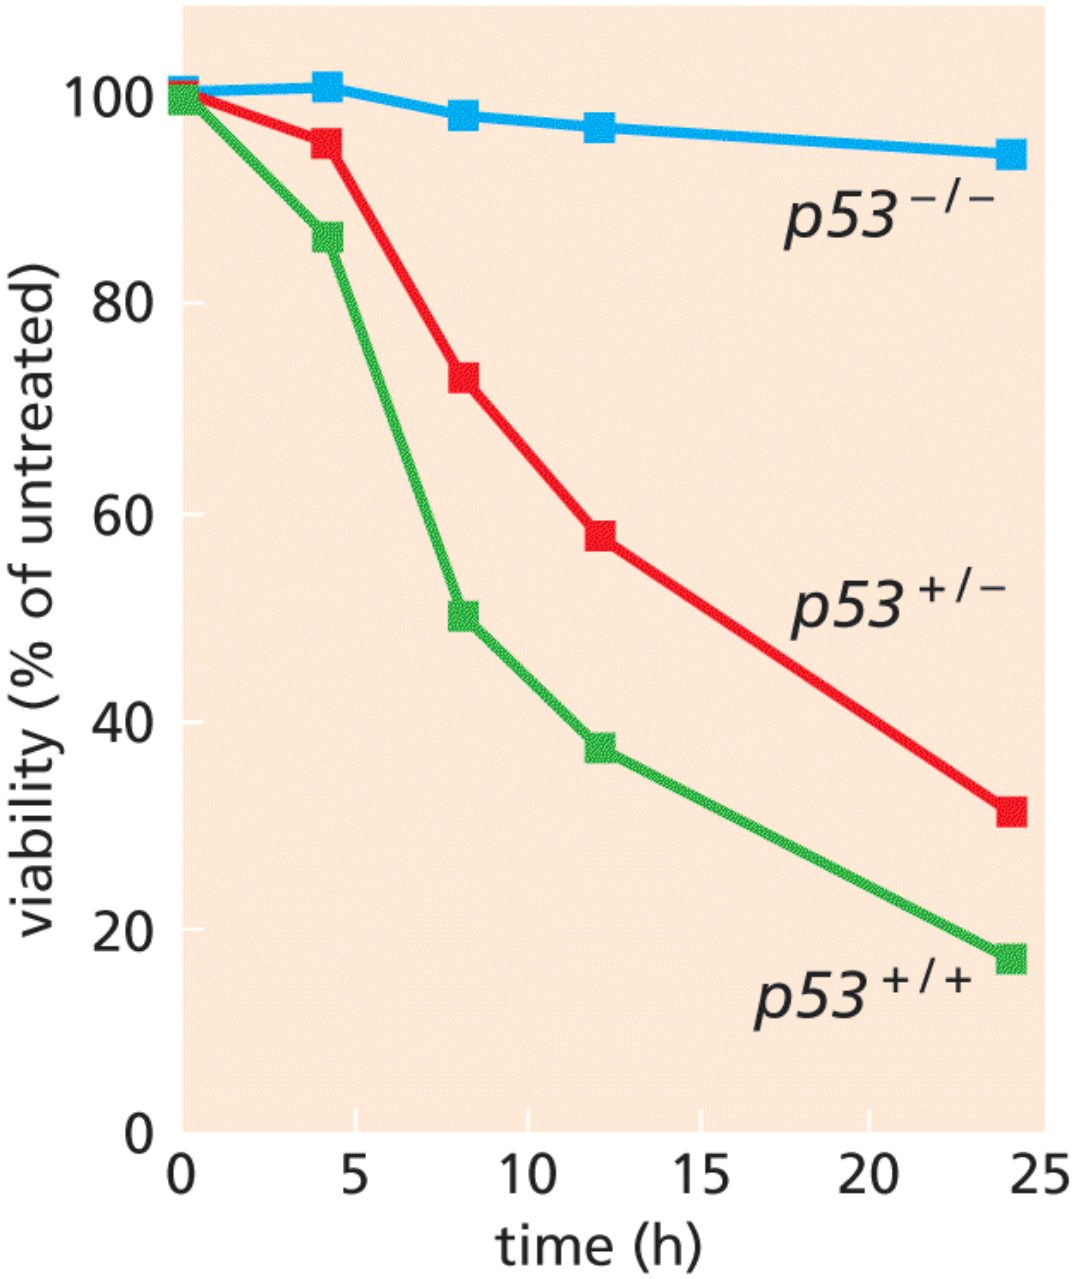
together, showed a striking parallel: toxic agents that induce cell cycle arrest, senescence, or apoptosis are also capable of inducing increases in p53 levels. Because such observations were initially only correlations, they did not prove that p53 somehow *caused* cells to arrest their growth or trigger apoptosis following exposure to toxic or stressful stimuli.

The definitive demonstrations of causality came from more detailed examinations of the effects of elevating p53. For example, the rise in cellular p53 levels that is triggered by treatment with genotoxic agents, such as X-rays, is followed by a subsequent increase in the levels of the mRNA encoding the CDK inhibitor $p21^{Cip1}$ (see Section 8.4); this induction is absent in cells expressing mutant p53 protein. The observation suggests that in some cell types, such as fibroblasts, p53 can halt cell cycle progression by inducing expression of this widely acting CDK inhibitor (**Figure 9.7A**, see also Figure 8.12). Indeed, the long-term biological responses to irradiation are often affected by the state of a cell's *p53* gene. For example, mouse embryo fibroblasts carrying two defective *p53* alleles show a greatly decreased tendency to enter into cell cycle arrest following irradiation. Likewise, in cell types such as T lymphocytes, which undergo apoptosis when exposed to radiation, a functional p53 is required to launch this cell's suicide response (Figure 9.7B).



Autoradiographs for three proteins, showing that following radiation exposure, p53 goes from a minimal presence to a major one within 8 hours, p21 Cip1 goes from no presence at all even after 8 hours to an abundance in 24 hours, and actin increases slightly after 8 hours. Actin bands are always present.

(A)

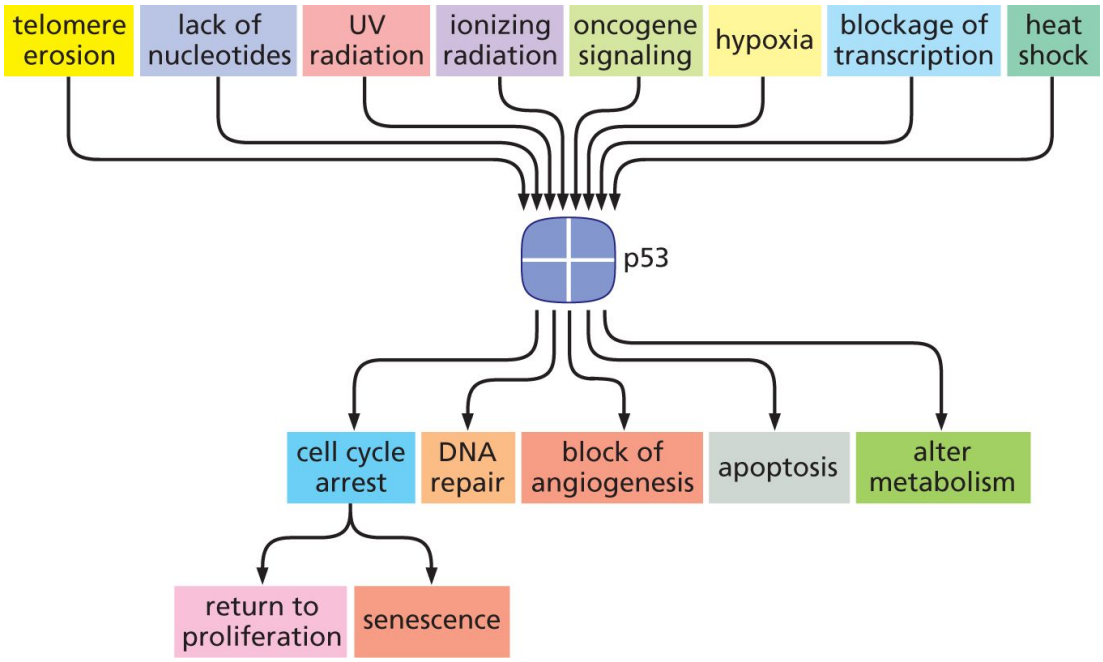


A line graph showing decreasing viability over time, measured as percent of untreated, for three genotypes. The wild-type genotype with two wild-type p53 alleles decreases rapidly, from 100 percent viability initially to just under 50 percent after 8 hours and under 20 percent after 25 hours. The genotype with just one wild-type allele decreases less rapidly, from 100 percent initially to about 60 percent after 10 hours and 30 percent after 25 hours. The genotype with no wild-type alleles decreases least rapidly, staying above 95 percent viability even after 25 hours.

(B)

Figure 9.7 p53 and the radiation response Exposure of cells to X-rays strongly increases p53 levels. (A) Once p53 is present in higher concentrations and is functionally activated via various covalent modifications (*not measured here*), it induces expression of the $p21^{Cip1}$ protein (see Section 8.4). $p21^{Cip1}$ acts as a potent CDK inhibitor of the cyclin–CDK complexes that are active in late G_1, S, G_2, and M phases and can thereby halt further cell proliferation at any of these phases of the cell cycle. The actin protein is included in all three samples as a "loading control" to ensure that equal amounts of protein were added to each lane of the gel prior to electrophoresis. (B) Thymocytes (leukocytes derived from the thymus) of wild-type ($p53^{+/+}$) mice show an 80% loss of viability relative to untreated control cells during the 25 hours following X-irradiation (*green*), and thymocytes from $p53^{+/-}$ heterozygous mice (with one wild-type and one null allele) show almost as much loss of viability (*red*). In contrast, thymocytes prepared from $p53^{-/-}$ homozygous mutant mice exhibit less than a 5% loss of viability during this time period (*blue*). In all cases, the loss of viability was attributable to apoptosis (*not shown*). (A, courtesy of K.H. Vousden. B, from S.W. Lowe et al., *Nature* 362:847–849, 1993. With permission from Nature.)

These various observations can be incorporated into a simple, unifying mechanistic model: a diverse array of cellular surveillance systems relay information to p53, which then triggers appropriate physiological responses: halting cell proliferation, activating DNA repair systems, adjusting metabolism, blocking angiogenesis (the growth of new blood vessels), or engaging the apoptotic suicide program described later (**Figure 9.8**). In fact, a number of stresses—including hypoxia, genomic damage, and imbalances in the signaling pathways governing cell proliferation—are commonly experienced by cancer cells during various stages of tumor development. Consequently, p53 activity must be blunted or even fully eliminated in these cells if they are to survive and prosper. In the same manner, normal cells must also avoid excessive p53 activity, because it threatens to cause their arrest or death, thereby affecting normal bodily functions (**Supplementary Sidebar 9.1**).



A diagram showing the signals that activate p53 and also the activated protein's downstream effects. The activating signals are telomere erosion, lack of nucleotides, U V radiation, ionizing radiation, oncogene signaling, hypoxia, blockage of transcription, and heat shock. The downstream effects are cell cycle arrest leading to return to proliferation or else to senescence, D N A repair, block of angiogenesis, apoptosis, and altered metabolism.

Figure 9.8 p53-activating signals and p53's downstream effects Studies of p53 function have revealed that a variety of cell-physiological stresses can cause a rapid rise in p53 level. The resulting accumulated p53 protein then undergoes post-translational modifications and proceeds to induce a number of responses. A cytostatic response ("cell cycle arrest," often called "growth arrest") can be either irreversible ("senescence") or reversible ("return to proliferation"). DNA repair proteins may be mobilized as well as proteins that alter metabolism or antagonize blood vessel formation ("block of angiogenesis"). As an alternative, in certain circumstances, p53 may trigger apoptosis.

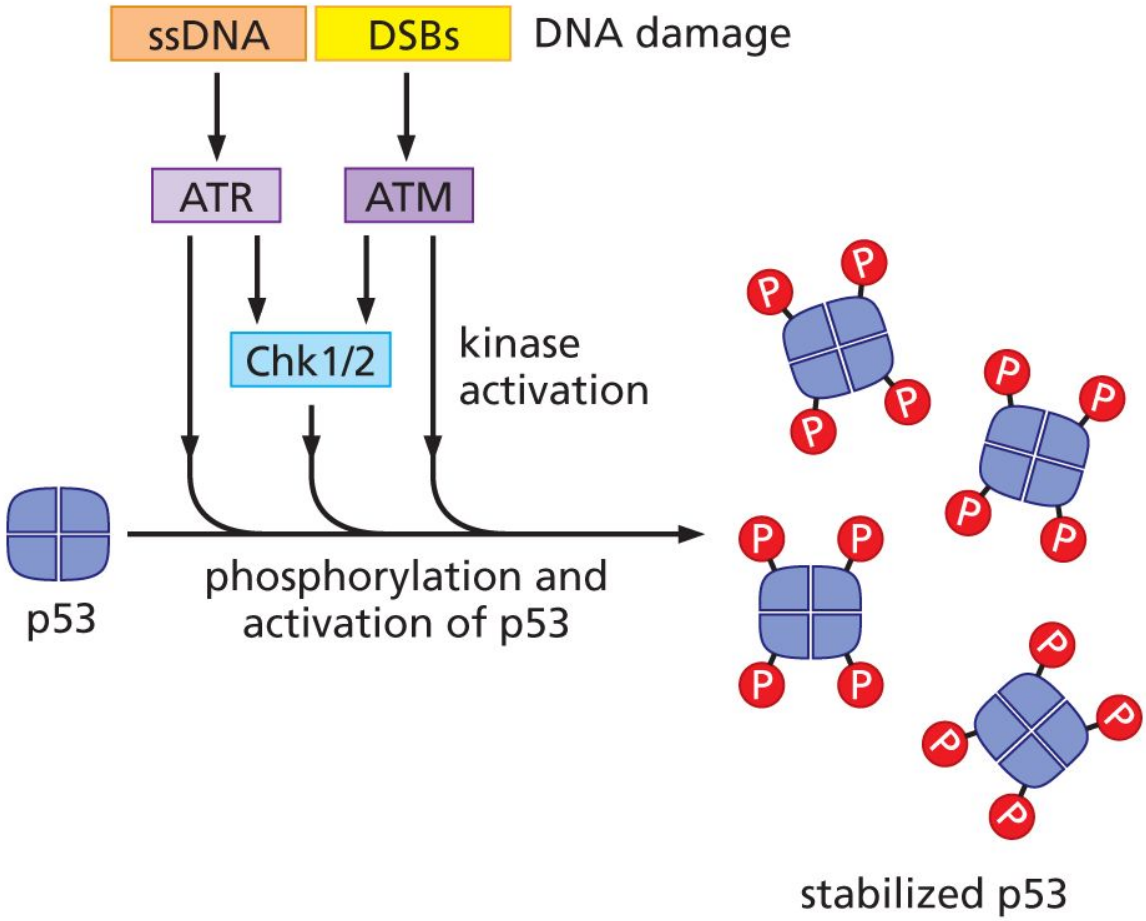
9.7 DNA damage and deregulated growth signals cause p53 stabilization

Three well-studied systems send alarm signals to p53 in the event that they detect damage or signaling imbalances. The first monitors chromosomal DNA for double-strand breaks (DSBs), including those that are created by ionizing radiation such as X-rays. Indeed, in some cell types, even a single DSB anywhere in the genome appears to be sufficient to induce a measurable increase in p53 levels. Many of the proteins that detect such breaks have been discovered; they act through a kinase called ATM. Not only does ATM phosphorylate p53 directly, but it also activates another kinase, Chk2, that proceeds to phosphorylate p53 as well (**Figure 9.9**). This phosphorylation stabilizes the p53 protein and protects it from destruction orchestrated by the protein Mdm2, as discussed in the next section. A deficiency of ATM—the cause of the disease ataxia telangiectasia—leads to a hypersensitivity of cells to X-irradiation (as described in Chapter 12). Thus, without ATM on the job, p53 fails to be properly stabilized and activated by DNA damage; in the absence of p53, cells will lose the ability to rapidly mount their DNA repair program, leading to DNA breaks that can impair their survival.



A diagram showing the Control of p53 levels by various kinases. D N A damage may take the form of single-stranded D N A or double-strand D N A breaks, called D S Bees. The former activate A T R, while the latter activate A T M. These two kinases phosphorylate p53 either directly or via C h k1 and C h k2. The output of this phosphorylation and activation of p53 is stabilized p thirty fives each with four phosphate groups.

Figure 9.9 Control of p53 levels by various kinases The cycle of p53 synthesis and destruction is modulated by a series of regulators. Extensive ssDNA regions and double-strand DNA breaks (DSBs) activate two kinases, ATR and ATM, respectively. These kinases can phosphorylate p53 directly, or indirectly via Chk1 and Chk2, in all cases in its N-terminal domain (see Figure 9.11B). This phosphorylation prevents the binding of the p53 antagonist Mdm2 (see Figure 9.10).

A second signaling pathway is activated by the presence of single-strand DNA. Single-strand DNA tends to persist at replication forks that have stalled, often because DNA polymerases have encountered nucleotides that have been altered by any one of a wide variety of DNA-damaging agents, including UV radiation and certain chemotherapeutic drugs. Proteins that detect single-strand DNA activate a kinase called ATR. Like ATM, this kinase both directly phosphorylates p53 and activates an additional kinase—in this case Chk1—which also phosphorylates p53 (see Figure 9.9).

A third pathway leading to p53 activation is triggered by aberrant growth signals, notably those that perturb the pRb–E2F cell cycle control pathway (see Section 8.7). As we will see shortly, this pathway does not depend on activation of intermediary kinases to induce increases in p53 levels and signaling. The mechanisms by which other physiological stresses or imbalances, such as hypoxia, trigger increases in p53 levels remain an active area of investigation.

These converging signaling pathways reveal a profound vulnerability of the mammalian cell. Through the course of evolution, a single protein—p53—has become entrusted with the task of receiving signals from lookouts that monitor a wide variety of important physiological and biochemical intracellular systems (see Figure 9.8). The funneling of these diverse signals to a single protein would seem to represent an elegant and economic design of the cellular signaling circuitry. But it also puts cells at significant risk, because loss of this single protein from a cell's regulatory circuitry will cause a catastrophic loss of the cell's ability to monitor its own well-being and respond with appropriate countermeasures in the event that certain operating systems malfunction.

In one stroke (or two strokes, if we consider the successive inactivation of both copies of the *p53* gene), a cell can become unresponsive to signals that arise from its own internal defects. Thus, a cell lacking intact p53 will continue to blunder on, continuing to proliferate under circumstances that would normally cause it to stop dividing or to enter into apoptotic death. In addition, as we will learn shortly, loss of the DNA repair and genome-stabilizing functions promoted by p53 make descendants of a $p53^{-/-}$ cell more likely to acquire further mutations and advance more rapidly down the road of malignancy (**Sidebar 9.2**, **Supplementary Sidebar 9.2**).

Sidebar 9.2 Sunlight, p53, and skin cancer

The p53 protein stands as an important guardian against skin cancer induced by sunlight. When the genome of a keratinocyte in the skin suffers extensive damage from ultraviolet-B (UV-B) radiation, p53 can rapidly trigger its apoptotic death. One manifestation of this reaction is the extensive scaling of skin several days after a sunburn. At the same time, UV-B exposure can induce the mutation and functional inactivation of *p53*. Indeed, *p53* alleles in human squamous cell carcinomas of the skin often harbor mutations at dipyrimidine sites—precisely the sites at which UV-B rays induce the formation of pyrimidine–pyrimidine cross-links (see Section 12.6). Such mutant *p53* alleles can also be found in outwardly normal skin that has suffered chronic sun damage. Once p53 function is compromised by these mutations, keratinocytes may be able to survive subsequent extensive exposures to UV-B irradiation, because apoptosis will no longer be triggered by their p53 protein. Moreover, loss of p53 results in a diminished ability to repair subsequent UV-B–induced DNA lesions. Hence, *p53*-mutant cells may subsequently acquire additional mutant alleles that enable them, together with the mutant *p53* alleles, to form a squamous cell carcinoma.

Human papillomaviruses (HPVs) are increasingly implicated as co-factors in many of these squamous cell carcinomas; a key function of the virus-encoded E6 oncoprotein may explain the synergistic actions of UV-B radiation and HPV in these relatively common tumors: E6 tags p53 for destruction by ubiquitylation and degradation in proteasomes, thereby phenocopying mutational inactivation of the *p53* gene (**Supplementary Sidebar 9.2**). Interestingly, mice that lack functional *p53* gene copies respond to UV-B exposure by developing uveal melanomas—tumors of pigmented cells in the front of the eye; similar tumors are suspected to be caused in humans by UV exposure.

Of additional interest, p53 in keratinocytes has another totally unrelated effect that illustrates its diverse functions: in response to the DNA damage created by UV radiation, p53 causes these cells to release melanocyte-stimulating hormone (αMSH); this hormone stimulates nearby skin melanocytes to produce the melanin pigment to protect against further sunlight-induced damage and, more productively, generate a suntan!

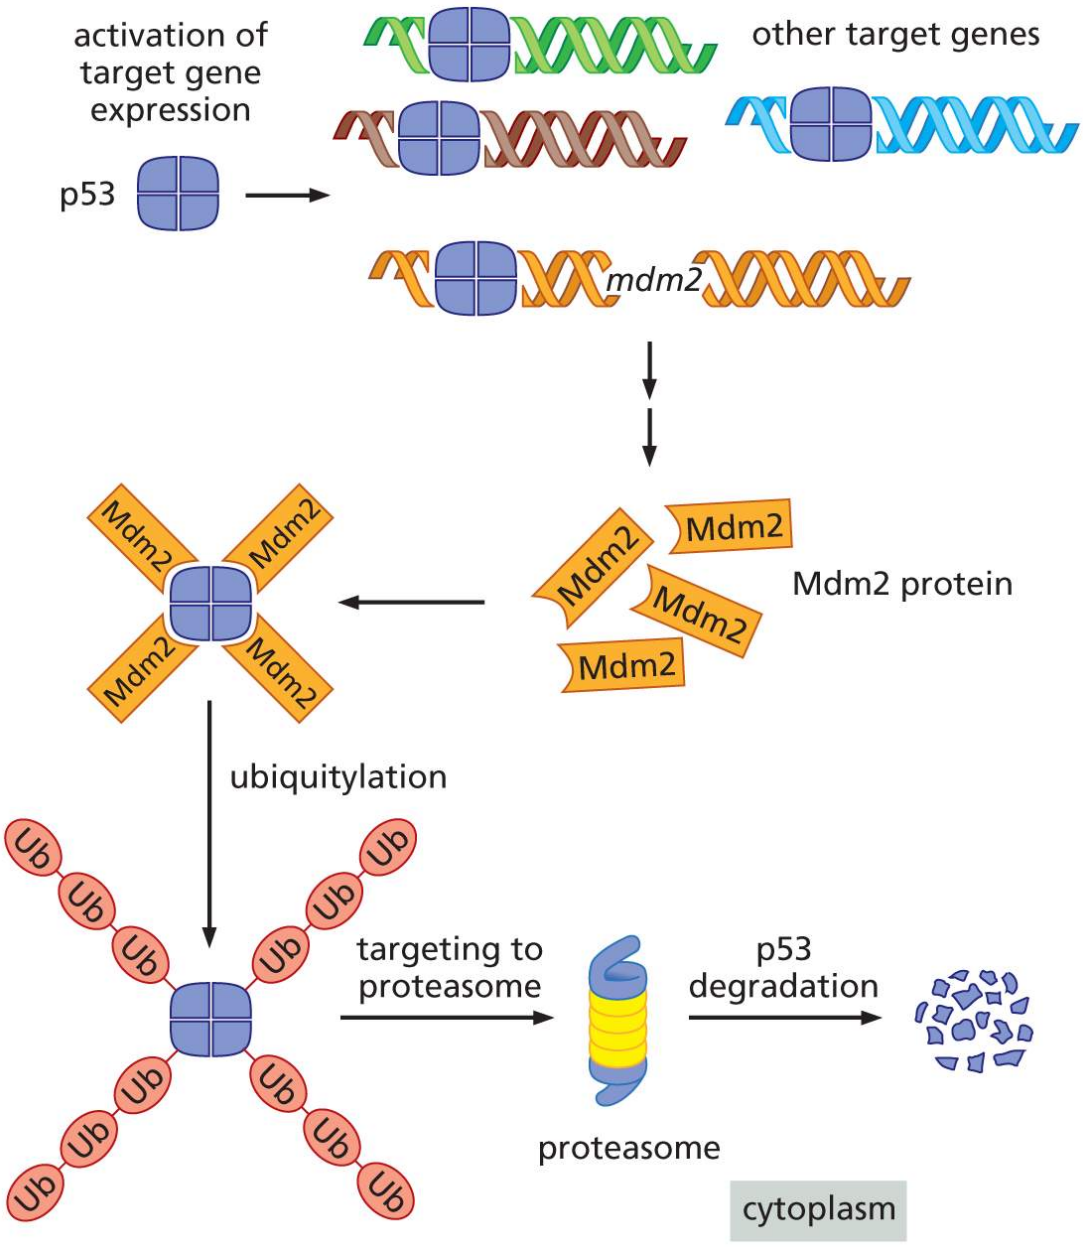
9.8 Mdm2 destroys its own creator

The diverse alarm signals that converge on p53 produce a common result: a rapid increase in the levels of the p53 protein. This response is achieved by a mechanism that we have discussed in previous chapters, specifically the regulation of protein stability by the ubiquitin–proteasome system (see **Supplementary Sidebar 7.5**). Proteins that are destined to be degraded by this system are initially tagged by the covalent attachment of polyubiquitin side chains, which direct the proteins to proteasomes, where they are digested into oligopeptides. The critical control point in this process is the initial tagging process.

In normal, unperturbed cells, the degradation of p53 is regulated by a protein cited earlier, the ubiquitin ligase termed Mdm2 in mouse cells and MDM2 or HDM2 in human cells. This protein recognizes p53 as a target for ubiquitylation shortly after its synthesis and thereby marks p53 for rapid destruction (**Figure 9.10**). As a consequence, the steady-state concentration of p53 is kept at a low level.



A diagram showing how M d m2 controls p53 levels. p53 binds to various target genes, including M d m2, and activates their expression. The M d m2 gene produces M d m2 proteins. Four of these bind to p53, one at each corner of the tetramer. Each M d m2 is then replaced by a ubiquilation chain. In the cytoplasm the ubuiquilated p53 is then targeted to a proteasome, within which it is degraded.

Figure 9.10 Control of p53 levels by Mdm2 After p53 concentrations increase in response to certain physiological signals (*not shown*), the p53 tetramers bind to the promoters of a large constituency of target genes whose transcription they induce (*above*); these target genes include the gene encoding the p53 antagonist Mdm2.

Mdm2 molecules then proceed to bind the p53 protein subunits and initiate their ubiquitylation, resulting in their export to the cytoplasm, further ubiquitylation, and, ultimately, degradation in proteasomes. This negative-feedback loop ensures that p53 concentrations eventually fall after danger signals, such as those shown in Figure 9.8, cease; such regulation ensures that p53 concentration will thereafter return to its normally low level.

Surprisingly, an opposing control also operates: the expression of Mdm2 in cells is regulated by p53. As mentioned earlier, p53 functions as a transcription factor and the *Mdm2* gene is one of its targets. This relationship between p53 and Mdm2 creates an autoregulatory loop in which p53 induces the synthesis of the protein that drives its own destruction (see Figure 9.10).

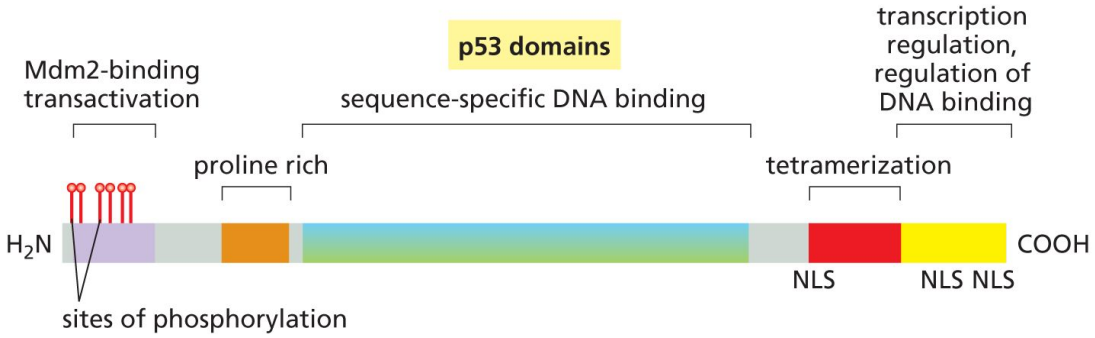
The *Mdm2* gene was initially identified because in murine sarcoma cells it is present in multiple copies on extrachromosomal fragments called double minute chromosomes (hence, **m**ouse **d**ouble **m**inutes). These derive from segments that break free from their original chromosomes and are replicated repeatedly (see Figure 1.9B). Subsequently, the human homolog of the *Mdm2* gene was discovered to be frequently amplified in sarcomas as well as in other tumor types. In certain other tumor types (e.g., lung carcinomas), the gene is overexpressed through mechanisms that remain unclear. As is the case with other oncogenes, it seemed at first that amplification of the *Mdm2* gene in mouse sarcoma cells afforded the cells some direct, immediate proliferative advantage. Only long after the Mdm2 protein was first identified did its role as the agent of p53 destruction become apparent.

In fact, Mdm2 has an additional effect on the activity of p53. By binding to p53, Mdm2 immediately blocks p53's ability to act as a transcription factor by preventing the protein's interaction with transcriptional co-factors, such as acetyltransferases and histone methyltransferases (see Section 1.8). After it exerts these direct effects on p53's function as a transcription factor, Mdm2 orchestrates the attachment of a ubiquitin moiety to p53 as well as its export from the nucleus to the cytoplasm. There, polyubiquitylation of p53 ensures its rapid degradation in cytoplasmic proteasomes (see Figure 9.10). The continuous, highly efficient actions of Mdm2 ensure the short, 20-minute half-life of p53 in normal, unstressed cells.

Although the present discussion and Figure 9.10 represent Mdm2 as a monomeric protein, it actually often forms heterodimeric complexes with its close cousin, MdmX (also called Mdm4). This complex may be responsible for much of the ubiquitylation activity that drives p53 degradation. Indeed, there is evidence that without the presence of MdmX, Mdm2 loses the ability to drive p53 degradation. When expressed on its own, however, MdmX seems to be limited to blocking p53-mediated transcriptional

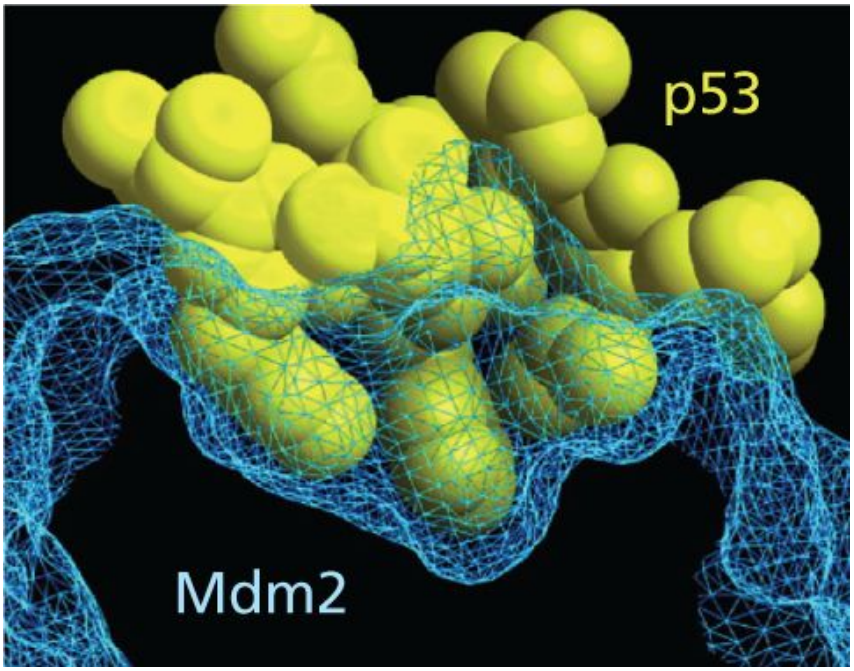
activation. Like *Mdm2*, the *MdmX* gene is a transcriptional target of p53, and it thus participates in the elaborate negative-feedback loop that controls p53 levels.

When cells suffer certain types of stress or damage, p53 protein molecules must be protected from their Mdm2/MdmX executioners (hereafter simply Mdm2) so that they can accumulate to functionally significant levels in the cell. This protection is often achieved by the phosphorylation of p53 described above (see Figure 9.9). The phosphorylation sites—recognized by kinases such as ATM, ATR, Chk1, and Chk2—lie in the N-terminal region of p53 in a domain that is normally recognized and bound by Mdm2 (**Figure 9.11A**). Thus, phosphorylation of p53 blocks the binding of Mdm2 and subsequent ubiquitylation (Figure 9.11B). At the same time, ATM kinase also phosphorylates Mdm2, causing its functional inactivation and destabilization (**Figure 9.12**). As a consequence of the phosphorylation of both p53 and Mdm2, p53 escapes destruction and its concentrations in the cell increase rapidly. Once p53 has accumulated in substantial amounts, the protein is then poised to evoke a series of downstream responses (see Figure 9.8). These responses will be discussed in detail below.



A schematic of p53, with the H2N end on the left and the C O O H end on the right. From left to right, the domains are the M d m2-binding transactivation domain, with six specific phosphorylation sites shown; a proline-rich domain; a long sequence-specific D N A binding domain; a tetramerization domain; and a domain for regulating transcription and D N A binding. The latter two domains have associated nuclear localization signals.

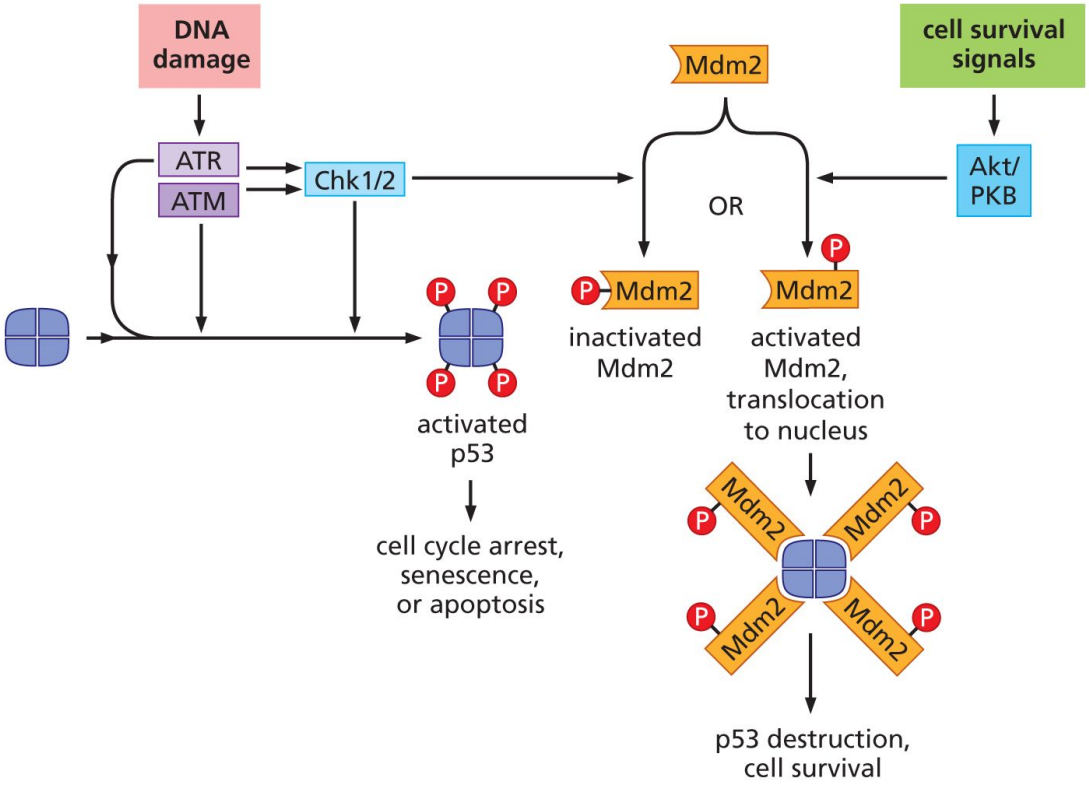
(A)



A model of p53 and M d m2 nestled against each other. p53 is shown as a space-filling model, M d m2 as a wire mesh. p 53 fits perfectly in the grooves of M d m2.

(B)

Figure 9.11 Specialized domains of p53 (A) The interaction of p53 with Mdm2 occurs in a small domain near its N-terminus, where the transactivation domain of p53 is also located. The phosphorylation of p53 amino acid residues in this region (*red lollipops; not all are indicated*) blocks Mdm2 binding and thus saves p53 from ubiquitylation and degradation. The nearby proline-rich domain (*salmon*) contributes to p53's pro-apoptotic functions. Its tetramerization domain is located toward its C-terminus. Nearby are nuclear localization signals (NLS), which allow import of recently synthesized p53 into the nucleus, as well as amino acid sequences that regulate its DNA binding. (B) The structure of the interface where p53 and Mdm2 interact has been revealed by X-ray crystallography. The interacting domain of p53 is shown as a yellow space-filling model that includes p53 residues 18 through 27, and the surface of the complementary pocket of Mdm2 is shown as a blue wire mesh. (A, from M. Ashcroft and K.H. Vousden in D.E. Fisher, ed., *Tumor Suppressor Genes in Human Cancer*. Totowa, NJ, Humana Press, 2000. With permission from Springer. B, from P.H. Kussie et al., *Science* 274:948–953, 1996. With permission from AAAS.)



A diagram showing how the activity of M d m2 is regulated by phosphorylation. On the left, D N A damage in the form of s s D N A and D S Bees activates A T R and A T M. These two phosphorylate p53 either directly or via C h k1 and C h k2. But C h k1 and C h k2 also phosphorylate M d m2 at the site where M d m2 would bind to p53. Then that binding is prevented as the M d m2 is inactivated. Then the phosphorylated, activated p53 accumulates, leading to cell cycle arrest, senescence, or apoptosis. On the other hand, cell survival signals prompt A k t / T K B to phosphorylate M d m2 at a different site, activating it and leaving it free to translocation to the nucleus and to attach, four at at time, to the p53 tetramer, which then undergoes destruction, which promotes cell survival.

Figure 9.12 The activity of Mdm2 is also regulated by phosphorylation The same DNA damage that induces phosphorylation of p53 by ATM and other kinases (resulting in “activated p53” in this figure) also stimulates phosphorylation of Mdm2. This phosphorylation inactivates and destabilizes Mdm2, preventing its binding to p53, resulting in accumulation of the latter. Mdm2 can also be phosphorylated at a different site by kinases, such as Akt/PKB, which are, in turn, activated by cell growth and survival signals. This phosphorylation promotes translocation of Mdm2 to the nucleus, where it can bind to p53, marking it for destruction, thereby reducing the likelihood of p53-triggered apoptosis.

Note that Mdm2 operates here as an oncoprotein, but one whose mechanism of action is very different from those of the various oncoproteins that we encountered in Chapters 4, 5, and 6. The latter function as components of mitogenic signal cascades and thereby induce cell proliferation by mimicking the signals normally triggered by the binding of growth factors to their receptors. Mdm2, in contrast, operates by antagonizing p53 and thereby prevents entrance of a cell into cell cycle arrest, senescence, or into the apoptotic suicide program. The final outcome is, however, the same: the actions of traditional oncoproteins and Mdm2 all favor increases in cell number. Of note, inherited genetic polymorphisms that in humans lead to increased Mdm2 expression—or otherwise disable the p53 alarm system—are also associated with familial cancer susceptibility (**Sidebar 9.3**).

Sidebar 9.3 Familial cancer susceptibility can arise from defects in other components of the p53 pathway

A familial cancer syndrome in which individuals inherit mutant, defective forms of the Chk2 kinase behaves very much like the Li–Fraumeni syndrome caused by mutations in the *p53* gene. Chk2 kinase is responsible for phosphorylating p53, saving it from destruction and thereby activating the p53 alarm machinery (see Figure 9.9). A mutant germ-line allele of the *Chk2* gene is present in 1.1 to 1.4% of Western populations, and in higher percentages (as much as 5%) in cohorts of breast cancer patients. This prevalence suggests that inheritance of a mutant *Chk2* allele confers a measurably increased risk of developing this malignancy.

Yet another related cancer predisposition syndrome derives from a single-nucleotide polymorphism (SNP) in the promoter of the *MDM2* gene. This region of the human gene contains enhancer sequences that enable *MDM2* gene transcription to respond to signals coming from p53 and the Ras signaling pathway. The polymorphism, a T-to-G substitution termed *SNP309*, is quite common, being present in homozygous configuration in about 12% of the American population. Cells from individuals homozygous for this polymorphism express as much as eightfold higher levels of *MDM2* RNA and greater than threefold higher levels of Mdm2 protein; because of the resulting attenuated p53 response, these cells are far more resistant to apoptosis induced by DNA damage.

The *SNP309* polymorphism exacerbates the cancer susceptibility of individuals in Li–Fraumeni families. Li–Fraumeni individuals carrying this polymorphism experience their first cancer at an average age of 22 years, compared with the 27-year age of those who lack this base substitution. The cancer risks are more dramatic for specific tumor types. For example, if Li–Fraumeni patients develop a soft-tissue sarcoma, these tumors appear, on average, at the age of 2 among those who are homozygous for the polymorphism, whereas they appear at the age of 12 among those who carry the more

prevalent allele. Moreover, this polymorphism increases the number of independently arising tumors in Li–Fraumeni patients carrying it in either a heterozygous or a homozygous configuration.

SNP309 homozygotes in the general population exhibit a markedly increased risk of developing soft-tissue sarcomas. In addition, female homozygotes who develop breast cancer do so at age 45, on average, rather than the 57-year average age of onset seen among those who do not carry this allele. In one meta-analysis, individuals who were homozygous at the *SNP309* locus and carried two *Pro/Pro* alleles of p53 (see **Supplementary Sidebar 9.1**) exhibited a greater than threefold increased overall risk for developing cancer. These observations demonstrate how relatively common genetic variant sequences can have profound effects on cancer susceptibility. And they raise the question whether the responsible base changes can be truly called "polymorphisms," because the term usually implies genetic variability that has no significant biological consequences.

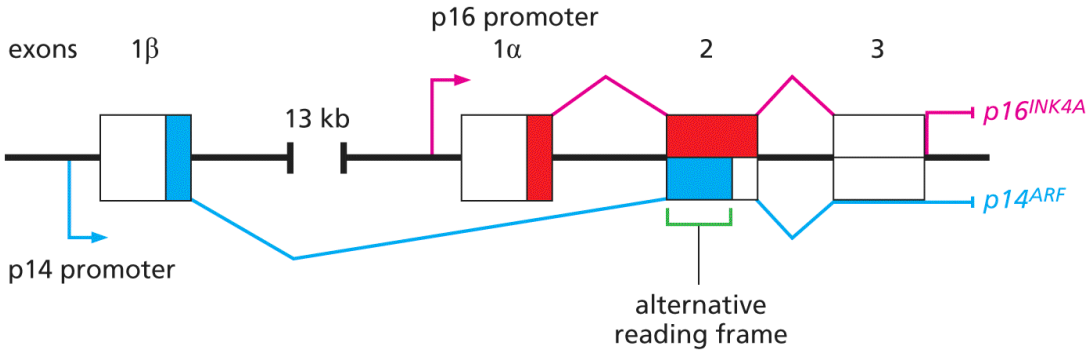
The activity and levels of the Mdm2 protein are affected by yet other positive and negative signals. The signaling pathway that favors cell survival through activation of the PI3 kinase (PI3K) pathway (see Section 6.6) leads, via the Akt/PKB kinase, to Mdm2 phosphorylation (at a site different from that altered by the ATM kinase described above). This phosphorylation results in the translocation of Mdm2 from the cytoplasm to the nucleus, where it is well-positioned to bind to and modify p53 (see Figure 9.12). Because PI3K itself is activated by Ras and growth factor receptors, it becomes clear that this mitogenic signaling pathway influences Mdm2 and, indirectly, p53.

In normal, unstressed cells, Mdm2 must be allowed to perform its normal role of keeping p53 levels very low, as is highlighted by the results of inactivating both *Mdm2* gene copies in the genomes of mouse embryos: these embryos die very early in development, because p53 levels increase to physiologically intolerable levels, preventing the normal proliferation of embryonic cells or causing them to die. These profoundly disruptive effects of *Mdm2* gene inactivation are attributed specifically to runaway p53 activity, as is made clear by studies in which both of these genes in a mouse embryo harbor homozygous inactivating mutations, yielding the $Mdm2^{-/-}$; $p53^{-/-}$ genotype. Once p53 is eliminated from the embryonic cells, the loss of Mdm2 becomes tolerable and embryonic development proceeds normally!

Yet another important mechanism that controls Mdm2 has been revealed through the discovery of a protein termed $p19^{ARF}$ in mouse cells and $p14^{ARF}$ in human cells. Astute sequence analysis led to the discovery of ARF, as we call it hereafter. Its gene was originally uncovered in mouse cells as one whose coding sequence overlaps the

gene that encodes $p16^{INK4A}$, an important CDK inhibitor involved in regulating the activation of pRb (see Section 8.4).

Transcription of the ARF-encoding gene is directed by a promoter located 13 kb upstream of the $p16^{INK4A}$ promoter; alternative splicing of the resulting transcript produces an mRNA that encodes—in an **a**lternative **r**eading **f**rame relative to that used to encode $p16^{INK4A}$—the ARF protein (**Figure 9.13**). Forced expression of an ARF-encoding cDNA in wild-type rodent cells was found to cause a strong inhibition of proliferation. However, this inhibition was not observed when the ARF cDNA was introduced into cells that lacked wild-type p53 function. This result indicates that the growth-inhibitory powers of ARF depend absolutely on the presence of functional p53.

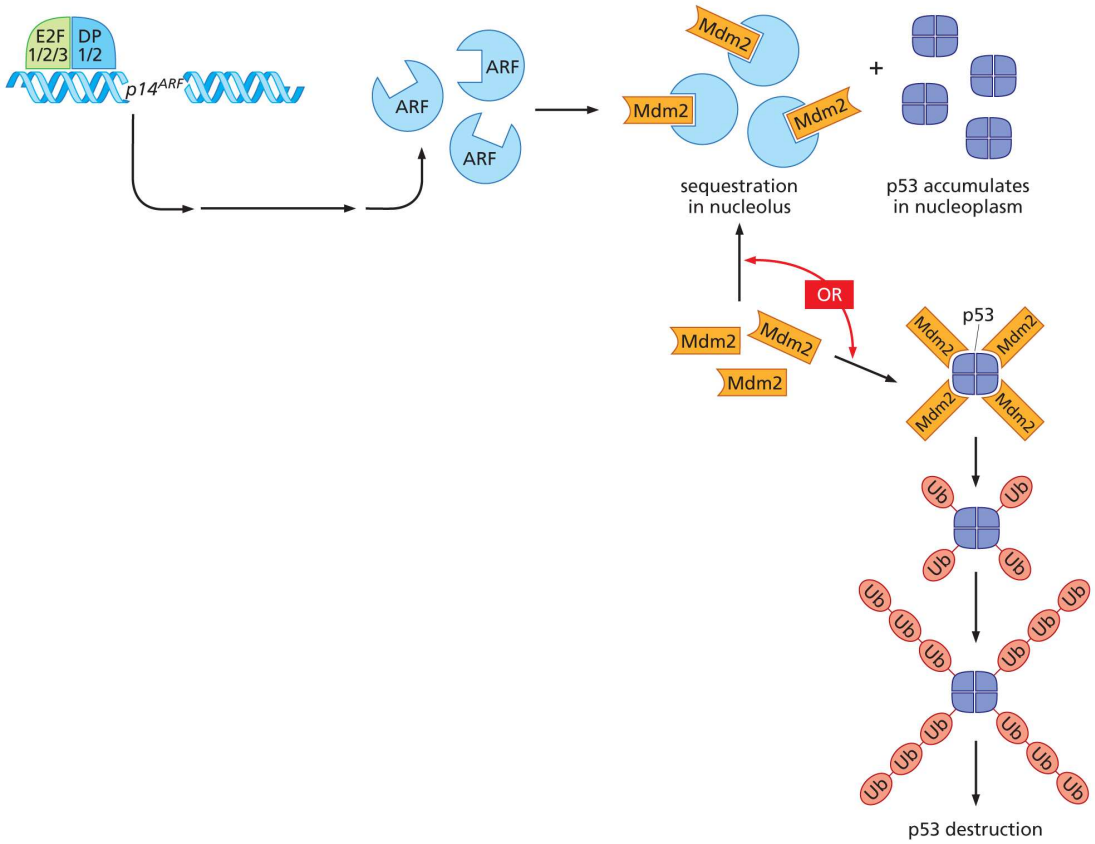


The structure of the gene encoding p16 INK 4A and p14 slash p19 A R F. The genes encoding p16 INK 4A and p14 slash p19 A R F are shown to each consist of three exons, with the second and third exon the same for both. The p14 promoter starts just before 1 beta, which contains the first of two reading frames associated with p14. More than 13 kilobases downstream is the p16 promoter, followed by exon 1 alpha, which contains the first of two reading frames associated with p16. This exon is joined to exon 2, which contains the second of the two reading frames associated with p14, labeled as the alternative reading frame. Coinciding with that reading frame but slightly longer is the second of the two reading frames associated with p16. This exon is joined to exon 3, the third exon for both p14 A R F and p16 INK 4A.

Figure 9.13 The gene encoding $p16^{INK4A}$ and $p14/p19^{ARF}$ Analysis of the *p16INK4A* gene (*red*) has revealed that it shares its second exon with a gene encoding a 19-kD protein in mice and a 14-kD protein in humans. The *p14/p19* gene uses an alternative transcriptional start site (*blue arrow, left*) located more than 13 kb upstream of the one used by *p16INK4A* (*red arrow, center*). Because translation of its mRNA uses an *a*lternative *r*eading *f*rame (*green bracket*) in exon 2 (*red, blue*), the resulting protein and thus gene came to be called $p19^{ARF}$ (or in humans $p14^{ARF}$). The patterns of RNA splicing are indicated by the carets

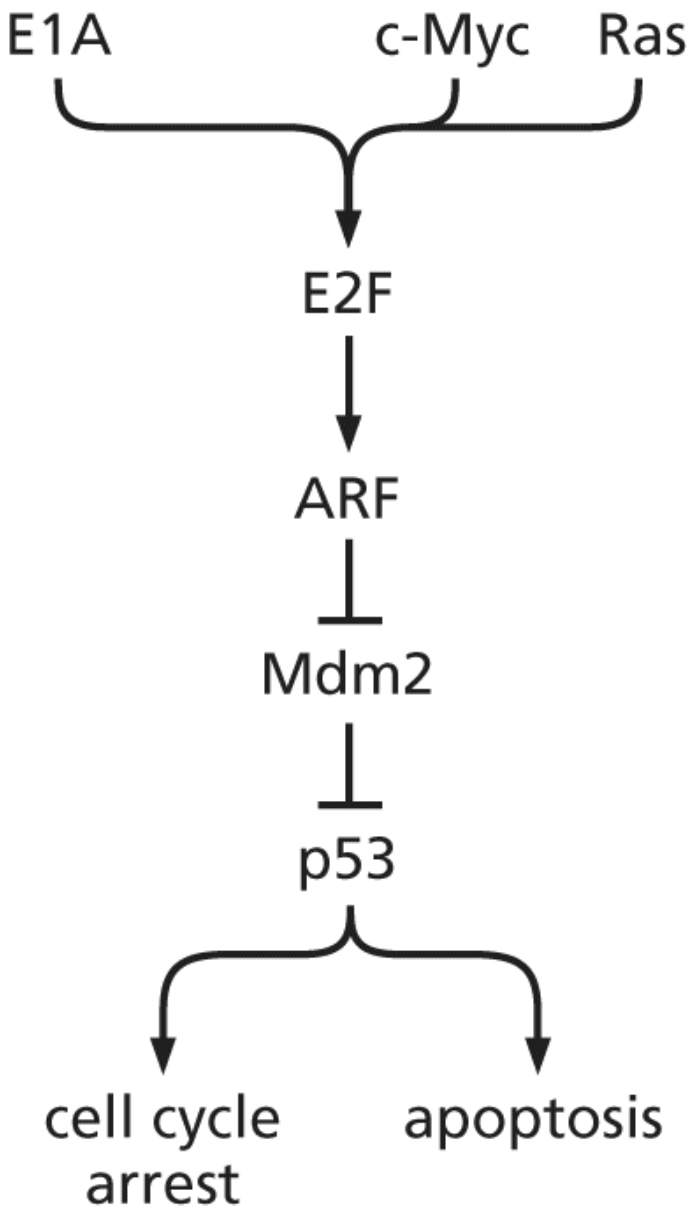
connecting the various exons of the two intertwined genes. The boxes indicate exons, and the filled areas within each exon indicate reading frames. Other research indicates the presence of four E2F-binding sites (*not shown here*) in the promoter region of the gene encoding $p14^{ARF}$, three upstream of the transcriptional start site and one downstream. (From C. Sherr, *Genes Dev.* 12:2984–2991, 1998. With permission from Cold Spring Harbor Laboratory Press.)

Further investigation revealed that in wild-type cells, the expression of ARF causes a rapid increase in p53 levels. We now understand the molecular mechanisms that underlie this response: ARF binds to Mdm2 and prevents its further action by driving its localization from the nucleoplasm to the nucleolus where it is sequestered; recall that the nucleolus is the nuclear organelle that is largely devoted to manufacturing ribosomal subunits (**Figure 9.14A**). Once Mdm2 is diverted from interacting with p53, the latter escapes Mdm2-mediated ubiquitylation and therefore accumulates rapidly to high levels in the nucleoplasm, where it is poised to activate expression of its constituency of target genes. The enemy of an enemy is a friend: ARF can induce rapid increases in p53 levels because it kidnaps and inhibits p53's destroyer, Mdm2.



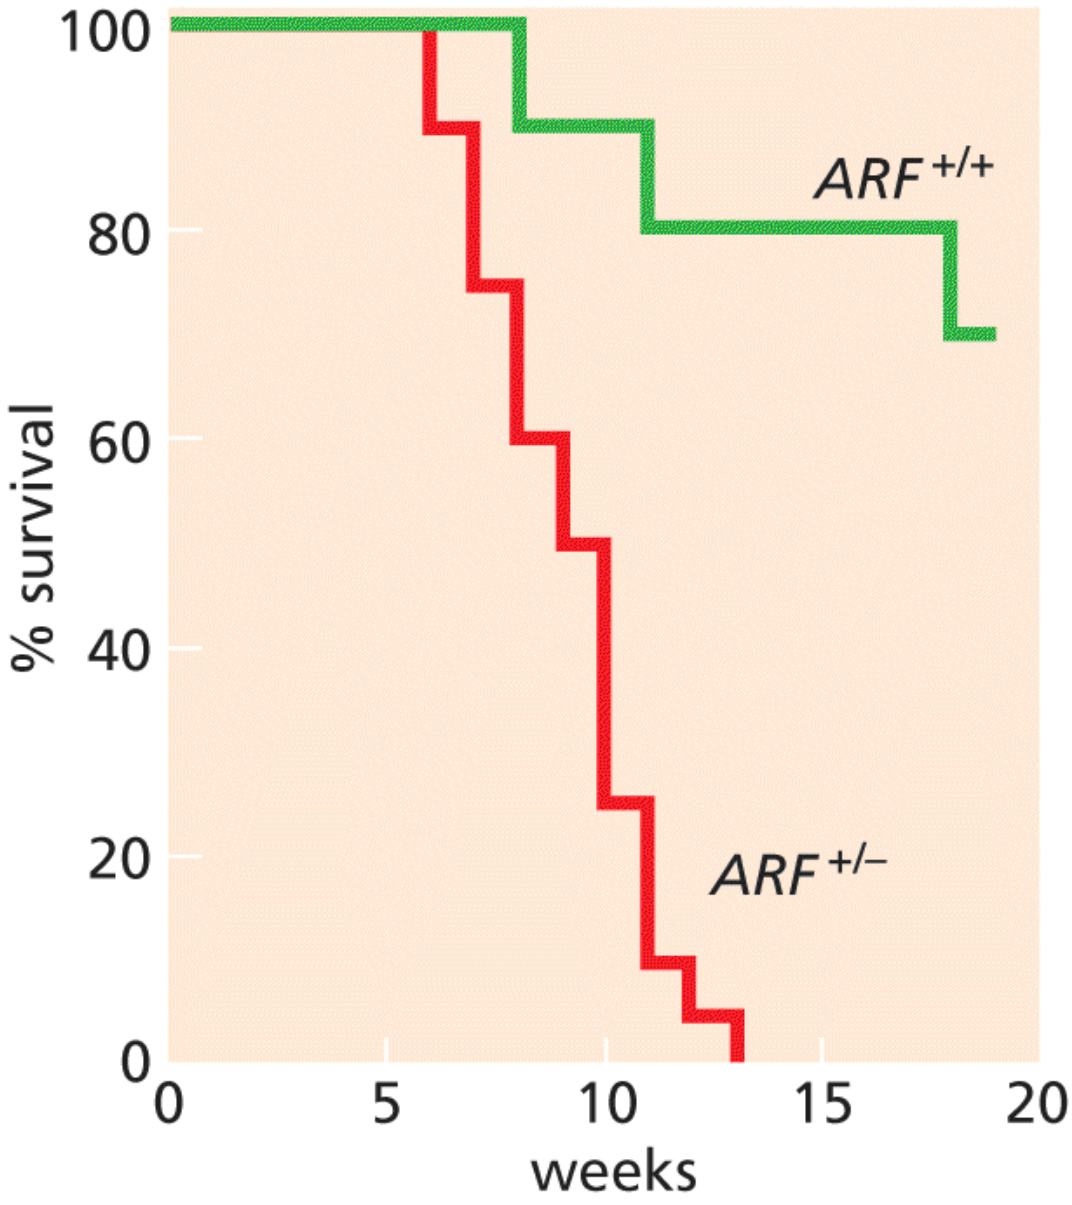
A sequence in which one of two things happens to M d m2. One possibility is that it binds, four at a time, to p53, after which the M d m twos are replaced by ubiquilation chains and the p53 is destroyed. The other possibility is that p14 A R effs produced through transcription initiated by E2F 1 2 3 D P 1 2 bind to the M d m twos and sequester them in the nucleolus. This leads to accumulation of p53 in the nucleoplasm.

(A)



A cascade in which E1A, c-M y c and R a s each activate E2F, which activates A R F, which inhibits M d m2, which inhibits p53, which promotes both cell

cycle arrest and apoptosis.
(B)



A line graph with percent survival on the vertical axis and time on the horizontal axis. Of wild-type mice, 100 percent survive 7 or 8 weeks. After that, the percentage drops in steps, to about 70 percent at 19 or 20 weeks. Of mice carrying an E mu m y c transgene known to cause B-cell lymphomas, 100 percent survive 6 weeks. After that, the percentage drops steeply, to zero by 13 weeks.

(C)

Figure 9.14 Control of apoptosis by ARF (A) The human $p14^{ARF}$ protein ($p19^{ARF}$ in mice), termed ARF in the figure (*light blue*), associates with and drags Mdm2 (*gold*) into the nucleolus, where it is sequestered. Once it is neutralized, Mdm2 can no longer tag p53 for destruction. Hence, elevated ARF levels cause increases in the levels of p53. [ARF can also add the ubiquitin-related SUMO groups to Mdm2 in the nucleolus (*not shown*).] (B) Transcription of the $p14^{ARF}$ gene is driven by E2F transcription factors composed of E2F1/2/3 and their DP1/2 partners (see also Figure 8.18). Various oncogenic signals favor apoptosis through their ability to induce E2F activity (see Sections 8.7 and 8.8), which leads, in turn, to increased ARF expression. Among these are the adenovirus E1A, and the Myc (c-Myc) and Ras oncoproteins. Thus, this signaling pathway seems to have evolved to eliminate cells with hyperactive E2F signaling driven by a variety of overly active mitogenic signals, specifically those released by various oncoproteins. (C) Mice that were engineered to be heterozygous for the *p19* gene ($ARF^{+/-}$) and wild-type mice ($ARF^{+/+}$) were mated with mice carrying an Eμ-*myc* transgene known to cause B-cell lymphomas (also described in Figure 9.20). The $ARF^{+/-}$ Eμ-*myc* mice (*red line*) developed fatal tumors far more rapidly than mice carrying only the Eμ-*myc* transgene (*green line*), and cells in these tumors shed their remaining wild-type *ARF* allele. Hence, in the absence of ARF function, the pro-apoptotic effects of a *Myc* oncogene (indicated in B) are largely lost, allowing survival of lymphoma cells and the proliferative effects of *Myc* to dominate and drive tumor formation. (B, from P.J. Iaquinta, A. Alanian, and J.A. Lees, *Cold Spring Harb. Symp. Quant. Biol*. 70:309-316, 2005. With permission from Cold Spring Harbor Laboratory Press. C, from F. Zindy et al., *Proc. Natl. Acad. Sci. USA* 100:15930–15935, 2003. With permission from National Academy of Sciences, U.S.A.)

Given the alliance between ARF and p53, one might predict that ARF, like p53, acts as a tumor suppressor. Indeed, inactivation of the $p16^{INK4A}/p14^{ARF}$ locus by genetic mutation or epigenetic promoter methylation (see Section 7.7) has been detected in many human tumors. Once a cell has lost ARF activity, it loses much of its ability to block Mdm2 function. As a consequence, Mdm2 is given a free hand to drive p53 degradation, and the cell is deprived of the services of p53 because the latter can never accumulate to functionally significant levels.

Because ARF has a central role in increasing p53 levels in many cellular contexts, the $p14^{ARF}$ gene is an extremely important TSG. Moreover, it seems likely that many of the human cancer cells that retain wild-type *p53* gene copies have eliminated p53 function by inactivating their two copies of the gene encoding ARF. We should note that the co-localization of the $p16^{INK4A}$ and $p14^{ARF}$ genes in the mammalian genome (see Figure 9.13) would seem to represent another dangerous concentration of power

leading to significant vulnerability for normal cells to oncogenic transformation (**Sidebar 9.4**).

Sidebar 9.4 Have mammalian cells placed too many eggs in one basket?

The discovery of the *p16*^{INK4A}/*p14*^{ARF} genetic locus, which is inactivated through one mechanism or another in about half of all human tumors, raises a provocative question: Why have mammalian cells invested a single chromosomal locus with the power to encode two proteins regulating the two most important tumor suppressor pathways, those of pRb and p53? Deletion of this single locus results in the simultaneous loss of normal regulation of both pathways. As was the case with *p53* itself, enormous power has been concentrated in a single genetic locus.

Placing two such vital eggs in a single genetic basket seems foolhardy for the mammalian cell, as it causes the cell to be vulnerable to two types of deregulation through loss of a single gene. To make matters even worse, the gene encoding p15^{INK4B}, another important regulator of pRb phosphorylation (see Section 8.4), is closely linked to the *p16*^{INK4A}/*p14*^{ARF} locus, indeed so close that all of these genetic elements are often lost through the deletion of only about 40 kb of chromosomal DNA. We have yet to discern the underlying rationale of this genetic arrangement. Maybe there is none, and perhaps mammalian evolution has produced a less-than-optimal design of its control circuitry.

OceanofPDF.com

Glossary

nucleoplasm
: The unstructured portion of the nucleus that does not include the nucleoli and chromosomes.

double-minute
: A chromosomal segment that becomes separated from the chromosome in which it normally resides and is able to perpetuate itself as an extrachromosomal particle unlinked to a centromere, so termed because it is visualized at metaphase as small spots that are doubled like the chromatids prior to anaphase.

negative feedback
: A regulatory process whereby a stimulatory signal upstream in a signaling pathway activates a downstream target that proceeds to inhibit the source of the initial upstream signal, thereby reducing further overall signaling. *See also* **positive feedback**.

9.9 ARF and p53-mediated apoptosis protect against cancer by monitoring intracellular signaling

The influential role ARF plays in increasing p53 levels raises the question of how ARF itself is regulated. The response to this question relates to our discussion of the pRb pathway in Chapter 8, and to the fact that mammalian cells are very sensitive to higher-than-normal levels of E2F1 activity. Indeed, cells seem to monitor the activity level of this particular transcription factor (together with that of E2F2 and E2F3) as a means of detecting whether their pRb circuitry is functioning properly: excessively high levels of active E2F transcription factors are a telltale sign that pRb function has gone awry and that entrance into senescence or apoptosis must quickly be triggered for the benefit of the tissue and organism.

It turns out that the $p14^{ARF}$ gene carries at least four E2F-binding sequences in its promoter (see Figure 9.13), and high levels of E2F1, E2F2, or E2F3A activity indeed induce production of $p14^{ARF}$ mRNA. When the ARF protein appears on the scene, it blocks Mdm2 action and p53 accumulates as described earlier. The elevated levels of p53 then trigger apoptosis. The signaling cascade is configured like this:

pRB —| E2F → ARF —| Mdm2 —| p53 → apoptosis

In fact, evolution has devised yet other ways to eliminate cells that carry too much E2F activity and, by implication, have lost proper pRb control. Runaway E2F1 activity drives expression of a number of genes that encode proteins that participate directly in the apoptotic program (to be described below). Included among these genes are those encoding several caspases (types 3, 7, 8, and 9), pro-apoptotic Bcl-2–related proteins (Bim, Noxa,

PUMA), Apaf-1, and p53's cousin, p73; these proteins collaborate to drive cells into apoptosis. We will learn more about them later.

These various mechanisms conspire to ensure triggering of the p53-dependent apoptotic program in response to excessive E2F activity. As an example, such E2F-initiated apoptosis contributes to lethality in mouse embryos that have been deprived of both copies of their *Rb* gene. These mice die in mid-gestation from the excessive proliferation and concomitant apoptosis of certain critical cell types, including those involved in erythropoiesis (formation of red blood cells) and in placental function.

Some of the effects of the *E1A* and *Myc* oncogenes are related to this mechanism as well. Both deregulate pRb control and are highly effective in inducing apoptosis. The adenovirus E1A oncoprotein binds and effectively sequesters pRb and its cousins, whereas Myc, for its part, induces changes in cell cycle control machinery that ensure that pRb is inactivated through phosphorylation (see Sections 8.5 and 8.8).

Many studies of *Myc* oncogene function indicate that this gene has both potent mitogenic and pro-apoptotic functions. Indeed, the pro-apoptotic effects of *Myc* are so strong that it is highly likely that most cells that happen to acquire an activating *Myc* mutation are rapidly eliminated through apoptosis. Only when the pro-apoptotic program of Myc is blunted or inactivated do its mitogenic actions become apparent.

As an example, when a *Myc* oncogene becomes activated in the lymphoid tissues of a mouse, it prompts a substantial increase in cell proliferation. However, there is no net increase in cell number because the newly formed cells are rapidly lost through apoptosis. If one of the *Myc* oncogene–bearing cells happens subsequently to inactivate its *p53* gene copies, then *Myc*-induced apoptosis is diminished and the cell proliferation driven by the oncogene leads to a net increase in the pool of mutant lymphoid cells. As might be expected from the organization of the pathway shown in Figure 9.14B, a similar effect occurs when one allele of the gene encoding ARF has been knocked out (Figure 9.14C). Loss of the remaining, wild-type *ARF* allele disrupts the pathway linking *Myc* over-expression to p53-dependent apoptosis, resulting in the development of lymphoma.

Although we have focused here on the role of the pRb–E2F axis in activating ARF, at least one other major oncogenic signaling pathway can also contribute significantly to increased ARF expression and thus to p53 activation: the signaling pathway downstream of Ras (see Figure 9.14B). Hyperactive signaling by Ras or its immediate downstream partners, Raf or B-Raf (see Figure 6.9A), drives increased ARF expression and p53 activation. The induction of p53 imposes great selective pressure on incipient cancer cells that experience intense Ras oncoprotein signaling, forcing them to either neutralize p53 function or to confront rapid elimination by p53-dependent apoptosis or senescence.

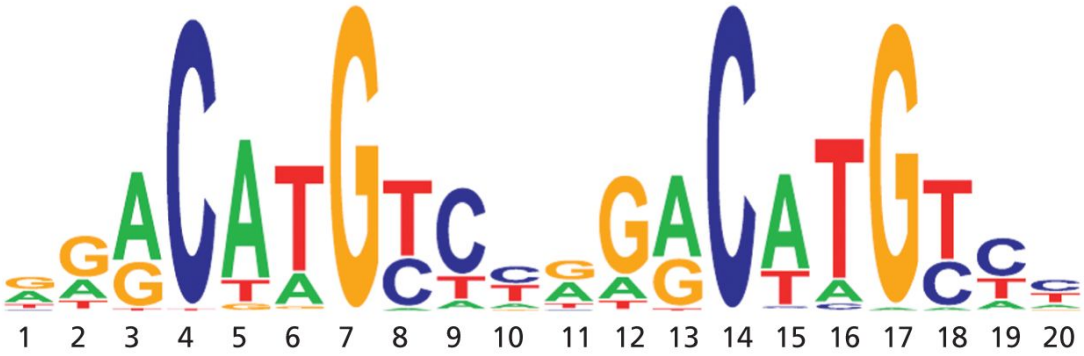
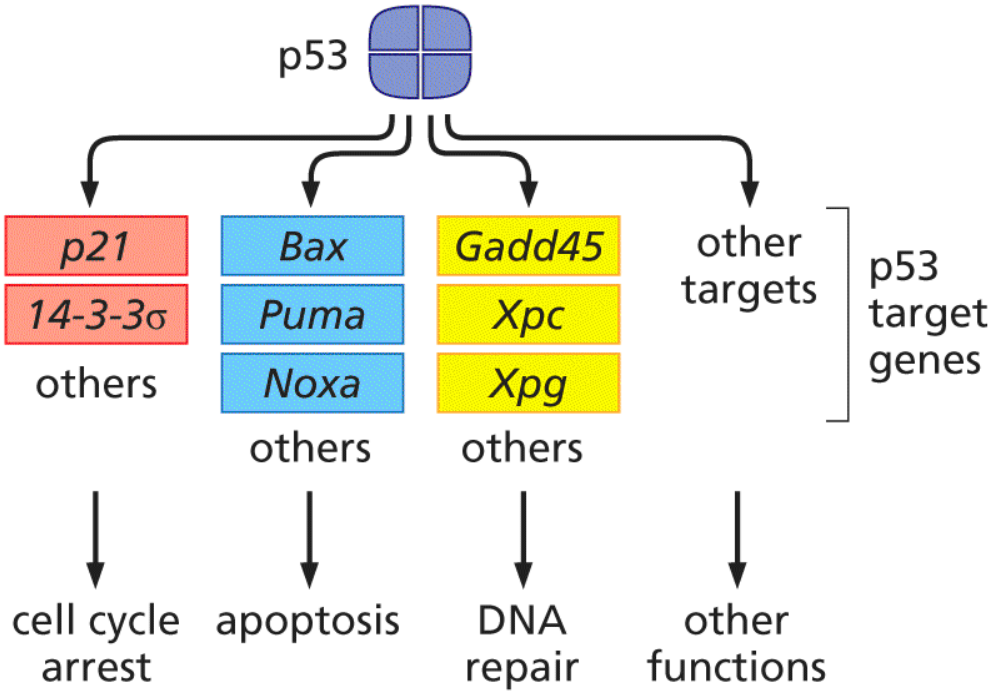
9.10 p53 functions as a transcription factor that halts cell cycle advance in response to DNA damage and attempts to aid in the repair process

The p53 protein functions by activating the expression of a diverse set of target genes. Its DNA-binding domain consists of a recognition sequence composed of 10 nucleotides repeated twice in tandem, separated by up to 20 nucleotides of random sequence (**Figure 9.15A**). This recognition sequence is present in the promoters or initial introns of dozens of p53 target genes, which collectively control the various downstream functions of p53 (Figure 9.15B). The great majority (>90%) of the mutant *p53* alleles found in human tumor cell genomes contain amino acid substitutions in the DNA-binding domain of p53 (see Figure 9.6). These mutations eliminate p53's ability to bind to its recognition sequences, thereby rendering the mutant protein unable to exert most of its multiple functions. Furthermore, as discussed above, p53 tetramers that contain even one mutant p53 subunit appear to have a reduced ability to bind DNA.



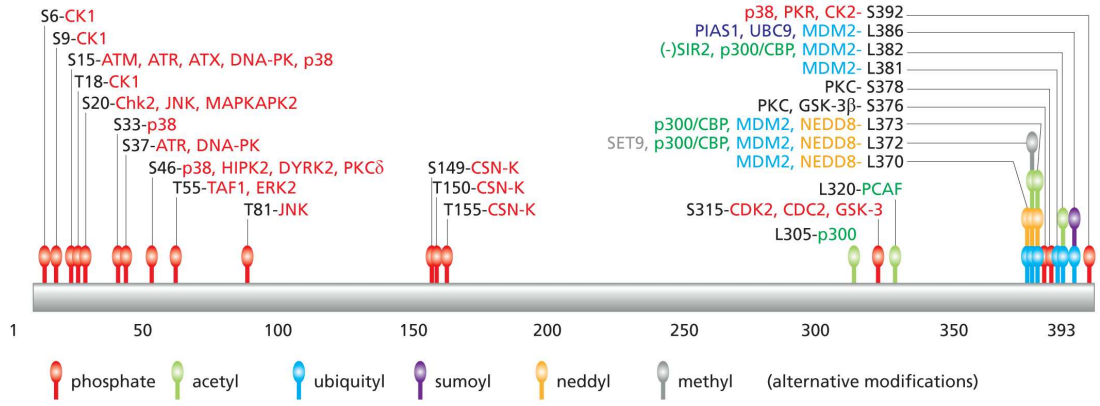
A consensus oligonucleotide sequence that is 20 nucleotides long. Position 4 has a large C, position 7 has a large G, position 14 has a large C, and position 17 has a large G, indicating at these positions, cytosine and guanine have very high frequencies of occurrence. Positions 5 and 6 and positions 15 and 16 each have medium sized ayze and tees, indicating less consensus but high likelihood of adenine or thymine. Other positions have smaller letters, indicating less consensus during sequencing.

(A)



A diagram showing some of the many target genes in which p53 induces expression. These include p21, 14 3 3 sigma, and others that trigger cell cycle arrest; Bax, Puma, Noxa and others that trigger apoptosis, Gadd 45, X p c, X p g, and others that trigger D N A repair, and other genes with other functions.

(B)



A detailed chart of post-translational modifications of p35, distributed over 393 numbered amino acid residues. There are many points of phosphate group attachment at positions 1 through 155, and points of attachment for groups of different types from position 300 on. The different group types are phosphate, acetyl, ubiquityl, sumoyl, neddyl, and methyl.

(C)

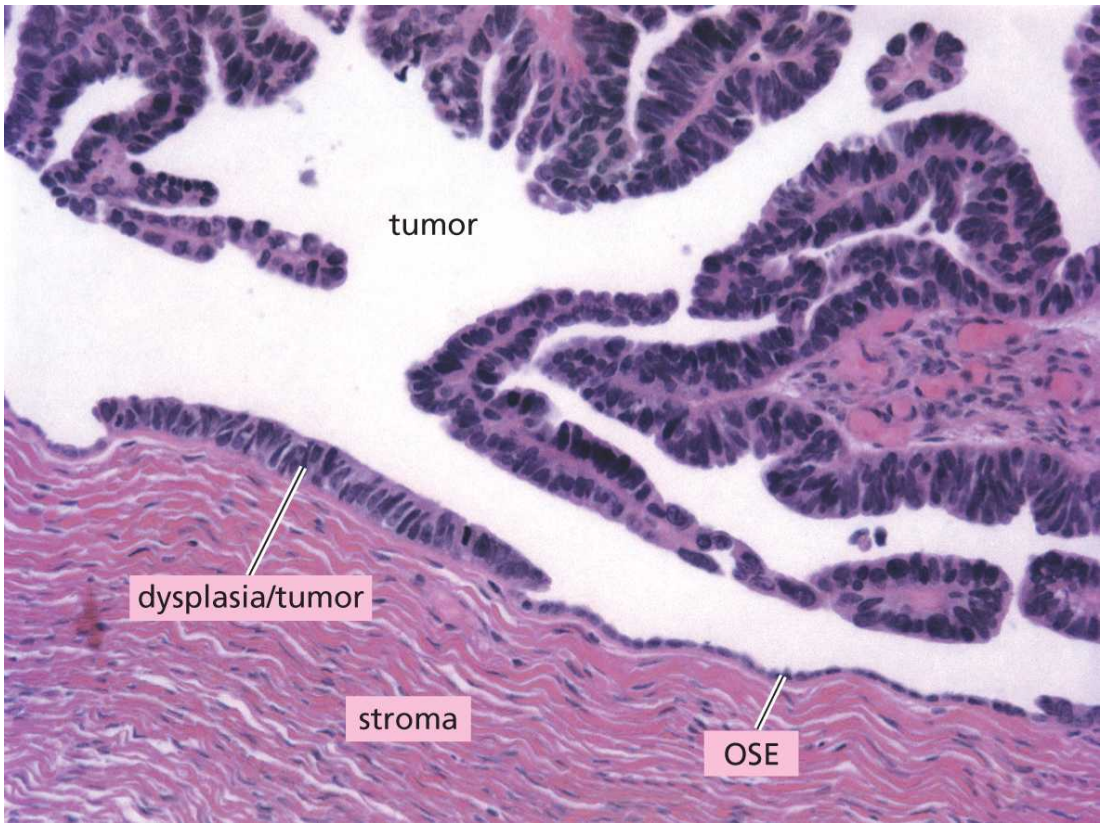
Figure 9.15 p53 functions as a transcription factor (A) The consensus oligonucleotide sequence recognized by p53. The sequence was determined by immunoprecipitation of p53–DNA complexes in human cells stressed by exposure to the drug actinomycin, a potent inhibitor of transcription and thus inducer of increased p53 levels. In more detail, the chromatin immunoprecipitation (ChIP) procedure employed anti-p53 antibodies to isolate p53–DNA complexes present in the chromatin of these actinomycin-treated cells. The DNA fragments in the immunoprecipitates were subsequently sequenced, which led to the identification of 1546 sites in the human genome to which p53 is bound; nucleotides that recurred frequently at a particular position in the immunoprecipitated DNA fragments are indicated in *large font* letters, and those that recurred less frequently are indicated by *smaller font* letters. As is apparent, p53 tetramers appear to bind to two similar octanucleotide sequences that are separated from one another by (in this case) two intervening nucleotides; far more intervening nucleotides may separate the two octanucleotide binding sites in other promoters. Interestingly, the majority of these 1546 sites were also recognized and bound by p53's cousins, p63 and p73, also discussed in this chapter. (B) p53 induces expression of a variety of genes involved in growth arrest, apoptosis, and DNA repair. Examples of genes involved in each response are shown, although many more are known. (C) The phosphorylation of p53 by various kinases (see Figure 9.9) represents only one type of post-translational modification (PTM) that is important to its functioning. In addition to the attachment of phosphate groups (*red*), other enzymes modify the protein by attaching acetyl (*green*), ubiquityl (*blue*), sumoyl (*purple*), neddyl (*yellow*), and methyl (*gray*) groups at the indicated amino acid residues and residue numbers (*black type*). The identities of the modifying enzymes are indicated (*various font colors*) next to the amino acid residue numbers. Only a small portion of these PTMs have been linked to specific p53 functions. Moreover and as an example, one of these PTMs, phosphorylation of serine 46, is accomplished by any of four distinct kinases and activates the pro-apoptotic functions of p53. Both neddyl and sumoyl groups are similar to ubiquityl groups but have very different effects on the proteins to which they become attached. A 2014 proteomics report describes as many as 150 distinct PTMs of p53. The functional consequences of these PTMs are largely unknown. (A, from L. Smeenk et al., *Nucleic Acids Res.* 36:3639–3654, 2008. With permission from Oxford University Press. C, Courtesy of K.P. Olive and T. Jacks.)

In addition to binding to its recognition sequence, p53 must interact with other factors that modulate its transcriptional functions. These interactions are governed by a complex array of covalent modifications to the p53 protein, including acetylation, glycosylation, methylation, phosphorylation, ribosylation, and sumoylation—

involving the attachment of, respectively, acetyl, sugar, methyl, phosphate, ribose, and sumo groups (the latter being a ubiquitin-like peptide that appears to target proteins for localization to specific intracellular sites, often in the nucleus; Figure 9.15C). Phosphorylation of p53's N-terminal transactivation domain (see Figure 9.6B), for example, can increase the protein's ability to bind the p300 co-activator as well as other transcription co-activators. Recruitment of p300 contributes to transcriptional activation by acetylating nearby histones H3 and H4 as well as p53 itself. Indeed, it is highly likely that combinatorial interactions of p53 with other transcription factors determine the identities of the specific target genes that are activated in various circumstances by p53.

In addition to functioning as a transcriptional activator, it is now clear that p53 can repress the expression of certain genes as well. However, the mechanisms underlying p53's transcriptional repression functions are less well understood. We therefore focus our attention on p53's ability to activate the expression of target genes.

One key target of the p53 transcription factor, as discussed earlier, is the *Mdm2* gene, the induction of which leads to a negative-feedback loop that functions to ensure the very low steady-state levels of p53 protein observed in normal, unperturbed cells. The operation of this p53–Mdm2 feedback loop explains a curious aspect of p53 behavior: in human cancer cells that carry mutant, defective *p53* alleles, the p53 protein is almost invariably present in high concentrations (**Figure 9.16**). At first glance, this might appear paradoxical, because high levels of a growth-suppressing protein like p53 would seem to be incompatible with malignant cell proliferation. However, because mutant p53 is unable to induce the expression of Mdm2 (among its other downstream target genes), this mutant, functionally inactive protein escapes Mdm2-driven degradation and accumulates to very high levels. This logic explains why the presence of readily detectable p53 in a population of tumor cells, usually revealed by immunostaining (see Figure 9.16), is a telltale sign of the presence of a mutant *p53* allele in the genome of these cells. (Such a conclusion cannot be drawn, however, from analyzing human tissue that has recently been irradiated because radiation can also evoke the widespread expression of p53 throughout a tissue for days, even weeks after radiotherapy.) The large amounts of p53 protein in SV40-infected or SV40-transformed cells can be explained analogously: in this case, sequestration of p53 by the viral large T antigen prevents p53-induced expression of the *Mdm2* gene and resulting p53 degradation. According to one measurement, when large T is expressed in previously normal cells, the half-life of p53 increases from 20 minutes to 24 hours. Alternatively, in cancer cells carrying wild-type *p53* alleles, the presence of chronic DNA damage signals as well as oncogene-induced stress signals may also contribute to the high levels of the p53 protein.



A histology image showing the accumulation of the p53 protein in p53-mutant cells. Across the bottom of the image is a relatively smooth, continuous mass of normal, pink stroma cells bordered by ovarian surface epithelium, or O S E. One part of the border of the stroma tissue, however, is made up of a thick band of cells stained dark blue; these are labeled dysplasia slash tumor. The upper part of the image is filled with irregular masses of dark-stained tissue, looking like many islands in a bay. This part of the image is labeled tumor.

Figure 9.16 Accumulation of p53 in *p53*-mutant cells This microscope section of ovarian tissue has been stained with an anti-p53 antibody coupled to the peroxidase enzyme, resulting in the blackened nuclei seen here. Large patches of epithelial cells in an ovarian carcinoma (*above*) are composed of cells that have high levels of p53; a patch of dysplasia (*left middle*) is also p53-positive. This staining pattern is an indication that relatively early in the course of tumor progression, the dysplastic precursors to this carcinoma already sustained a *p53* somatic mutation. Stromal cells (*small black nuclei, pink matrix, below*) are unstained, as is a patch of normal ovarian surface epithelium (OSE, *below, right*). (Courtesy of R. Drapkin and D.M. Livingston.)

Mdm2 is only one of a large cohort of genes whose expression is induced by p53. As mentioned earlier, another highly important target gene is *p21^{Cip1}* (sometimes called *Cdkn1a* in the mouse), which is key to p53's ability to arrest progression through the cell cycle. In fact, the gene encoding p21^{Cip1} was originally discovered in an effort to uncover genes whose expression is increased by p53. Soon after its discovery, it became apparent that p21^{Cip1} functions as an important inhibitor of a number of the cyclin-dependent kinases (CDKs). The ability of p21^{Cip1} to inhibit two CDKs—CDK2 and CDK1/CDC2—that are active in the late G_1, S, G_2, and M phases of the cell cycle (see Figures 8.6 and 8.11A) explains how p53 is able to block forward progress at multiple points in this cycle.

The consequences of p53 activation can differ at different points in the cell cycle (see Figures 8.6 and 8.11A). For example, if a cell suffers DNA damage during the G_1 phase of the cell cycle, p53 will become activated and will induce p21^{Cip1} synthesis; p21^{Cip1}, in turn, will halt further cell proliferation. At the same time, components of the cellular DNA repair machinery will be mobilized to repair the damage. The genes encoding some of these repair proteins are directly induced by p53. As such, cells lacking functional p53 are unable to efficiently repair the DNA lesions caused by agents such as benzo[*a*]pyrene (a potent carcinogen present in tars) or the cyclobutane pyrimidine dimers caused by ultraviolet (UV) radiation (described in Chapter 12). In addition, DNA polymerase β, which plays a critical role in reconstructing DNA strands after chemically altered bases have been excised by DNA repair proteins, is much less active in p53-negative cells than in their wild-type counterparts. We will return to these DNA repair proteins and their mechanisms of action in Chapter 12. In the event that the DNA is successfully repaired, the signals that have protected p53 from destruction (see Figure 9.12) will disappear and the concentrations of p53 and, in turn, of p21^{Cip1}, will fall. In the absence of p21^{Cip1}, cell cycle progression will resume, enabling cells to enter S phase, where replication of the now-repaired DNA can proceed.

The rationale for this series of steps is a simple one: by halting cell cycle progression in G_1, p53 prevents a cell from entering S phase and inadvertently copying still-unrepaired DNA, which could be passed on to daughter cells. The importance of these cytostatic actions of p21^{Cip1} can be seen from the phenotype of genetically altered mice in which both germ-line copies of the *p21^{Cip1}* gene have been inactivated. Although not as tumor-prone as p53-null mice, they show an increased incidence of tumors late in life.

If, alternatively, a cell suffering DNA damage has already advanced into S phase and is therefore in the midst of actively replicating its DNA, the p21^{Cip1} induced by p53 can engage the DNA polymerase machinery at the replication forks and halt its further

advance along the DNA template molecules. It does so by binding PCNA (proliferating-cell nuclear antigen), which interacts, in turn, with the key DNA polymerases δ and ε, thereby blocking further advance of replication forks along the DNA. Once again, the effect here is to hold DNA replication in abeyance until DNA damage has been successfully repaired.

In addition, the p53 protein uses yet other genes and proteins to halt further cell cycle advance. For example, p53 induces the expression of 14-3-3σ(see Figure 9.15B), which helps to govern the G_2/M transition. The 14-3-3σ protein, for its part, sequesters the cyclin B–CDC2 complex in the cytoplasm, thereby preventing it from moving into the nucleus, where its actions are required to drive the cell into mitosis; a similar mechanism allows 14-3-3σ to bind and sequester the Cdc25A, Cdc25B, and Cdc25C phosphatases, whose actions are also required for entry into mitosis. This mechanism delays mitosis until the chromosomal DNA is determined to be in good repair.

These extensive actions of p53 have caused some to portray this protein as the "guardian of the genome." By preventing cell cycle advance and DNA replication while chromosomal DNA is damaged and by inducing expression of DNA repair enzymes, p53 can reduce the rate at which mutations accumulate in cellular genomes. Moreover, in the event that severe DNA damage has been sustained (for example, damage that exceeds a cell's ability to repair DNA), p53 may trigger apoptosis, thereby eliminating mutant cells and their damaged genomes. This outcome contrasts with the behavior of cells that have lost p53 function: they may replicate their damaged, still-unrepaired DNA, and this can cause them to exhibit relatively mutable genomes—that is, genomes that accumulate mutations at an abnormally high rate per cell generation.

In one particularly illustrative experiment, pregnant $p53^{+/-}$ mice that had been bred with $p53^{+/-}$ males were treated with the highly mutagenic carcinogen ethylnitrosourea (ENU). Of the pups that were subsequently born with the $p53^{-/-}$genotype, 70% developed brain tumors; only 3.6% of the $p53^{+/-}$ pups developed similar tumors, whereas none of those that were $p53^{+/+}$ did. Hence, in the absence of p53 function, fetal cells that had been mutated by ENU could survive and spawn the progeny forming these lethal tumors.

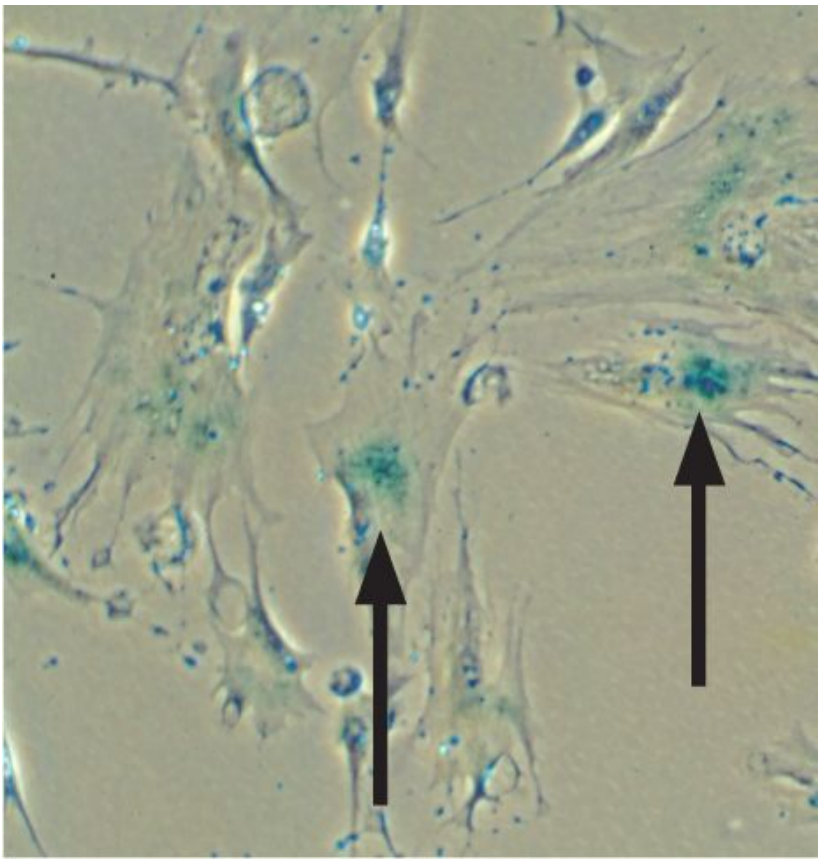
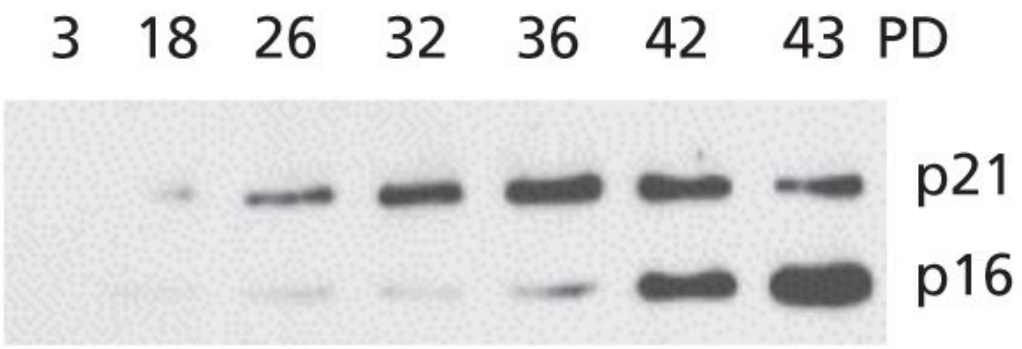
9.11 Prolonged DNA damage and oncogene activation can induce p53-dependent senescence

As described above, p53 can orchestrate entrance into apoptosis or impose a temporary cell cycle arrest. In fact, as part of its anti-neoplastic functions, p53 can also induce a more permanent form of cell cycle arrest cited above and termed senescence. First observed in experiments performed in the mid-1960s using cells prepared from rodent or human embryos, one form of senescence, “replicative senescence” was associated with limiting the life span of cells growing in tissue culture. Thus, after a certain number of population doublings, the cells would undergo an irreversible cell cycle arrest, accompanied by an enlarged surface area and a “fried egg” appearance (**Figure 9.17A**). Although metabolically active (sometimes for months), these senescent cells would no longer divide, even when presented with adequate nutrients and growth factors.



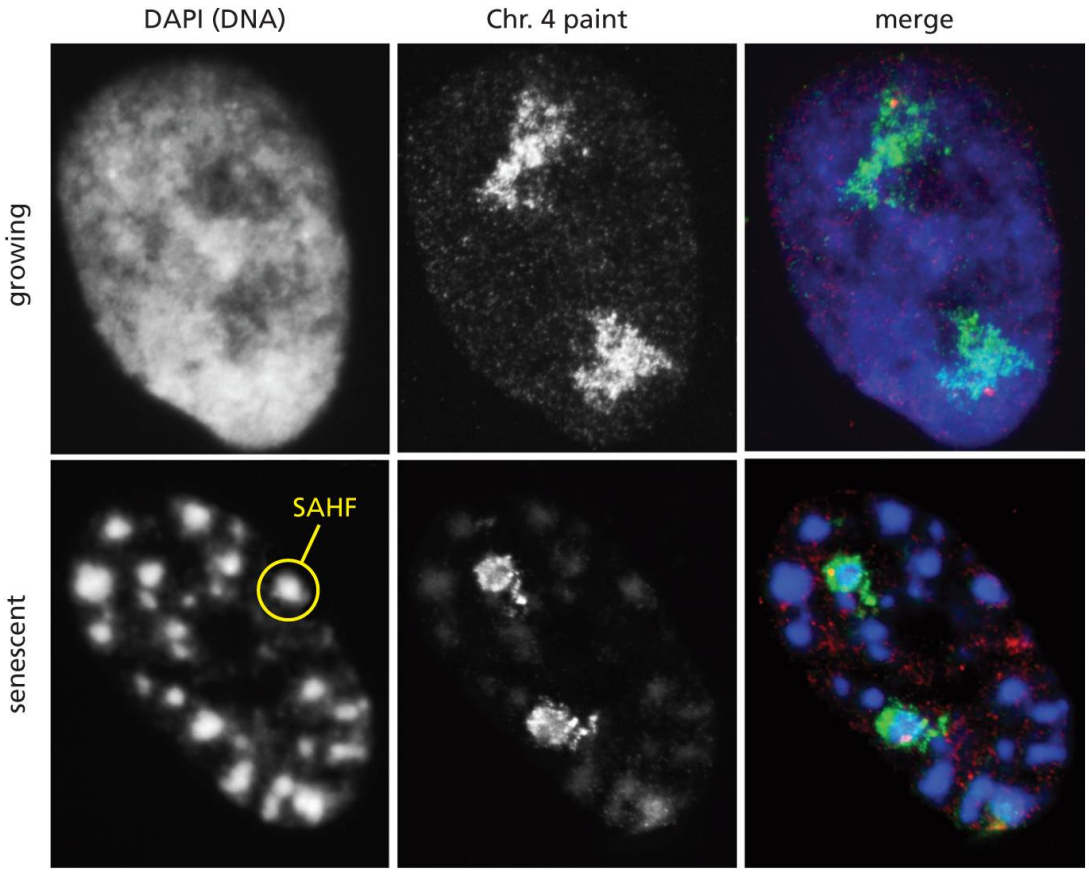
A micrograph of senescent cells, with arrows indicating blue patches in two of them.

(A)



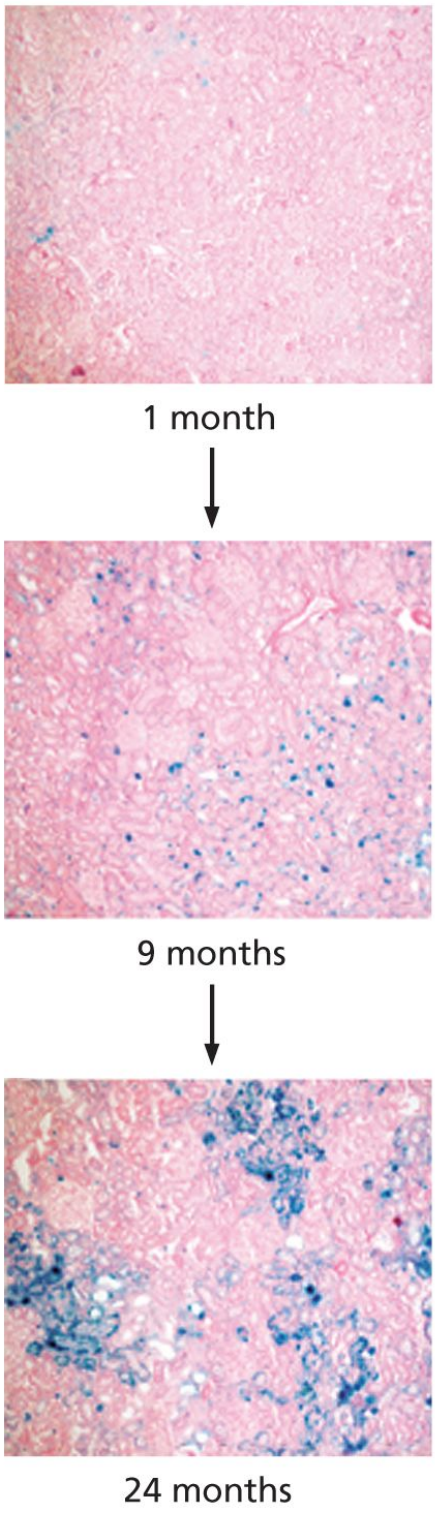
An autoradiograph for p21 and p16, showing cells at 3, 18, 26, 32, 36, 42 and 43 population doublings. For p21, the signature is strongest at 36 doublings; for p16, it is strongest at 43 doublings.

(B)



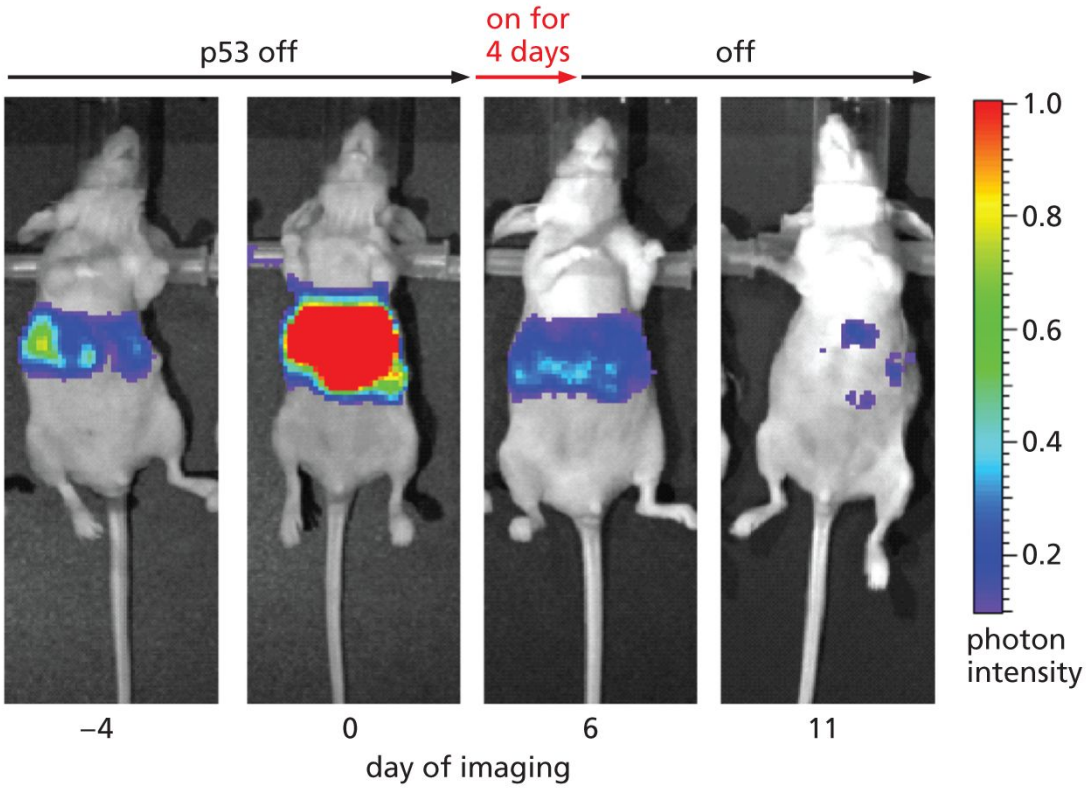
A 2 by 3 array of 6 images of a cell nucleus. In the left two images, D A P I staining shows chromosomal D N A distributed more or less evenly throughout the nucleus of a proliferating cell but congealed into clumps, Senescence-associated heterochromatin foci, in a senescent cell. In the middle two images, a paint specifically of chromosome 4 reveals two large areas in a proliferating cell and two much smaller, brighter areas in a senescent cell. The right two images are color composites merging the two preceding images for each type of cell.

(C)



Three stains in which proliferating cells appear pink and senescent cells appear blue. At age 1 month there are almost no senescent cells, at 9 months there are many specks of senescent cells, and at 24 months there are large patches of senescent cells.

(D)



Imaging of liver tumors in a mouse shows the tumors being allowed to grow for 4 days by shutting off p53 expression. The tumors shrink after p53 expression is turned on for 4 days, and they continue to shrink up to day 11, 7 days after p53 expression has been turned back off.

(E)

Figure 9.17 Senescent cells arise *in vitro* and *in vivo* (A) Cells that enter into senescence cease proliferating but remain viable. Many develop extremely large cytoplasms, giving them a “fried egg” appearance. Senescent cells also characteristically express acidic β-galactosidase enzyme, which can be detected by supplying them with a substrate that turns *blue* upon cleavage by this enzyme (*arrows*). (B) When adult human endometrial fibroblasts are propagated *in vitro*, expression of both the $p16^{INK4A}$ and $p21^{Cip1}$ CDK inhibitors (see Section 8.4) is induced, albeit with different kinetics. These cells have an expected life span of 40 to 43 population doublings (PD) in culture, whereupon they enter into senescence. Much of this senescence may reflect a response to the stresses suffered by cells being propagated under sub-optimal conditions of culture. (C) Senescence-associated heterochromatin foci (SAHF) arise during senescence and derive from covalent modifications of the N- and C-terminal tails of histones within the

nucleosomes (see Section 1.8). Human fibroblasts were induced to enter senescence through introduction of an activated *ras* oncogene (*lower row*). In the nuclei of control cells that continued active growth (*upper row*), the chromosomal DNA was dispersed throughout the nucleus, as indicated by the DAPI stain (*white*). In contrast, the DNA of the senescent cells was concentrated in a number of discrete foci—SAHFs. The use of *in situ* hybridization with a DNA probe specific for Chromosome 4 (Chr. 4 paint) revealed that the Chromosome 4 DNA was far more dispersed in the nuclei of growing cells than in the senescent cells. The overlap between these two imaging procedures (merge, *green*) shows that the DNA of each Chromosome 4 has coalesced into a single SAHF within a senescent cell. (The behavior of Chromosome 4 is presumed to be representative of the behavior of all other chromosomes, which were not analyzed here.) Other studies indicate that SAHFs represent chromosomal regions in which transcription is irreversibly repressed. (D) Kidney tissue from rats of the indicated ages was stained for the presence of senescence-associated β-galactosidase (SA-β-gal; *blue*). Observations like these indicate that normal aging is accompanied by increasing numbers of senescent cells within tissues. (E) In a mouse model of liver cancer pathogenesis, an activated H-*ras* oncogene was introduced into cultured hepatoblasts in which p53 expression was suppressed by an inducible siRNA vector construct (see **Supplementary Sidebar 1.5**). The cells were injected into the spleens of host mice, leading to their subsequent implantation in the liver. The resulting tumors were allowed to grow to a significant size (day 0), at which point expression of the siRNA construct was shut down for 4 days, permitting p53 function to return; p53 expression was then shut down once again for the remaining time of the experiment. By day 6, tumors were markedly smaller, and by day 11, they were almost undetectable. Because the tumors continued to shrink long after p53 expression was suppressed, the brief (4-day-long) period of p53 expression seems to have forced tumor cells to enter irreversibly into the post-mitotic senescence state, and the senescent cells were ostensibly cleared by cells of the innate immune system, such as the macrophages described in Chapter 15. Tumors were imaged *in vivo* through light released by a luciferase gene borne by the tumor cells. (A, courtesy of C. Scheel. B, from S. Brookes et al., *Exp. Cell Res*. 298:549–559, 2004. Melk et al., *Kidney Int.* 63:2134–2143, 2003. With permission from International Society of Nephrology. E, from W. Xue et al., *Nature* 445:656–660, 2007. With permission from Nature.)

We now know that senescence can be caused by a number of stimuli, including telomere shortening (which can induce a DNA damage response; see Section 10.4), exposure to high levels of reactive oxygen species (ROS), or other forms of chronic

DNA damage. Experiments that showed delayed induction of senescence following expression of the SV40 large T antigen—which inactivates both p53 and the pRB family of proteins (see Sections 8.5 and 9.1)—helped to establish that both of these tumor suppressor pathways are required for the induction of senescence.

Cells that are approaching senescence show increased levels of p53 as well as $p21^{Cip1}$. The cyclin kinase inhibitor $p16^{Ink4a}$ is also strongly induced in senescent cells, which causes pRB to be maintained in a hypo-phosphorylated state (see Section 8.5), contributing to the prolonged cell cycle arrest (Figure 9.17B). Under some conditions, senescent cells undergo pronounced changes in their chromatin, including trimethylation of histone 3 at lysine 9. This modification resembles that present in heterochromatin and likely contributes to the irreversibility of the senescent state. Indeed, nuclear regions of senescence-associated heterochromatin foci (SAHF) are used as a marker for cells that have undergone senescence rather than temporary cell cycle arrest (Figure 9.17C; see also **Supplementary Sidebar 10.3**).

Senescent cells can also be characterized by their secretion of a variety of pro-inflammatory cytokines, including several interleukins, IGFBPs, and TGF-β. The cytokines that are released as part of this senescence-associated secretory phenotype (SASP) include those that act in an autocrine fashion to promote senescence and those that act in a paracrine fashion to recruit pro-inflammatory cells of the innate immune system. Another commonly used marker of senescence is a senescence-associated isoform of β-galactosidase (SAβ-gal), which we already encountered in Figure 9.17A. Although this enzyme is not mechanistically required for senescence, it is frequently found to be upregulated in senescent cells and can be easily detected by incubating cells with the substrate X-gal at pH 6 (see Figure 9.17A).

If cellular senescence can limit the reproductive life span of cells in the body, as it does in tissue culture, this mechanism could represent a powerful form of tumor suppression. Indeed, as we discuss in greater detail in Chapter 10, overcoming senescence—and thereby achieving cellular immortality—is one of the commonly observed hallmark changes that transformed cells undergo on the path leading to the formation of advanced tumors. Cancer cells frequently mutate one or more of the tumor suppressor genes implicated in triggering senescence, suggesting that diversion of cells into this state may act as an effective barrier to tumorigenesis; still, the same genes and encoded proteins are also involved in regulating reversible growth arrest and apoptosis (see Figure 9.17B), which suggests alternative explanations for their inactivation that is observed in cells en route to high-grade malignancy.

There is accumulating evidence that cellular senescence does indeed occur in living tissues, including the detection of increasing numbers of cells that stain for SAβ-gal activity in aged mice and humans (Figure 9.17D). However, it remains to be determined whether senescence associated with aging, telomere shortening, or chronic

DNA damage is an effective anti-tumor mechanism in humans. In fact, there is a growing body of research literature demonstrating that an increase in inflammation, such as that caused by the SASP response, can actually create a pro-tumorigenic microenvironment (see Section 11.15). As such, in some settings, senescent cells in aging animals may actually *promote* cancer development.

Cellular senescence can also be induced in response to inappropriate oncogene expression, as first demonstrated by experiments examining the effects of introducing multiple copies of a *ras* oncogene into wild-type fibroblasts. Rather than driving unrestrained proliferation, the expression of this potent oncogene was found to cause the cells to undergo irreversible cell cycle arrest, accompanied by a rise in SA-β-gal expression and other markers of senescence. The central role of p53 in this response was shown by the finding that oncogenic Ras expression in p53-deficient fibroblasts failed to induce senescence and led instead to cellular transformation. Hence, a *ras* oncogene could collaborate with a mutant *p53* gene in generating transformed cells, illustrating the ability of multiple mutant genes within a cell genome to create neoplastic cells, a theme that we will explore in detail in Chapter 11.

Examples of **o**ncogene-**i**nduced **s**enescence (OIS) have been shown to limit the further development of the pre-neoplastic lesions in animal models as well as in human tissues. For example, in humans, melanomas can arise at low frequency from benign tumors called nevi (or moles), which can otherwise remain in a growth-arrested state for decades. Nevi frequently harbor mutations in the B-Raf oncogene but lack the additional mutations that are required for full melanoma development. These pre-neoplastic lesions have been shown to upregulate expression of the $p16^{Ink4a}$ gene and to induce SA-β-gal activity; expression of the oncogenic B-Raf protein in normal human or mouse melanocytes in culture likewise causes cell cycle arrest and multiple markers of senescence. Finally, using genetically engineered mouse models of cancer in which *p53* alleles can be switched on and off, researchers have observed that restoring p53 function can induce cellular senescence and profound tumor regression in certain mouse models of tumor development, the latter resulting from the actions of immune cells in clearing the senescent cancer cells created by the restored p53 function (Figure 9.17E). These data strongly support the notion that OIS is a hardwired cellular response mechanism designed to eliminate cells that have activated certain oncogenes. Accordingly, OIS can operate as an important tumor-suppressive mechanism and the accumulation of inactivating mutations in *p53* and in genes specifying other mediators of the senescence program may be required in order for incipient cancer cells to circumvent this fate.

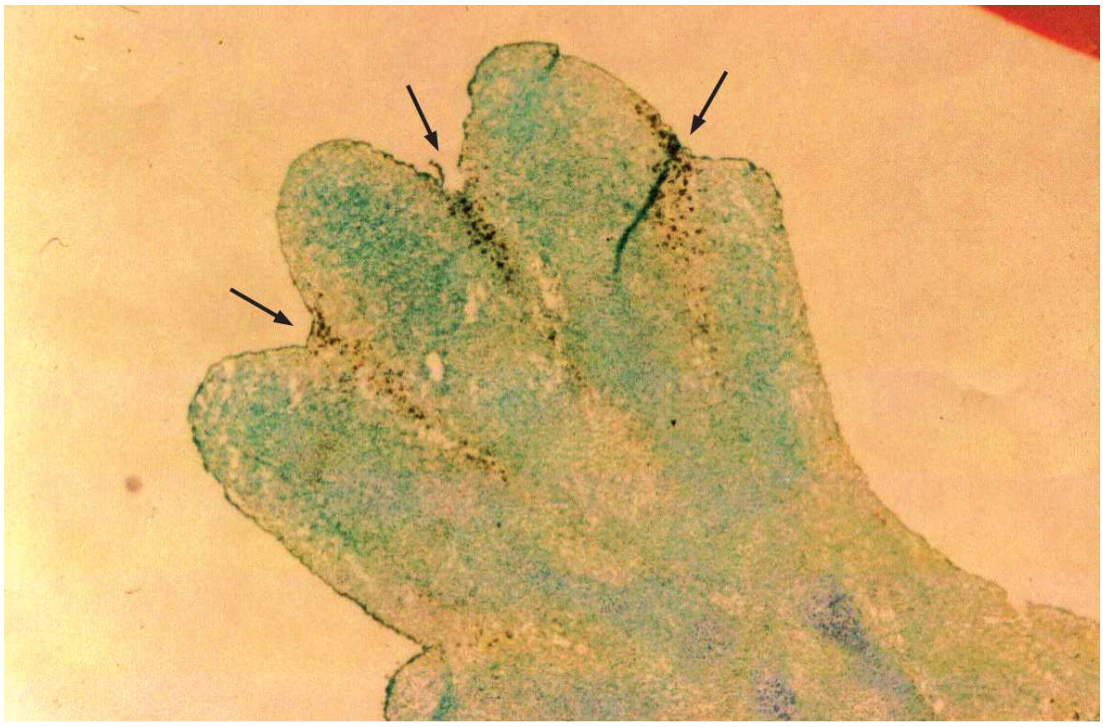
9.12 The apoptosis program participates in normal tissue development and maintenance

We have introduced the role of p53 in inducing apoptosis as a protective mechanism for eliminating damaged or pre-cancerous cells. However, this cell suicide program has a larger role in the organism beyond the removal of cells that teeter on the brink of malignancy. Apoptosis is used routinely during normal morphogenesis to chisel away unneeded cell populations during the sculpting of well-formed, functional tissues and organs (**Figure 9.18**). Mice that have been genetically deprived of various key components of the apoptotic machinery show a characteristic set of developmental defects, including excess neurons in the brain, facial abnormalities, delayed removal of the webbing between digits, and abnormalities in the palate and lens. In the case of the developing brain, more than half of all initially formed neurons are normally eliminated by apoptosis during formation of various neural circuits.



An embryonic mouse paw appears green. Between the nubs that will develop into digits, tiny streaks of black grains are visible, as indicated by arrows.

Figure 9.18 Apoptosis and normal morphogenesis The webs of tissue between the future toes of a mouse paw are still in evidence in this embryonic paw. They were preferentially labeled, as indicated by the numerous dark dots (*arrows*), using the TUNEL assay (see Supplementary Sidebar 9.3). As in humans, the apoptosis of cells forming the webs ultimately results in the formation of digits that are joined by webs only near the palm. (Courtesy of Z. Zakeri.)

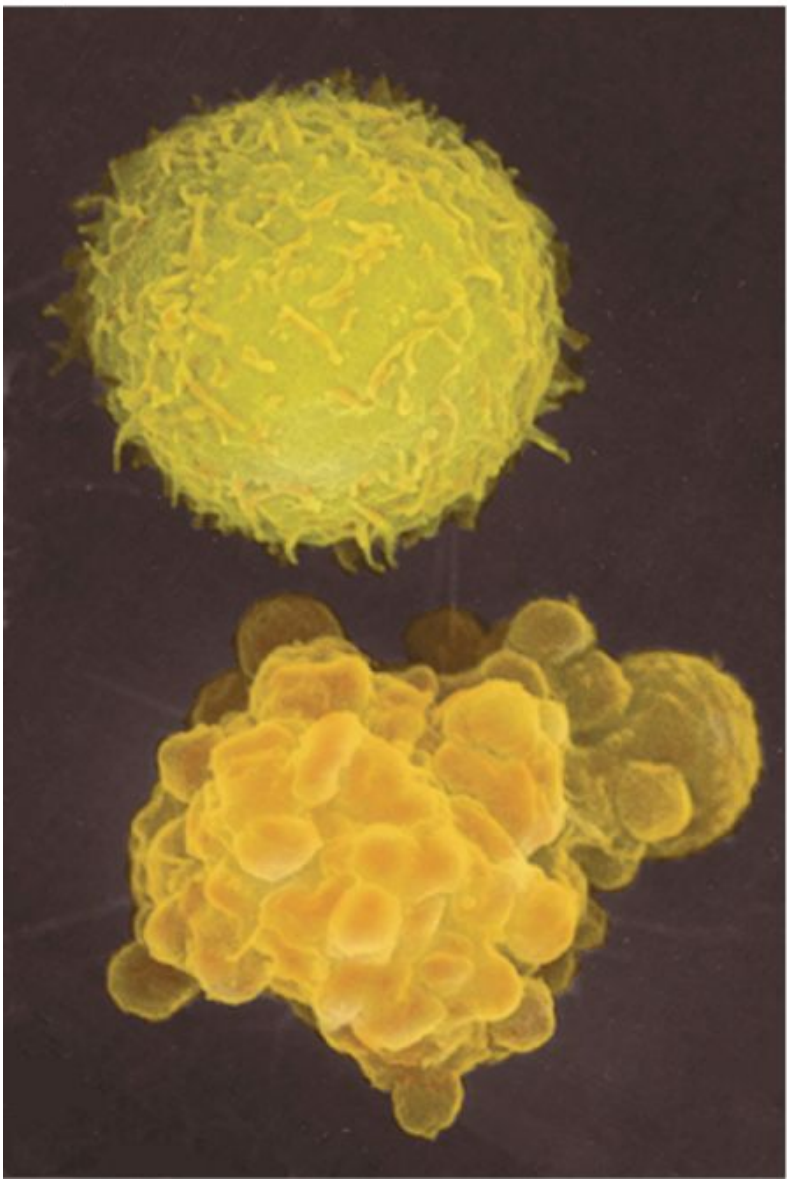
Apoptosis also plays an important role in normal adult tissue physiology. In the small intestine, for example, epithelial cells are continually being eliminated by apoptosis after a four- or five-day journey from the bottom of intestinal crypts to the tips of the villi that protrude into the lumen (see Section 7.10). During the development of red blood cells (the process of erythropoiesis), more than 95% of the erythroblasts—the precursors of mature red cells—are destroyed as part of the routine operations of the bone marrow. However, in the event that the rate of oxygen transport by the blood falls below a certain threshold level—as a result of hemorrhage, various types of anemia, or low oxygen tension in the surrounding air—a rapid rise in the concentration of the blood-forming hormone erythropoietin (EPO; see Section 5.7) blocks apoptosis of these erythrocyte precursors, enabling their maturation into functional red blood cells. This mechanism yields a rapid increase in the levels of these cells in the blood.

The regression of the cells in the mammary gland following the weaning of offspring is a particularly dramatic example of the contribution of apoptosis to normal physiology. As many as 90% of the epithelial cells in the mammary gland, which have accumulated in large numbers during pregnancy to produce milk for the newborn, die via apoptosis during this regression, which is usually termed involution.

In a more general sense, apoptosis is used to maintain appropriate numbers of different cell types in a wide variety of human tissues. The importance of this process is indicated by the turnover of cells—the number that are newly formed and the equal number that are eliminated in each year of our lives—which exceeds by a factor of ~4 the total number of cells ($\sim 3 \times 10^{13}$) present in the adult body at any one time. Most of these discarded cells appear to be eliminated by apoptosis.

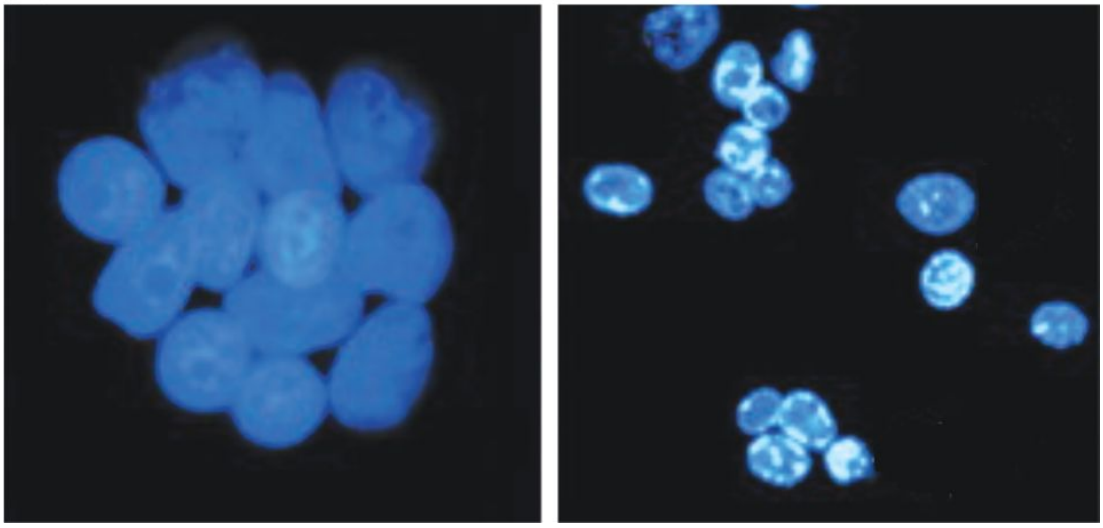
As observed through the microscope, the cellular changes that constitute the apoptotic program proceed according to a precisely coordinated schedule. Within minutes, patches of the plasma membrane herniate to form structures known as blebs; indeed, in time-lapse movies, the cell surface appears to be boiling. The nucleus collapses into a dense structure—a state termed pyknosis—and fragments, as the chromosomal DNA is cleaved into small segments. Ultimately, usually within an hour, the apoptotic cell breaks up into small pieces, sometimes called *apoptotic bodies*, which are rapidly ingested by neighboring cells in the tissue or by itinerant macrophages, thereby

removing all traces of what had recently been a living cell. These changes are illustrated in **Figure 9.19**.



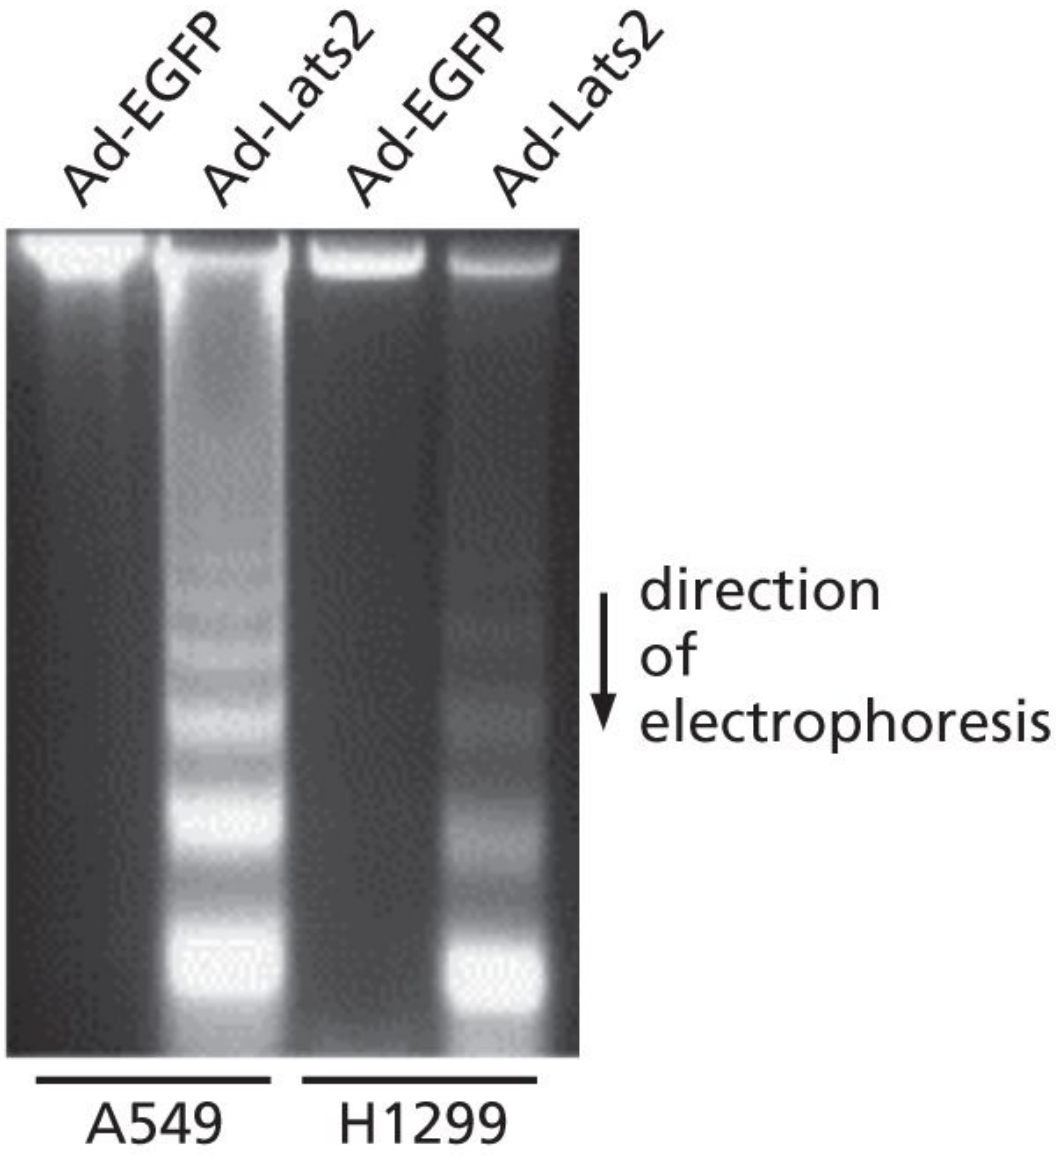
Two lymphocytes shown in yellow. The upper one is round and fuzzy, while the lower one is irregular in shape and lumpy in texture.

(A)



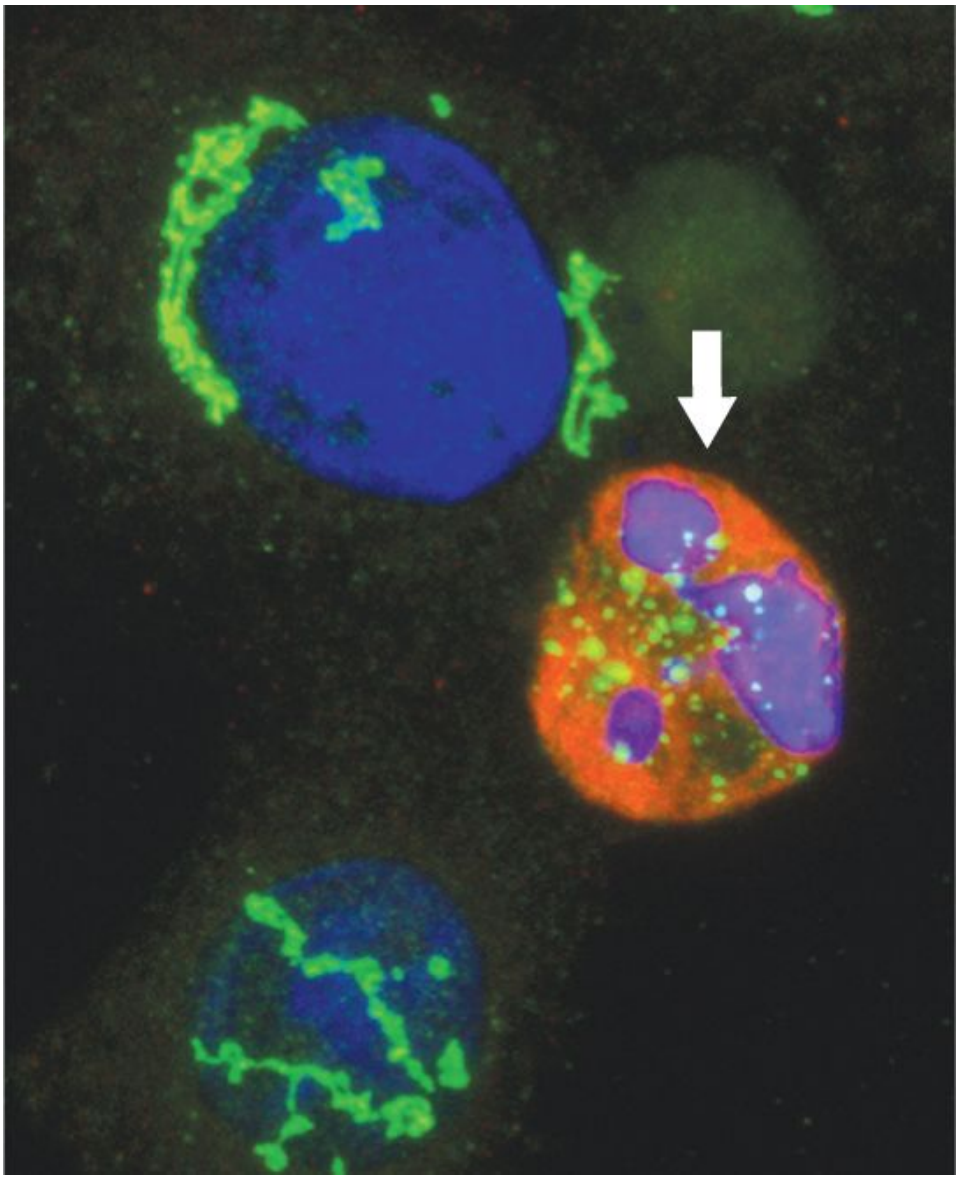
A cluster of plump, blue stained nuclei looking like a bowl of grapes, and beside it an image of scattered nuclei, some mottled white, looking like moldy blue raisins.

(B)



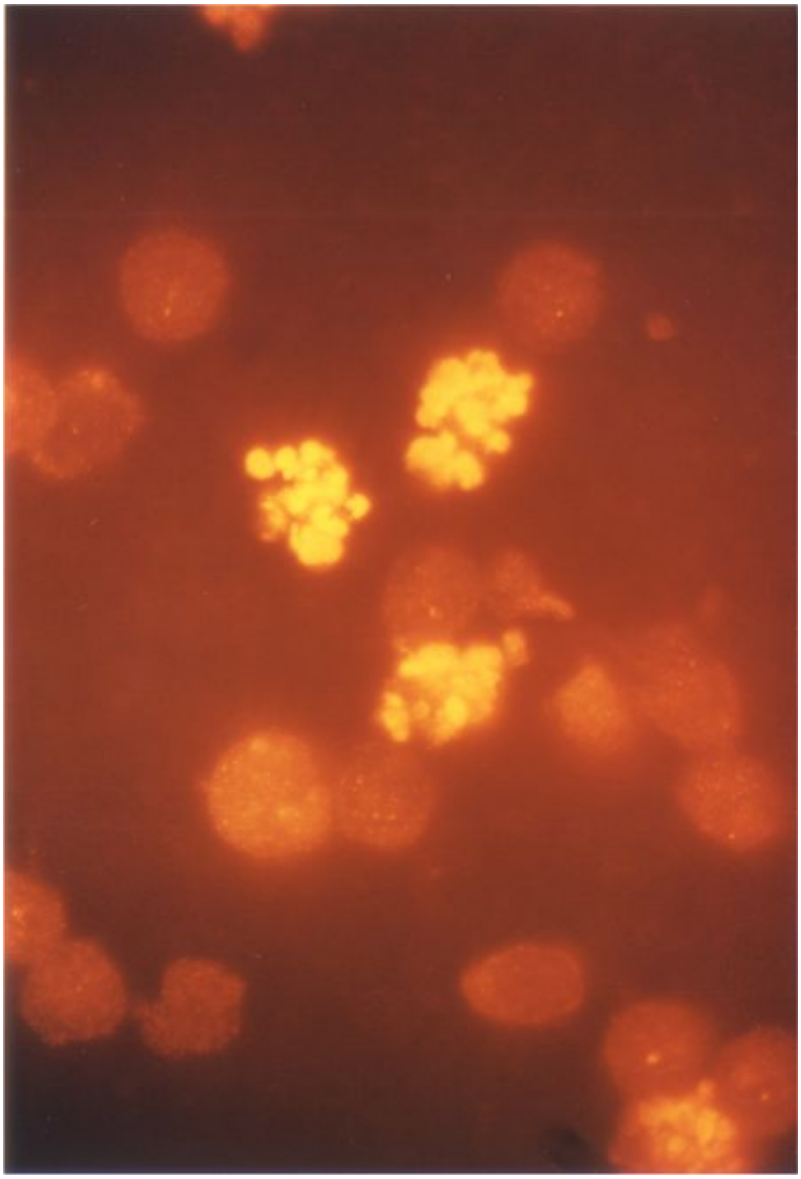
The results of gel electrophoresis, with the direction being down, with A549 in lanes 1 and 2 and H1299 in lanes 3 and 4. Lanes 1 and 3, for treatment with A d-E G F P, are dark. Lanes 2 and 4, for treatment with A d-L a t s 2, show banding that gets brighter toward the bottom. Lane 2 is brighter than lane 4.

(C)



Two cells with blue nuclei and large extended green Golgi bodies near the nucleus are on the left, and a red nucleus with many small green specks appears on the right. In Part E, many nuclei appear in orange-red. Most are uniform in color and not bright, but three or four of them appear brighter and highly granulated.

(D)



Many nuclei appear in orange-red. Most are uniform in color and not bright, but three or four of them appear brighter and highly granulated.

(E)

A cluster of plump, blue stained nuclei looking like a bowl of grapes, and beside it an image of scattered nuclei, some mottled white, looking like moldy blue raisins.

(F)

Figure 9.19 Diverse manifestations of the apoptotic program (A) The upper of these two lymphocytes, visualized by scanning electron microscopy (SEM), is healthy, whereas the lower one has entered into apoptosis, resulting in the numerous blebs protruding from its surface. (B) HeLa cells—a line of human cervical carcinoma cells—have been fused, forming a syncytium (*left*). Prior to fusion, some of these cells were treated with staurosporine, an apoptosis-inducing drug. As a consequence, the nuclei of these cells, which are normally quite large (*left*), have undergone *pyknosis* (*right*), a process that accompanies apoptosis and involves condensation of chromatin (*white*) and collapse of nuclear structure. Fragmentation of nuclei (*not shown*) typically follows soon thereafter. (C) Apoptosis causes the cleavage of a cell's chromosomal DNA into low–molecular-weight fragments that appear as a "DNA ladder" on gel electrophoresis. Cell lines A549 and H1299 were treated with the pro-apoptotic protein Lats2 (*2nd and 4th lanes*), which was introduced via an adenovirus (Ad) vector; cells infected with the vector alone (Ad-EGFP) were included as controls (*1st and 3rd lanes*). (D) The Golgi bodies (*green*) are usually found in perinuclear locations in a normal

cell (*upper left*); in an apoptotic cell (*arrow*), the Golgi bodies have become fragmented. Chromatin is stained *blue*, and an antibody specific for cleaved PARP [poly(ADP-ribose) polymerase], which is degraded during apoptosis, reveals this form of the protein (*red*) in the nucleus of an apoptotic cell. (E) Here, an antibody that specifically reacts with histone 2B molecules (in the chromatin) that are phosphorylated on their serine 14 residues during apoptosis was used to stain apoptotic nuclei (which are already undergoing fragmentation). (F) The end result of apoptosis is the phagocytosis of apoptotic bodies—the fragmented remains of apoptotic cells—by neighboring cells or by macrophages. In this image, the pyknotic nuclear fragments of a phagocytosed apoptotic cell are seen above (*white arrows*) and contrast with the normal nucleus of the phagocytosing macrophage (*below*). (A, courtesy of K.G. Murti. B, from K. Andreau et al., *J. Cell Sci.* 117:5643–5653, 2004. With permission of The Company of Biologists. C, from H. Ke et al., *Exp. Cell Res.* 298:329–338, 2004. The phagocytosis by neighboring cells and macrophages depends on the display of a specialized “eat-me” signal on the surfaces of cells entering apoptosis. Normal cells contain phosphatidylserine (PS) molecules only in the inner leaflet (facing the cytoplasm) of the lipid bilayer forming the plasma membrane. This asymmetric distribution is lost, however, during the fragmentation of apoptosis. As a result, PS is displayed on the exterior face of an apoptotic cell, where it is recognized by a specialized annexin receptor on the surface of phagocytic cells. The resulting binding of neighboring cells or specialized phagocytes (that is, macrophages) to the apoptotic cell surface triggers phagocytosis. A related annexin protein, when coupled to a fluorescent dye, can be used to stain cells that have initiated apoptosis and flipped many of their PS molecules to the outer cell surface. This approach—and other procedures that can be used to detect apoptotic cells within a tissue or in culture—are outlined in **Supplementary Sidebar 9.3**.

OceanofPDF.com

Glossary

involution
: Regression or disappearance of a tissue, notably, the regression of the mammary epithelium upon weaning.

bleb
: A small, bubble-like herniation through a membrane such as the plasma membrane.

pyknosis
: (also **pycnosis**) Chromatin condensation and shrinkage of nuclei creating small, densely staining structures observed as products of apoptosis and necrosis.

annexin V
: A cellular protein that has strong affinity for binding of phosphatidylserine (PS); binding of this protein to the surface of intact cells indicates that the usual segregation of PS to the inner leaflet of the bilayered plasma membrane has been disrupted, as occurs during apoptosis and other forms of cell death.

9.13 Apoptosis is a complex biochemical program that often depends on mitochondria

Although the apoptotic program had been recognized as a normal biological phenomenon in animal tissues by nineteenth-century histologists, it was rediscovered and described with far greater precision in 1972. Prior to this rediscovery, cells in metazoan tissues were thought to be eliminated solely by necrosis. As indicated in **Table 9.2**, necrosis and apoptosis are actually quite different. By the late 1980s, genetic research on the worm *Caenorhabditis elegans* revealed that apoptosis is exploited to eliminate various cell types as part of the normal developmental program of these tiny animals (see also Figure 10.1). This research led to the recognition that apoptosis is a basic, genetically driven biological process that is common to all metazoa.

Table 9.2 Apoptosis versus necrosis

	Apoptosis	**Necrosis**
Provoking stimuli		
	programmed tissue remodeling	metabolic stresses
	maintenance of cell pool size	absence of nutrients
	genomic damage	changes in pH, temperature
	metabolic derangement	hypoxia, anoxia
	hypoxia	

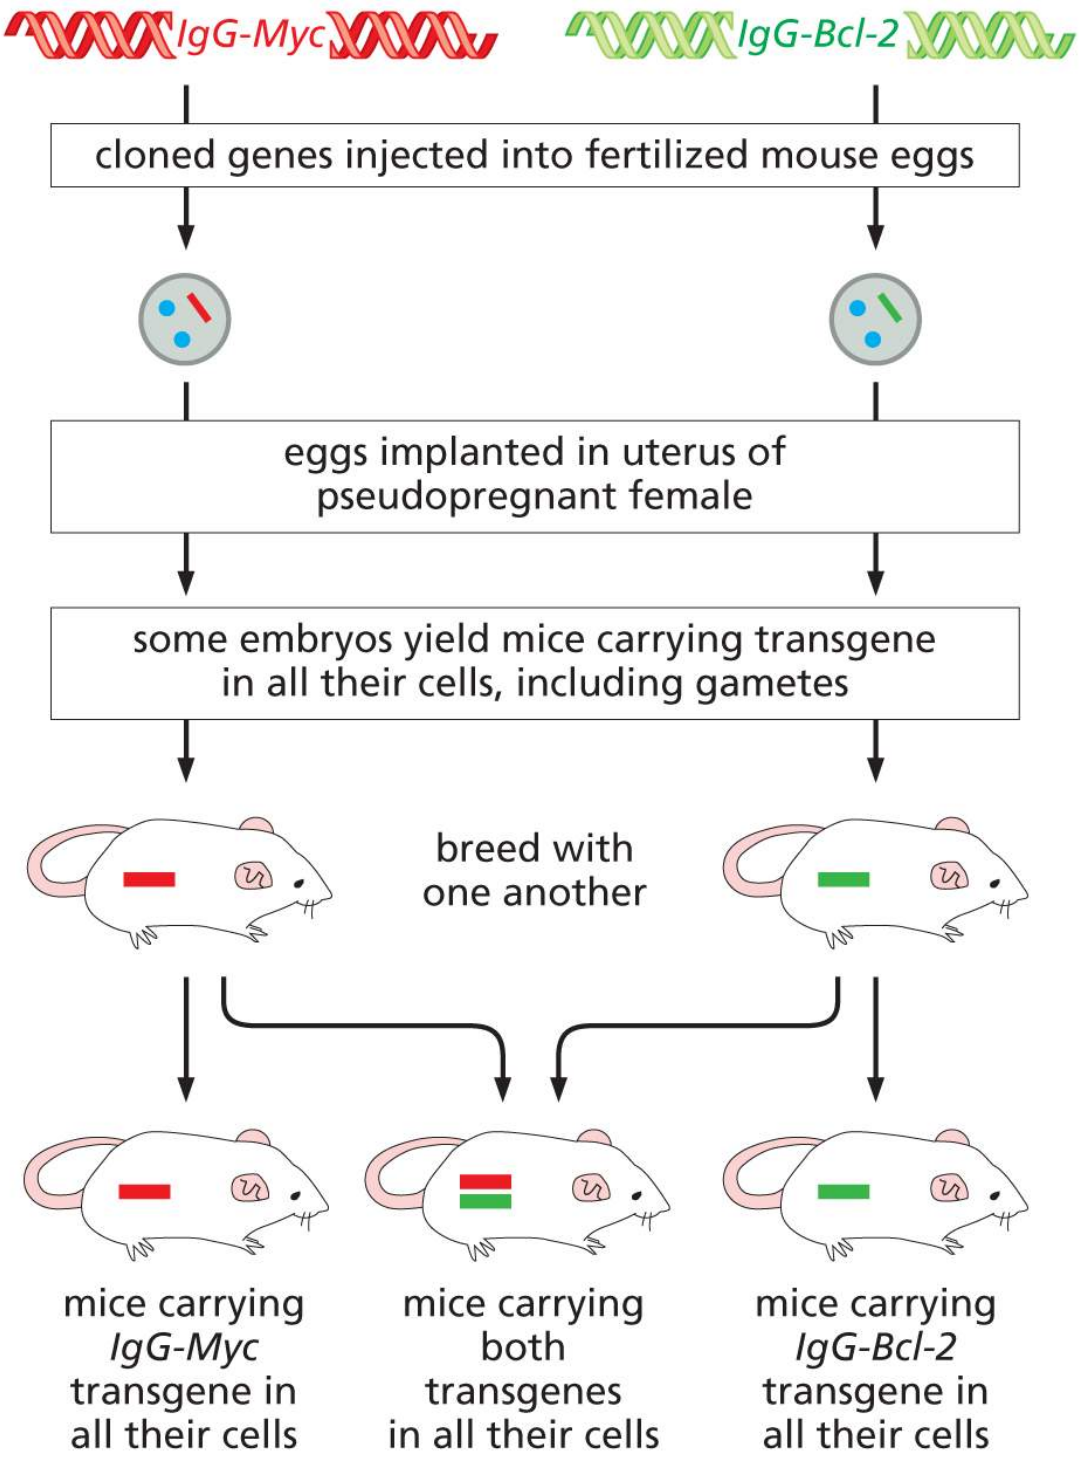
	Apoptosis	**Necrosis**
	imbalances in signaling pathways	
Morphological changes		
Affected cells	individual cells	groups of cells
Cell volume	decreased	increased
Chromatin	condensed	fragmented
Lysosomes	unaffected	abnormal
Mitochondria	morphologically normal initially	morphologically aberrant
Inflammatory response	none	marked
Cell fate	apoptotic bodies consumed by neighboring cells	lysis
Molecular changes		
Gene activity	required for program	not needed

	Apoptosis	**Necrosis**
Chromosomal DNA	cleaved at specific sites	random cleavage
Intracellular calcium	increased	unaffected
Ion pumps	continue to function	lost

Adapted from R.J.B. King, Cancer Biology, 2nd ed. Harlow, UK: Pearson Education, 2000.

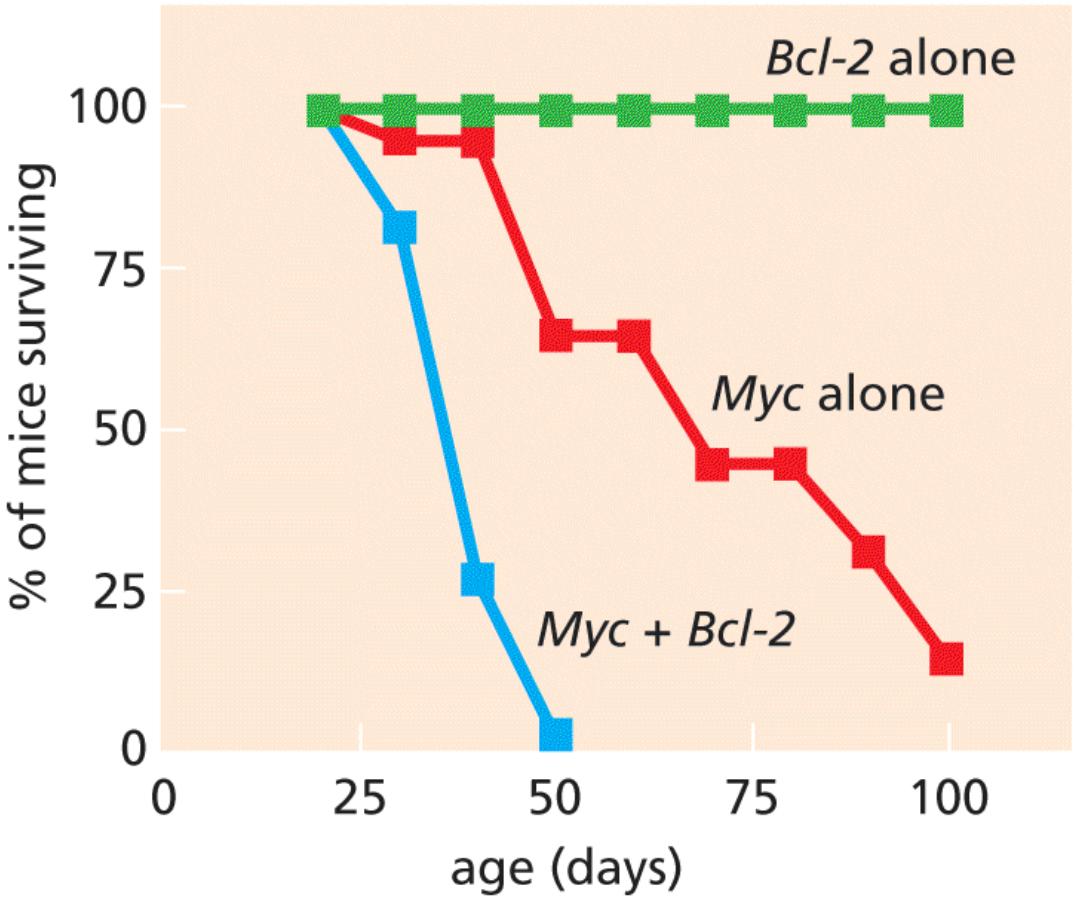
The first indication that cancer-associated proteins contribute to the regulation of apoptosis came from an exploration of the functioning of the *Bcl-2* (B-cell lymphoma gene-2) oncogene. The oncogenic version of the *Bcl-2* gene is formed through reciprocal chromosomal translocations occurring during the formation of human follicular B-cell lymphomas. These events—which result in the exchange of portions of the arms of human Chromosomes 14 and 18 observed in these tumors—place the reading frame of the *Bcl-2* gene under the control of a promoter that drives its high, constitutive expression.

When such a *Bcl-2* oncogene was inserted into the germ line of mice under conditions that ensured its expression in lymphocyte precursor cells, there was no observable effect on the animals' long-term survival (**Figure 9.20A and B**). In contrast, expression of an oncogenic *Myc* transgene in these cells led to lymphomas and to the death of half the mice within two months of birth. However, when both oncogenes were expressed simultaneously (by breeding *Bcl-2* transgenic mice with *Myc* transgenic mice), the offspring fared even worse: virtually all of the mice died less than two months after birth.



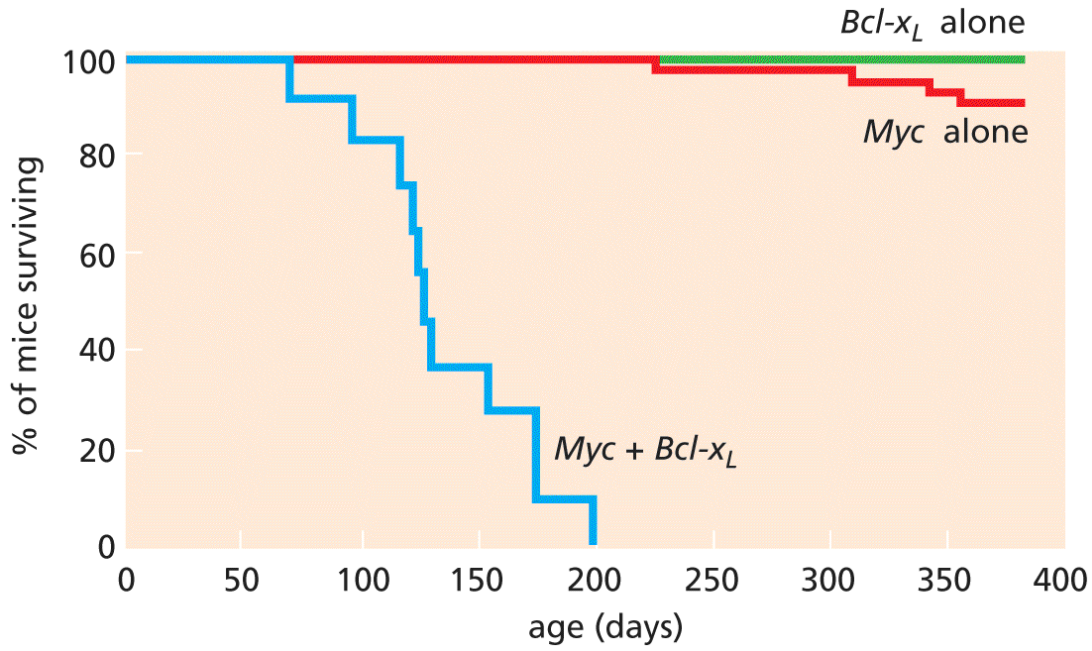
The process for conducting an experiment. First, cloned I g G-M y c genes are injected into fertilized mouse eggs. Next, the eggs are implanted in the uterus of a pseudopregnant female. Some embryos yield mice that carry the transgene in all their cells, including gametes. At the same time as all this is being done with I g G-M y c genes, the same process is carried out with I g G-

B c l-2 genes. The two types of mice with the transgene in all their cells are then cross-bred. Some of the offspring mice carry both of the transgenes in all their cells, some carry just the one, and some carry just the other.
(A)



A line graph showing percent survival as a function of age for the three types of offspring mice, starting with 25 day-old mice. 100 percent of the B c l-2 alone mice survive past age 100 days. Of the M y c alone mice, less than 50 percent survive to age 75 days and less than 15 percent survive to age 100 days. Of the mice with both genes, none survive past age 50 days.

(B)



A line graph showing percent survival as a function of age for the three types of mice, starting with newborn mice. 100 percent of B c l-x L alone mice survive a full year. Of M y c alone mice, 100 percent survive 10 months and about 90 percent survive a full year. Of the mice with both genes, none survive past age 200 days.

(C)

Figure 9.20 Synergy of *Bcl-2*-like genes with *Myc* (A) Clones of the *Myc* and the *Bcl-2* genes were engineered to be expressed under the control of an antibody gene transcriptional promoter (*IgG*). This promoter ensures that both genes will be expressed specifically in cells of the B lymphocyte lineage. The engineered clones are then injected into eggs and, with a certain frequency, the DNA becomes integrated via nonhomologous recombination into a chromosomal site. Southern blotting was subsequently used to verify the presence of the integrated sequences in the cells of the resulting mice and in their progeny. Such a heritable inserted gene is termed a *transgene*. (B) Mice bearing the *IgG–Bcl-2* transgene experienced no increased mortality (*green squares*). In contrast, the *IgG-Myc* transgene led to a greatly increased mortality from lymphomas, with almost all of the mice dying from this disease by 100 days of age (*red squares*). However, when both *Bcl-2* and *Myc* transgenes are present, lymphomagenesis was greatly accelerated and virtually all mice succumbed to lymphomas by 50 days of age (*blue squares*). (C) An even more dramatic outcome was observed when two strains of transgenic mice were developed that expressed the *Myc* or the *Bcl-x_L* oncogenes specifically in the plasma cell (antibody-secreting) lymphocytes of the

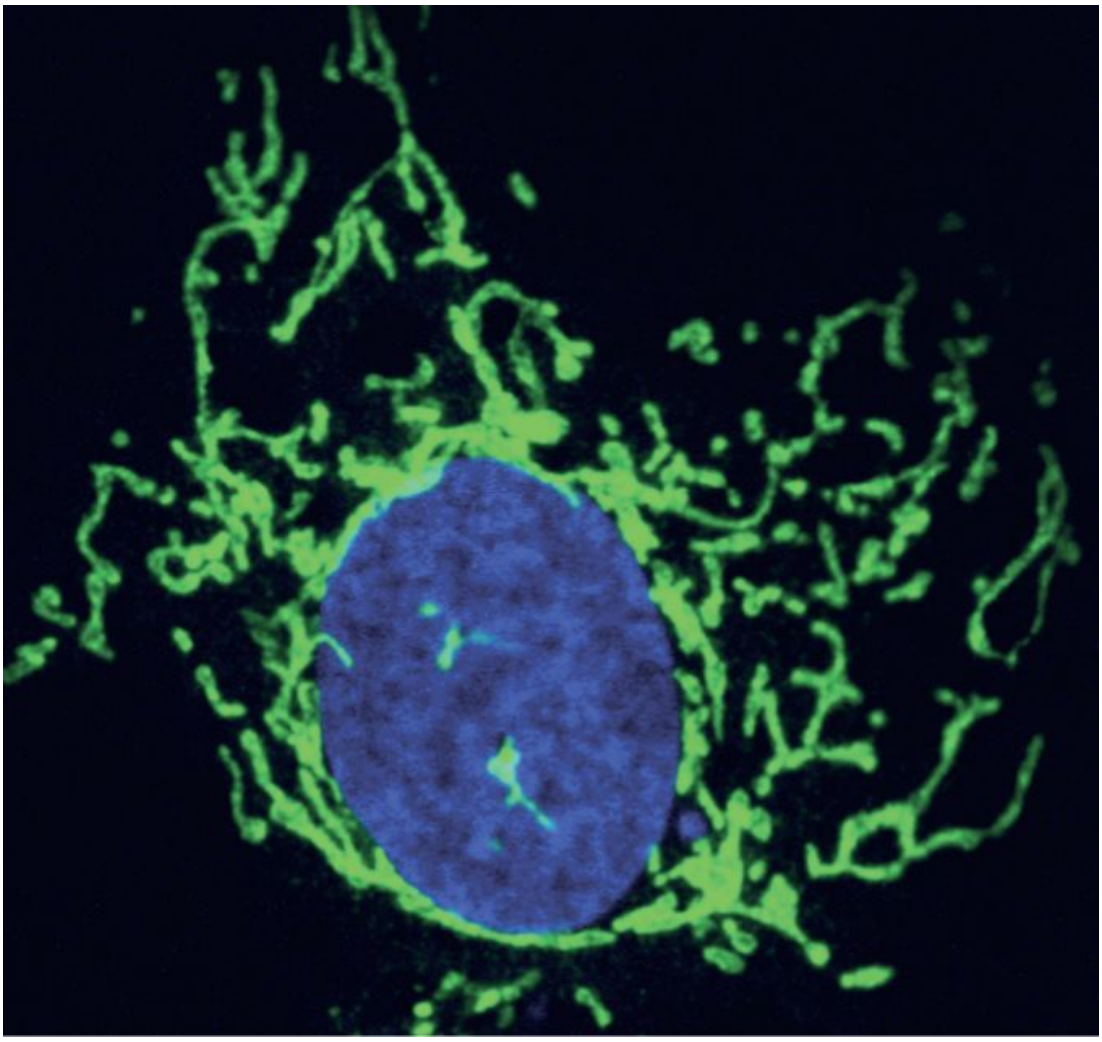
immune system. (*Bcl-x_L* is a cousin of *Bcl-2* and functions in a very similar fashion.) Normal mice and transgenic mice carrying only the *Bcl-x_L* transgene all survived for more than a year without any tumor development (*green line*); similarly, mice expressing a *Myc* transgene were largely healthy until about 10 months of age, when a small number of them developed plasma cell tumors. However, when the two strains of mice were bred, the double-transgenic progeny developed plasma cell tumors rapidly, beginning at about 75 days of age; all died from these tumors by 200 days of age. (B, adapted from A. Strasser et al., *Nature* 348:331–333, 1990. C, from W.C. Cheung et al., *J. Clin. Invest.* 113:1763–1773, 2004. With permission from American Society for Clinical Investigation.)

The inability of *Bcl-2*, on its own, to trigger tumor formation argued against its acting as a typical oncogene, such as *Myc*, which emits potent growth-promoting signals. Careful study of the lymphocytes in mice carrying only the *Bcl-2* transgene indicated that the effects of this gene on cells were actually quite different from those of *Myc* or *Ras*: *Bcl-2 prolonged the lives* of lymphocytes that were otherwise destined to die rapidly. Indeed, when B lymphoid cells from these transgenic mice were cultured *in vitro*, they showed a remarkable extension of life span. *In vivo*, the lymphocytes in which *Bcl-2* was being expressed accumulated in amounts several-fold above normal; however, these cells were not actively proliferating, which explains the absence of hematopoietic tumors in mice carrying only the *Bcl-2* transgene.

The *Myc* oncogene, when present on its own, acted as a potent mitogen, but its growth-stimulatory powers were attenuated by its apoptosis-inducing effects (see Section 9.9). However, when *Myc* and *Bcl-2* acted collaboratively, they created an aggressive malignancy of the B-lymphocyte lineage; *Myc* would drive rapid cell proliferation, and its accompanying death-inducing effects were neutralized by the life-prolonging actions of *Bcl-2*. Because these were early experiments, even more dramatic examples of synergy between *Myc* and *Bcl-2*-like oncogenes, such as that shown in Figure 9.20C, have been reported. These dynamics parallel the situation we discussed in Section 9.9, in which the death-inducing effects of *Myc* were blunted by inactivation of the *p53* gene.

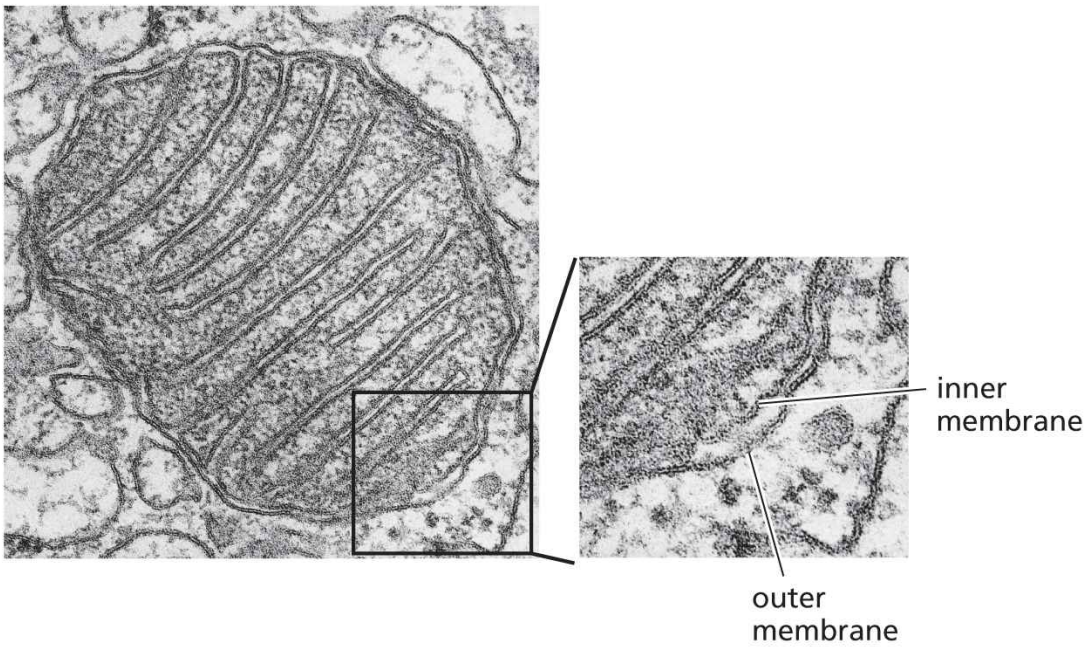
Once the details of the apoptotic program were clearly understood, the role of Bcl-2 in cancer pathogenesis became apparent. This oncoprotein operates as an anti-apoptotic agent rather than as a mitogen. Hence, Bcl-2 acts in a fashion precisely opposite to that of p53. Whereas p53 promotes apoptosis, Bcl-2 blocks it. Stated in genetic terms, activation of the *Bcl-2* oncogene and inactivation of the *p53* tumor suppressor gene confer similar (but not identical) benefits on cancer cells, in that both reduce the likelihood of inducing the apoptotic program.

Careful biochemical and cell-biological sleuthing eventually revealed the surprising site of Bcl-2 action: the outer membrane of the mitochondrion (**Figure 9.21**). At first, this discovery made little sense. Mitochondria were thought to be specialized for metabolic tasks, namely, generating energy in the form of ATP for the cell. As a by-product of this energy production, mitochondria were also known to make metabolites of glucose that are used in the biosynthesis of some of the cell's diverse biochemical species.



A fluorescence microscopy image in which a dark blue nucleus is surrounded by bright green structures that look like short, thick filaments.

(A)



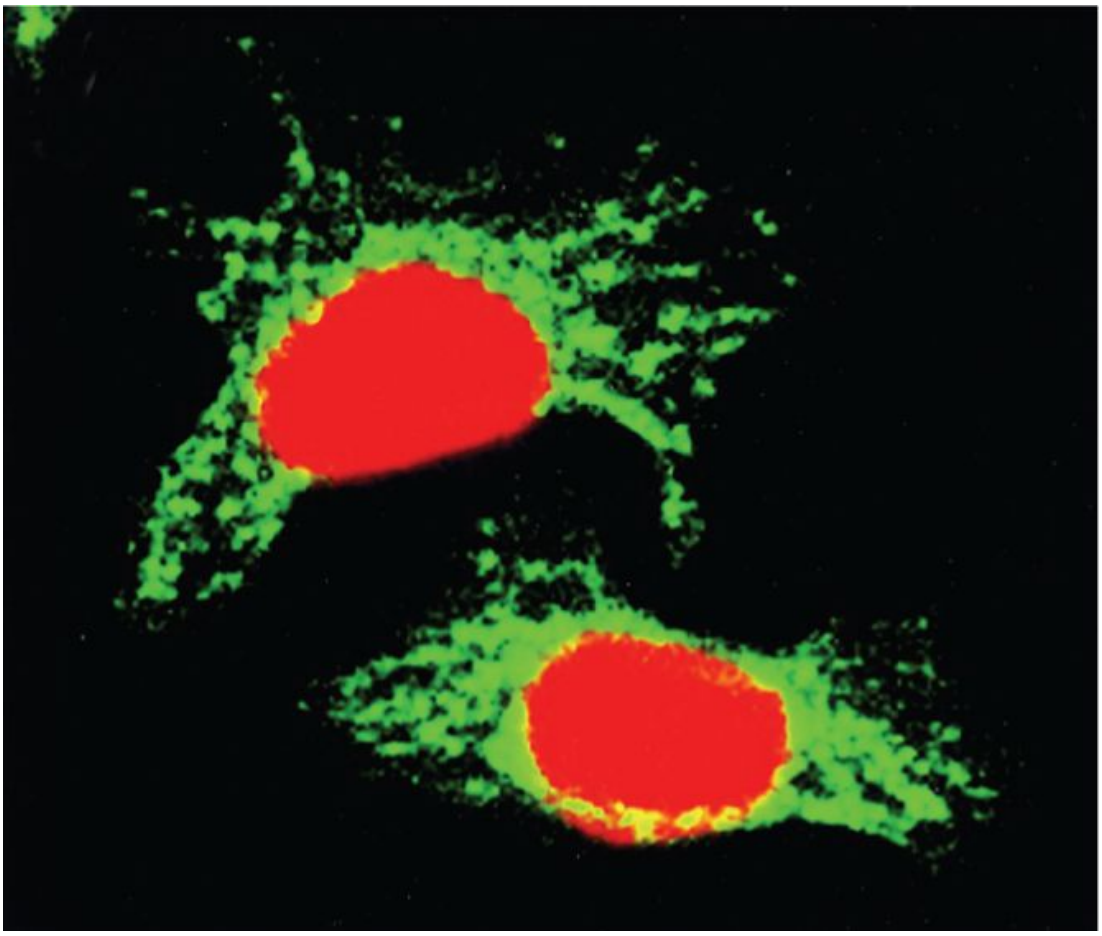
An electron micrograph of a mitochondrion. A magnified detail labels the inner membrane and the outer membrane. The inner membrane has many folds.

(B)

Figure 9.21 Mitochondria (A) Mitochondria (*green*), stained here in the cytoplasm of a human liver cell, were once regarded only as the sites of oxidative phosphorylation and biosynthesis of certain key metabolites. The discovery of their ability to regulate apoptosis through cytochrome *c* release forced a major rethinking of their role in the life of a cell. (B) Cytochrome *c* is stored in the space between the outer mitochondrial membrane and the inner membrane, where it normally plays a key role in electron transport. When this outer membrane is breached (a condition called mitochondrial outer membrane permeabilization, or MOMP), cytochrome *c* escapes into the cytosol. (A, courtesy of Althea Bock-Hughes and Kay Macleod. B, courtesy of D.S. Friend.)

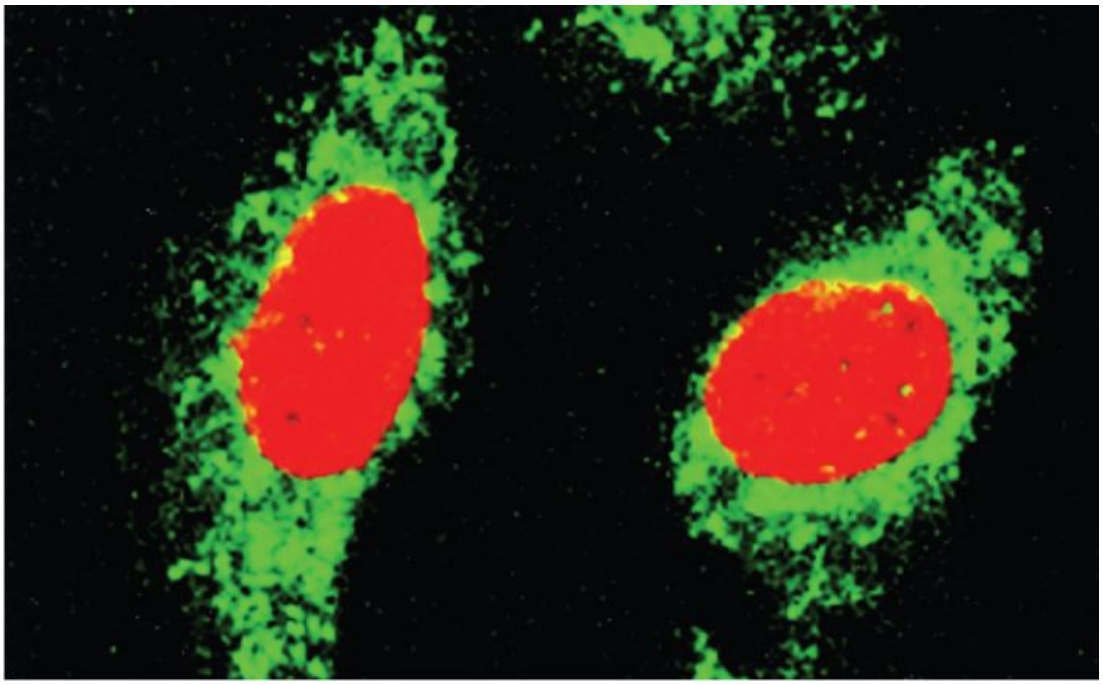
Soon, however, the role of mitochondria in the apoptotic program was clarified. Cytochrome *c*, the central actor in this process, normally resides in the space between the inner and outer mitochondrial membranes (see Figure 9.21B), where it functions to transfer electrons as part of oxidative phosphorylation, the main energy-generating reaction in our cells. However, when certain signals trigger the initiation of apoptosis, pores form in the mitochondrial outer membrane creating a condition known as MOMP (**m**itochondrial **o**uter **m**embrane **p**ermeabilization). Cytochrome *c* then spills

out of the organelle and into the surrounding cytosol (**Figure 9.22**). Once present in the cytosol, cytochrome *c* associates with other proteins to trigger a cascade of events that together yield apoptotic death, as discussed below. Smac/DIABLO, another mitochondrial protein that escapes during MOMP, also has a direct role in the induction of apoptosis. Yet other proteins are released from mitochondria during apoptosis, but the evidence supporting their role in regulating the process is less clear.



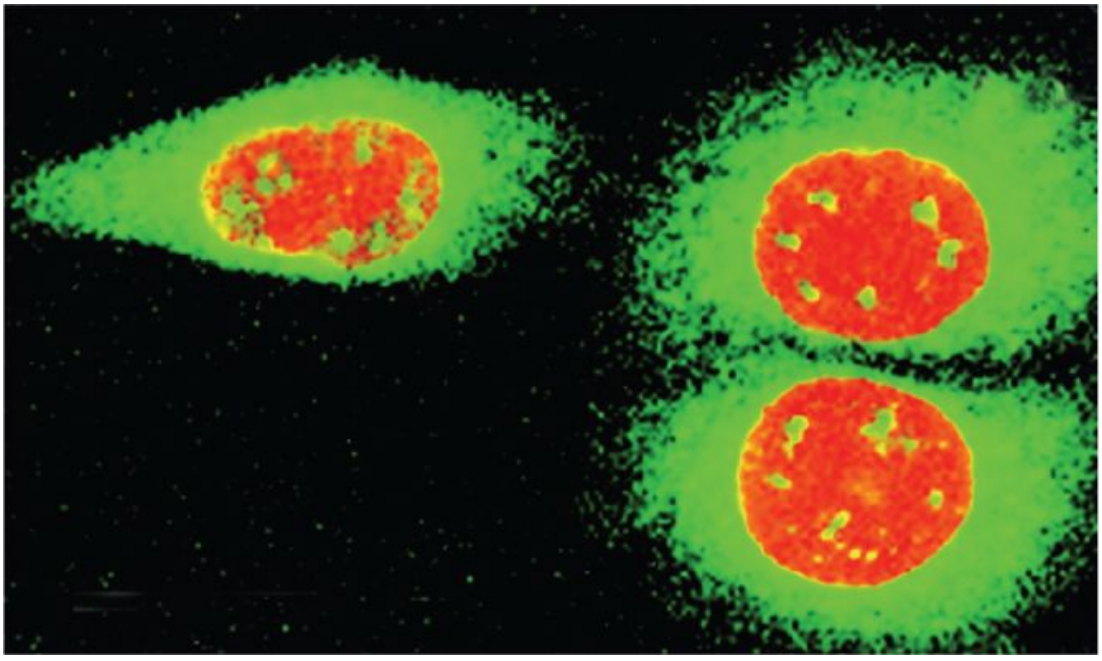
Two nuclei in red are surrounded by mitochondria looking like thick green fibers.

(A)



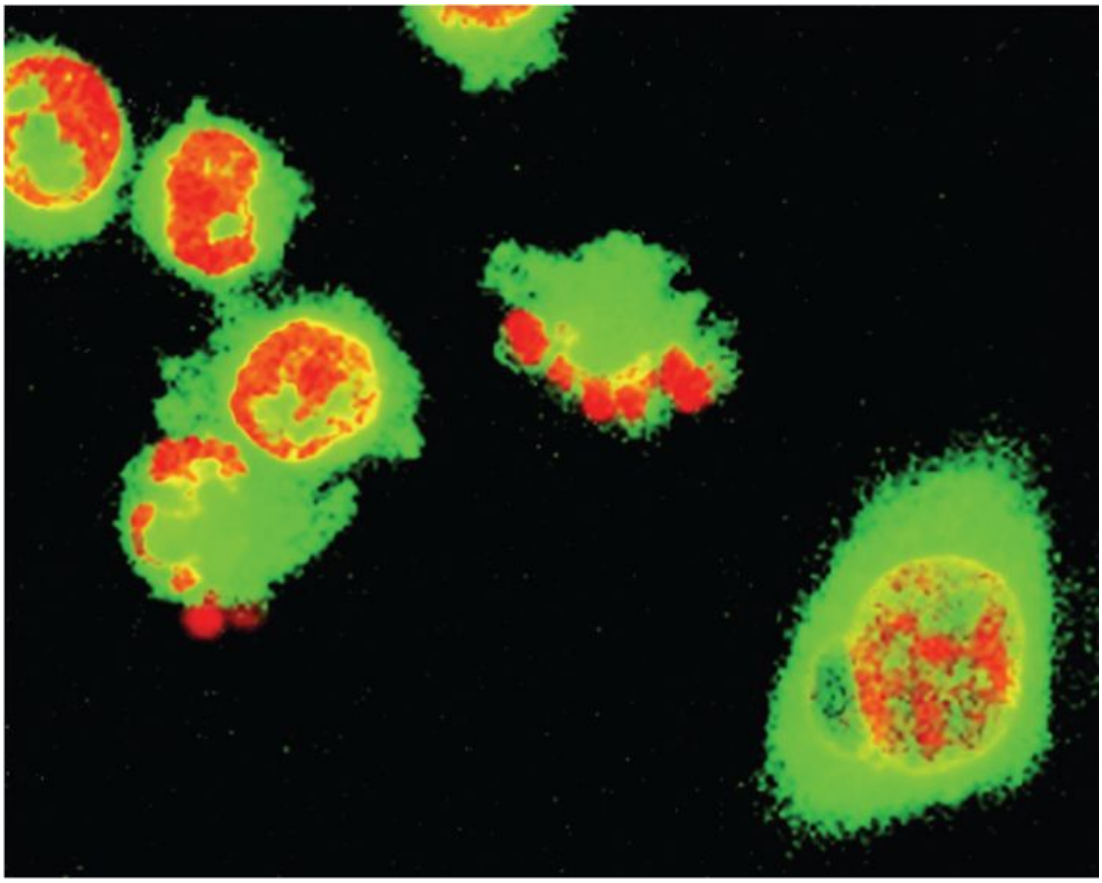
The green mitochondria have started to blur, and a few green specks have infiltrated the nuclei.

(B)



The nuclei are surrounded by blurry green halos, and green infiltration has started to make the nuclei look like tomato slices.

(C)



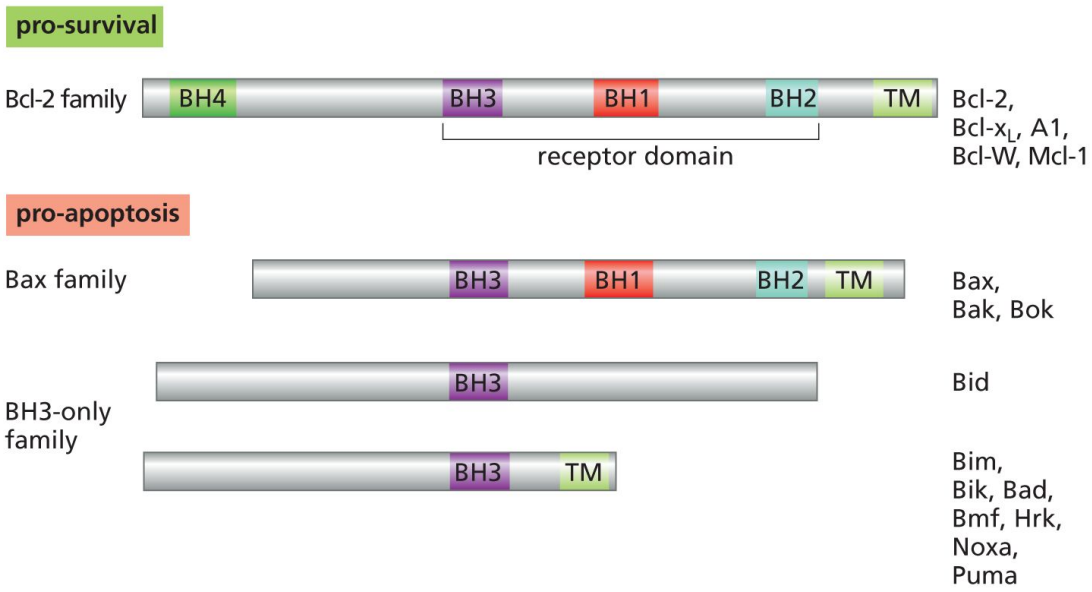
The nuclei have started to disintegrate and are blotchy with green stain.

(D)

Figure 9.22 Release of cytochrome *c* from mitochondria into the cytosol The presence of cytochrome *c* can be detected by staining with a specific fluorescence-labeled antibody (*green*), which contrasts with the dye-labeled nuclei (*red orange*). (A) Initially, the distribution of cytochrome *c* coincides with the distribution of mitochondria in the cytoplasm (see Figure 9.21A). As apoptosis proceeds, however (B, C, D), cytochrome *c* staining becomes increasingly uniform in the cytoplasm as this protein is released from the mitochondria into the cytosol. At the same time, some nuclei give evidence of the fragmentation that is associated with apoptosis (C, D). (From E. Bossy-Wetzel et al., *EMBO J.* 17:37–49, 1998. With permission from John Wiley & Sons.)

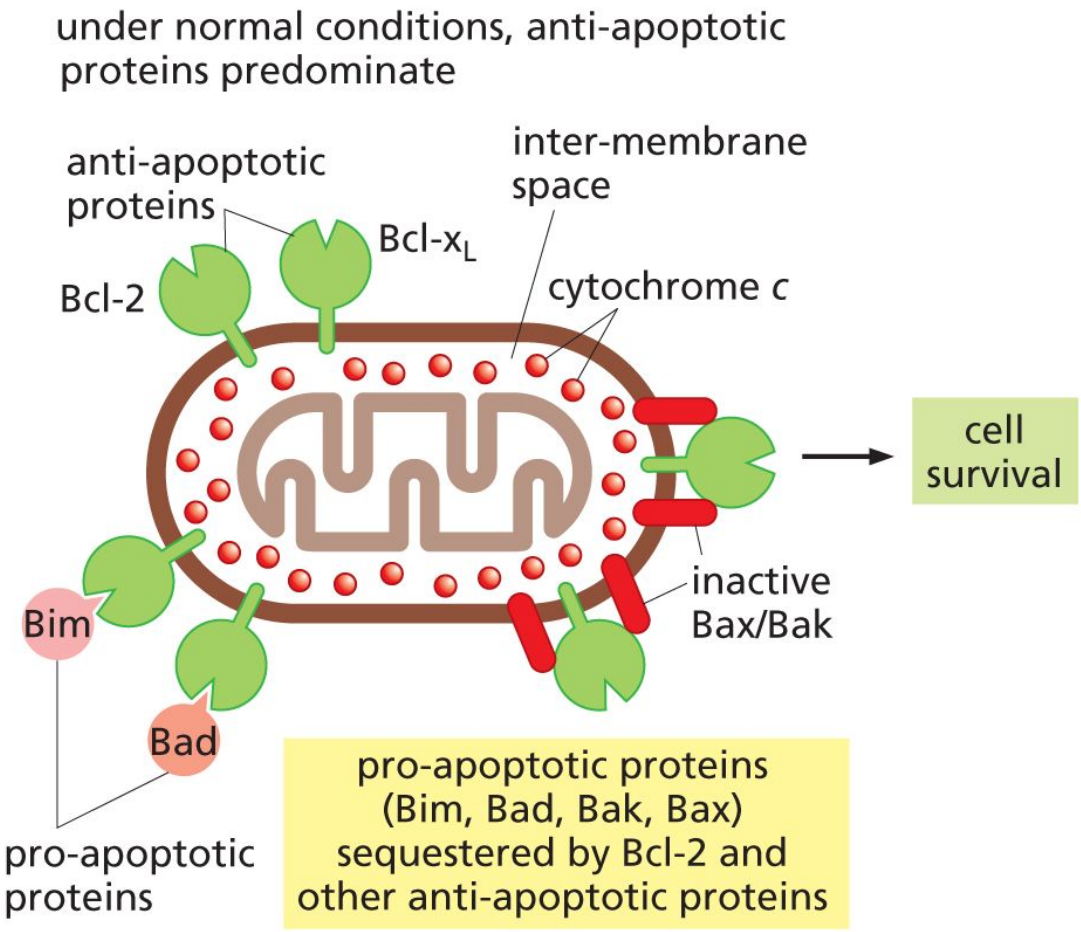
We now know that the Bcl-2 protein is a member of a large and complex family of proteins, which consists of at least 24 members expressed in different patterns

depending on cell and tissue type (**Figure 9.23A**). They have in common one or more protein domains, which are referred to as **B**cl-2 **h**omology (or BH) domains. By acting through a series of physical associations, the Bcl-2 family of proteins collectively controls the formation and function of the mitochondrial outer membrane pores and therefore MOMP. The pores themselves contain homo-oligomers of two of the pro-apoptotic members of the Bcl-2 family: Bax and Bak. Anti-apoptotic members of the family—such as Bcl-2, Bcl-X_L, and Mcl1—form heterodimers with these pore-forming proteins, resulting in inhibition of MOMP (Figure 9.23B).



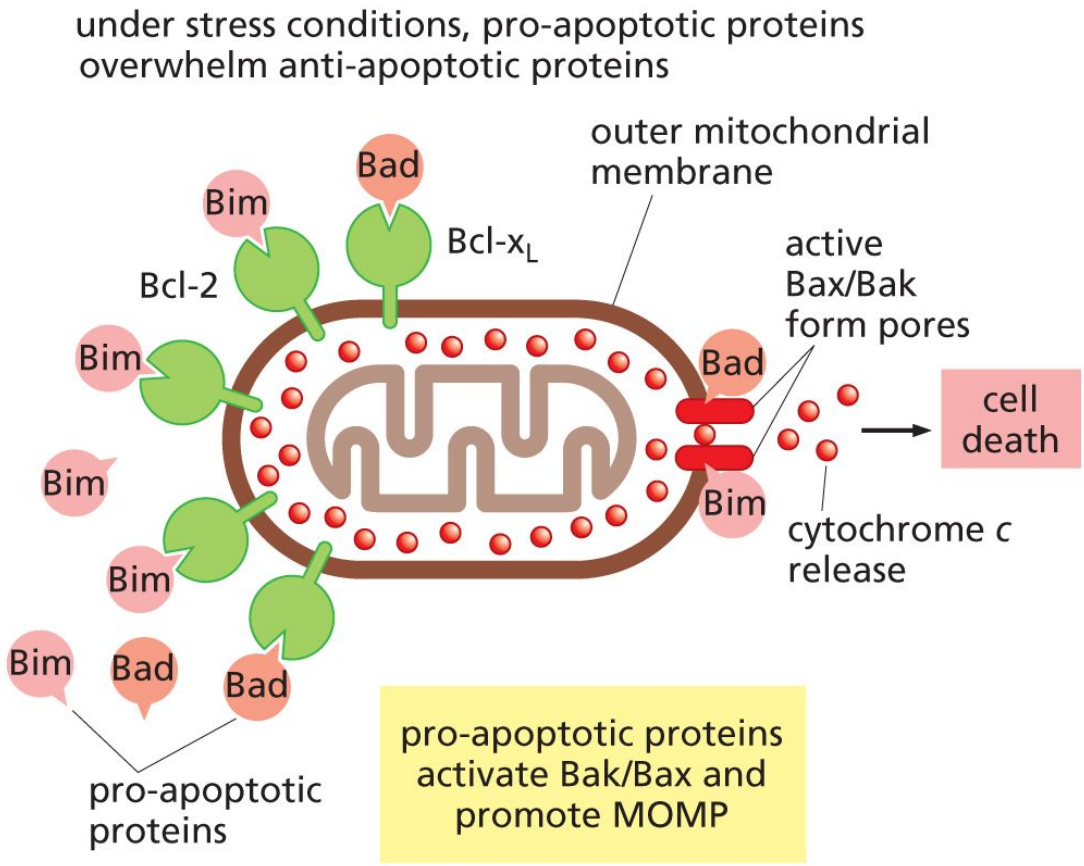
Schematic diagrams for the structures of pro-survival and pro-apoptosis proteins. The pro-survival category is represented by the B c l-2 family, which includes B c l-2, B c l-x L, A1, B c l-W, and M c l-1. There is a B H 4 domain near the left and a T M domain at the right end. In between there are, left to right, B H 3, B H 1, and B H 2 domains that together constitute the receptor domain. The pro-apoptosis category is represented by Bax family and the B H 3-only family. The Bax family includes Bax, and Bak, and Bok. These have B H 3, B H 1, and B H 2 domains in the middle and a T M domain near the right end. The B H 3-only family includes Bid, Bim, Bik, Bad, B m f, H r k, Noxa, and Puma. These have B H 3, B H 1, and B H 2 domains in the middle and a T M domain near the right end. These have a B H 3 domain in the middle and a T M domain near the right end, except for Bid, which only has the B H 3 domain.

(A)



A mitochondrion under normal conditions, where anti-apoptotic proteins predominate. The inter-membrane space between the inner and outer membranes contains many cytochrome sees. Many Bcl-2 and B c l-x L anti-apoptotic proteins are attached to the outside of the mitochondrion. A couple of these have pro-apoptotic proteins Bad or Bim attached to the free end. A couple more anti-apoptotic proteins have inactive Bax or Bak attached at the sides and attached to the mitochondrion, like tethers. Thus the pro-apoptotic proteins (Bim, Bad, Bak, and Bax) are sequestered by B c l-2 and other anti-apoptotic proteins.

(B)



A mitochondrion under stress conditions, where pro-apoptotic proteins overwhelm anti-apoptotic proteins. The Bcl-2 and B c l-x L anti-apoptotic proteins attached to the outside of the mitochondrion all have pro-apoptotic proteins Bad or Bim attached to the free end. Other Bads and Bims float free. One Bad and one Bim have combined with two Baxes or Baks to open a pore in the outer membrane, allowing cytochrome sees to escape into the cytoplasm, where they cause cell death. So the pro-apoptotic proteins activate Bak and Bax and promote mitochondrial outer membrane permeabilization.

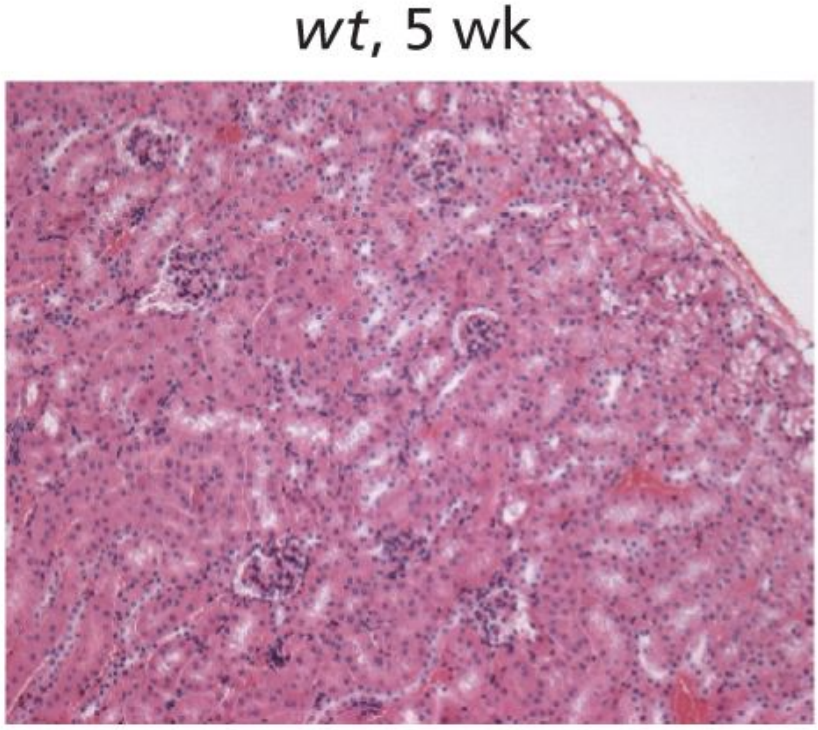
(C)

Figure 9.23 Bcl-2 and related proteins and the control of apoptosis. (A) Bcl-2 is a member of a large family of proteins involved both in preventing (*top*) and promoting (*bottom*) apoptosis. Each of these proteins possesses one or more Bcl-2-homology (BH) domains. All have a BH3 domain (*purple*), and some, like Bcl-2 itself, also have BH1 and BH2 domains (*red*, *aquamarine*). Several also have transmembrane (TM) domains (*light green*), used for membrane anchorage, and BH4 domains (*darker green*), which inhibit apoptosis, in part by blocking release of calcium ions from the endoplasmic reticulum. The pro-apoptotic proteins are subgrouped into the “Bax” family and have several domains that are homologous

to domains of Bcl-2; in contrast, the “BH3-only” proteins have only the BH3 domain in common with Bcl-2. Members of the Bax family normally reside in inactive form in the outer mitochondrial membrane or in the cytosol, whereas inactive members of the BH3-only family normally are limited to the cytosol; both classes of proteins are activated and/or translocated to the mitochondria by pro-apoptotic signals. (B) When anti-apoptotic proteins, such as Bcl-2, are present in sufficient concentrations, they can sequester pro-apoptotic BH3-only proteins and thereby inhibit apoptosis. (C) When pro-apoptotic BH3-only proteins are in relative abundance, they stimulate the homo-oligomerization of the pore-forming proteins Bax and Bak. This association promotes MOMP and thereby triggers apoptosis. (A, from S. Cory and J.M. Adams, *Nat. Rev. Cancer* 2:647–656, 2002. With permission from Nature. B and C, adapted from R. Singh, A. Letai, and K. Sarosiek, *Nat. Rev. Mol. Cell Biol*. 20: 175–193, 2019.)

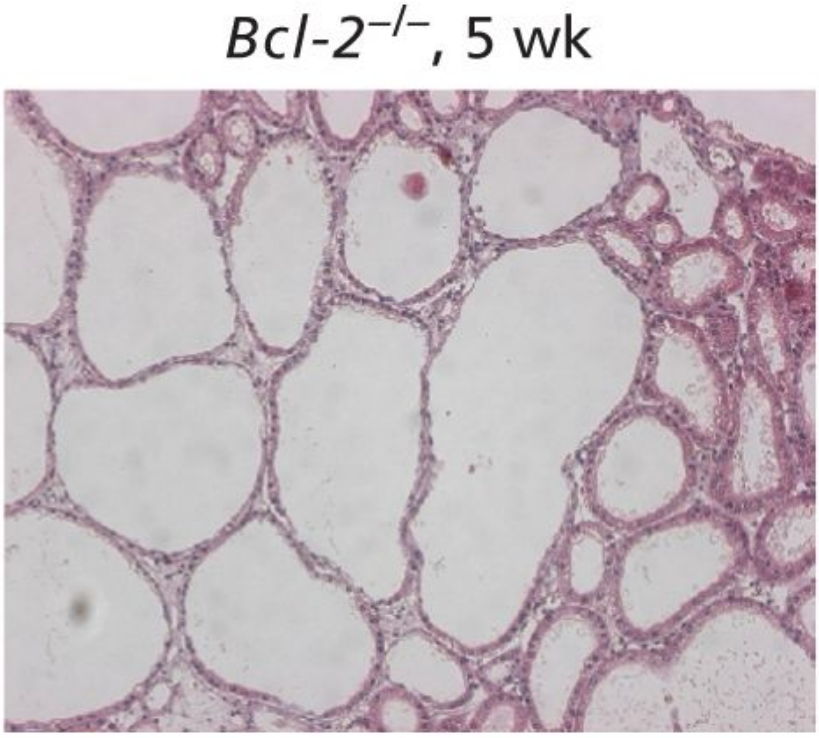
By contrast, the so-called “BH3-only” members of the family (so named because they carry just one of the four conserved BH domains present in Bcl-2; see Figure 9.23A) *promote* MOMP, and thus apoptosis. The BH-3 only proteins—which include Bid, Bim, Noxa, Bad, and PUMA—act either by binding to the pore-forming proteins directly and stimulating homo-oligomerization or by binding to and inhibiting anti-apoptotic Bcl-2 family members (Figure 9.23C). Interestingly, several pro- and anti-apoptotic members of the Bcl-2 family of proteins also associate with the endoplasmic reticulum, where they modulate release of calcium ions from this organelle, which also affects regulation of apoptosis.

The relative levels of the pro- and anti-apoptotic proteins ultimately determine whether MOMP will occur, cytochrome *c* will spill out, and apoptosis will ensue (see Figure 9.23B, C). In this fashion, MOMP determines the life and death of a cell. For example, mice that have been deprived of both germ-line copies of the anti-apoptotic *Bcl-2* gene suffer from kidney failure and immune collapse as a result of widespread apoptotic death of cells in these tissues; these lethal phenotypes can be avoided through the additional deletion from their germ line of just one copy of *Bim*, one of the pro-apoptotic cousins of *Bcl-2* (**Figure 9.24**). These results illustrate how, in tissues like these, the delicate balance between pro- and anti-apoptotic Bcl-2-like proteins governs the fate of individual cells.



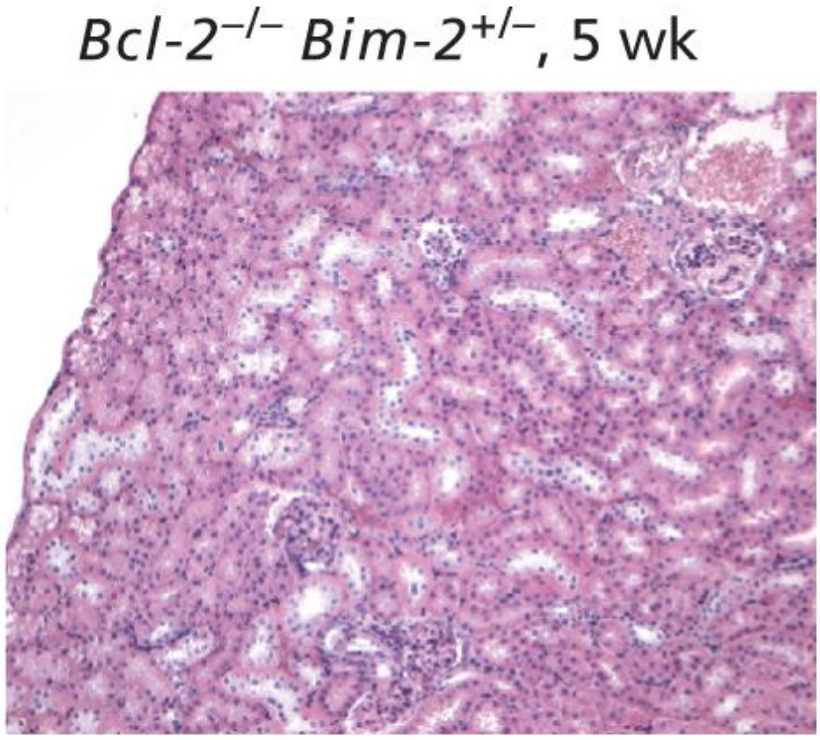
Wild-type mouse kidney tissue at 5 weeks of age. It is pink, smooth, and dense.

(A)



Kidney tissue from a B c l-2 minus minus mouse at 5 weeks. The tissue consists almost entirely of large white cysts.

(B)



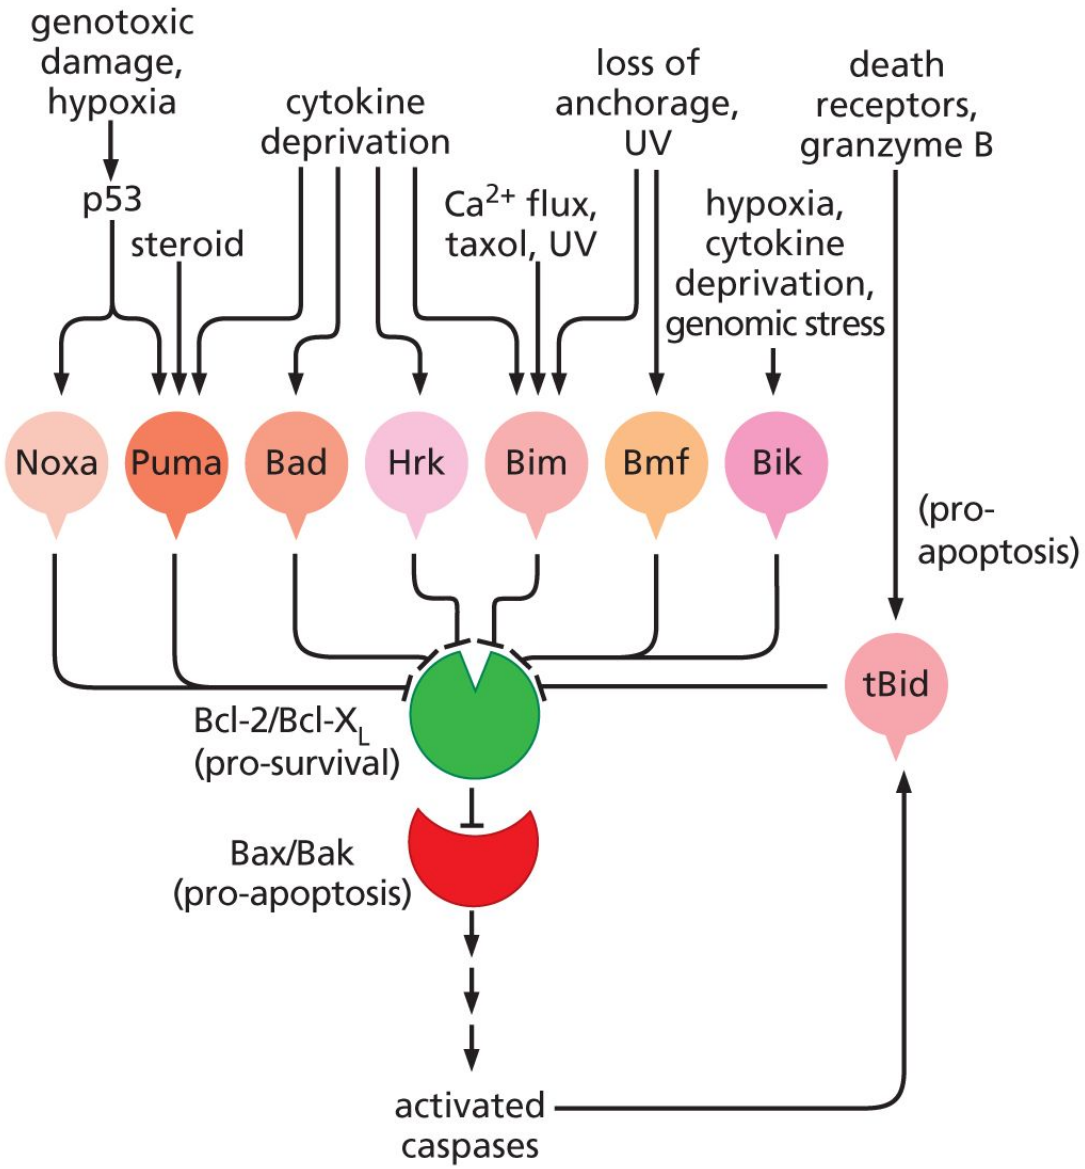
Kidney tissue from a B c l-2 minus minus, Bim-2 plus minus mouse at 5 weeks. The tissue is nearly as healthy and uniform looking as the tissue in Par A.

(C)

Figure 9.24 The delicate balance between pro- and anti-apoptotic proteins (A) The wild-type mouse kidney is a well-consolidated tissue at 5 weeks of age. (B) However, deletion of both germ-line copies of the anti-apoptotic *Bcl-2* gene (resulting in the *Bcl-2*$^{-/-}$ genotype) results in widespread apoptosis and polycystic kidney disease at this age. (C) These effects can be largely reversed if one copy of the pro-apoptotic *Bim* gene is also deleted from the germ line (yielding the *Bcl-2*$^{-/-}$*Bim*$^{+/-}$ genotype). (From P. Bouillet et al., *Dev. Cell* 1:645–654, 2001. With permission from Elsevier.)

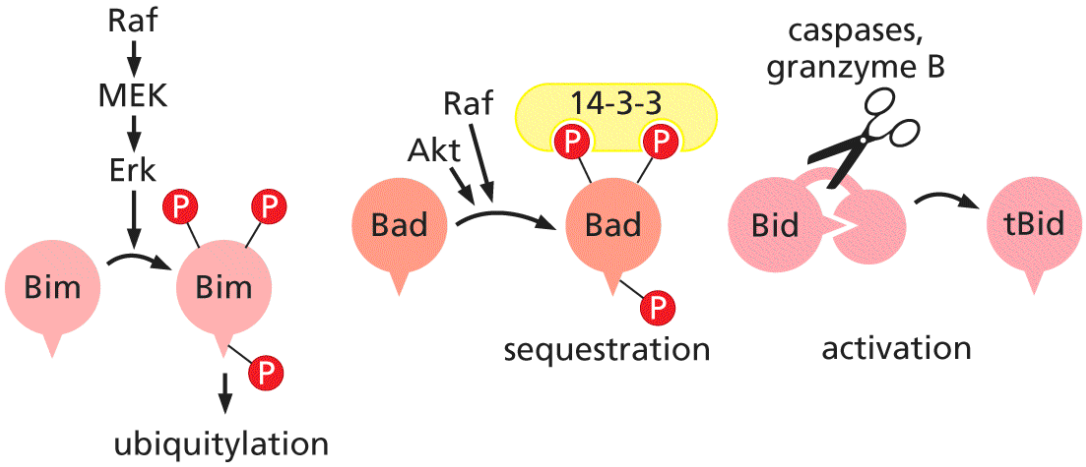
A large number of cell-physiological stimuli and signaling pathways converge on the cell death decision, and this complexity is reflected in the plethora of Bcl-2-related proteins that control this process. As an example, the form of apoptosis called anoikis, which occurs when epithelial cells undergo detachment from a substratum (also termed loss of anchorage), is dependent on the BH3-only protein Bim. By contrast,

p53 induces the expression of the BH3-only proteins PUMA and Noxa, whereas other stimuli act by regulating distinct members of the family (**Figure 9.25A**).



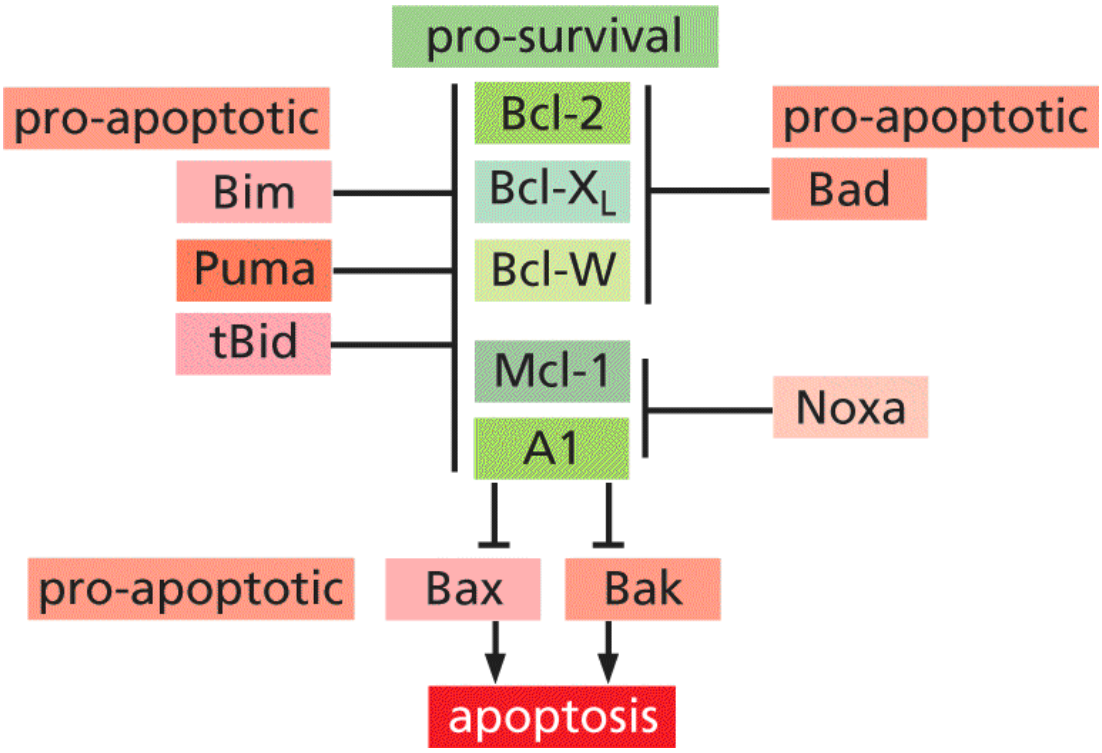
A diagram in which various cell-physiological stresses each activate certain pro-apoptotic proteins. The stresses are genotoxic damage, hypoxia, steroids, cytokine deprivation, calcium plus 2 flux, taxol, loss of anchorage, U V radiation, genomic stress, death receptors, and granzyme B. The pro-apoptotic proteins are Noxa, Puma, Bad, H r k, Bim, B m f, Bik, and t Bid. Each stress activates between 1 and 4 of the proteins. Each of the proteins, in turn, inhibits the pro-survival proteins B c l-2 and B c l-X L and thereby prevents them from inhibiting the pro-apoptosis proteins Bax and Bak. An activation cascade

from Bax and Bak leads to activated caspases, which in a feedback loop activate t Bid, one of the pro-apoptotic proteins.
(A)



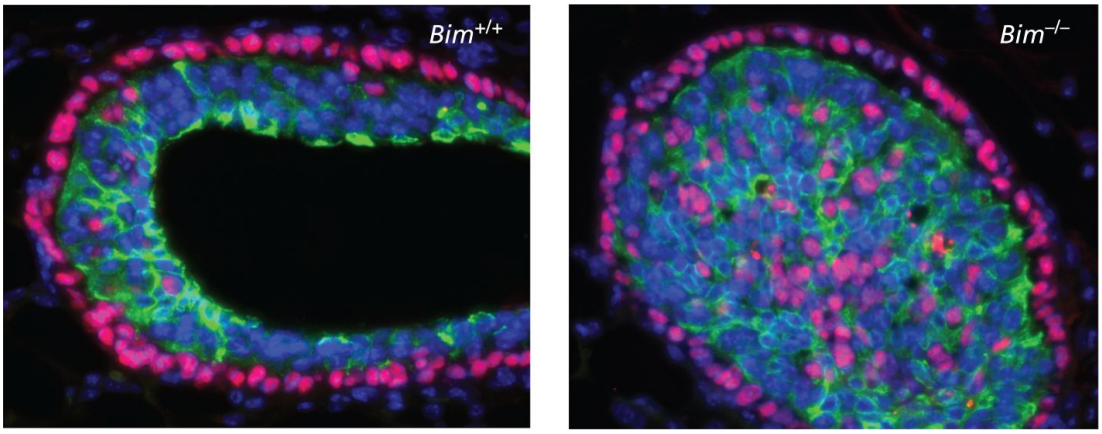
Some of the ways in which the activities of pro-apoptotic proteins are controlled. Bim is phosphorylated when R a f activates M E K, which then activates E r k. Ubiquilation Bim follows. Bad is phosphorylated by R a f and A k t, and then sequestered by 14-3-3 binding to two of the phosphate groups. t Bid is produced when a caspase or granzyme B removes the inhibitory domain from Bid.

(B)



A schematic in which pro-apoptotic proteins Bim, Puma, t Bid, Bad and Noxa inhibit pro-survival proteins B c l 2, B c l X L, B c l W, M c l 1, and A 1, preventing them from inhibiting pro-apoptotic proteins Bax and Bak. The end result is apoptosis.

(C)



Two fluorescence microscopy images. In the left one, cells in a wild-type Bim plus plus mouse organize into a C-shaped structure, with red cells around the outer edge and blue and green cells elsewhere. In the right image, cells in a

Bim minus minus mouse form an egg-shaped structure, with red cells around the outer edge but also scattered around the interior.
(D)
